## Abstract

This note is a short elaboration of the conjecture of Saniga *et al* (J. Opt. B: Quantum Semiclass. **6** (2004) L19-L20) by regarding a set of mutually unbiased bases (MUBs) in a  $d$ -dimensional Hilbert space,  $d$  being a power of a prime, as an analogue of an arc in a (Desarguesian) projective plane of order  $d$ . Complete sets of MUBs thus correspond to  $(d+1)$ -arcs, i.e., ovals. The existence of two principally distinct kinds of ovals for  $d$  even and greater than four, viz. conics and non-conics, implies the existence of two qualitatively different groups of the complete sets of MUBs for the Hilbert spaces of corresponding dimensions.

**Keywords:** Quantum Information, Mutually Unbiased Bases, Finite Geometries

It has for a long time been suspected but only recently fully recognized [1–4] that finite (projective) geometries may provide us with important clues for solving the problem of the maximum cardinality of MUBs,  $\mathcal{M}(d)$ , for Hilbert spaces whose dimension  $d$  is not a power of a prime. It is well-known [5,6] that  $\mathcal{M}(d)$  cannot be greater than  $d+1$  and that this limit is reached if  $d$  is a power of a prime. Yet, a still unanswered question is if there are non-prime-power values of  $d$  for which this bound is attained. On the other hand, the minimum number of MUBs,  $\mu(d)$ , was found to be  $\mu(d)=3$  for all dimensions  $d \geq 2$  [7]. Motivated by these facts, Saniga *et al* [1] have conjectured that the question of the existence of the maximum, or complete, sets of MUBs in a  $d$ -dimensional Hilbert space if  $d$  differs from a power of a prime number is intricately connected with the problem of whether there exist projective planes whose order  $d$  is not a power of a prime number. This letter aims at getting a deeper insight into this conjecture by introducing particular objects in a finite projective plane, the so-called ovals, which can be viewed as geometrical analogues of complete sets of MUBs.

We shall start with a more general geometrical object of a projective plane, viz. a  $k$ -arc – a set of  $k$  points, no three of which are collinear [see, e.g., 8,9]. From the definition it immediately follows that  $k=3$  is the minimum cardinality of such an object. If one requires, in addition, that there is at least one tangent (a line meeting it in a single point only) at each of its points, then the maximum cardinality of a  $k$ -arc is found to be  $d+1$ , where  $d$  is the order of the projective plane [8,9]; these  $(d+1)$ -arcs are called *ovals*. It is striking to observe that such  $k$ -arcs in a projective plane of order  $d$  and MUBs of a  $d$ -dimensional Hilbert space have the *same* cardinality bounds. Can, then, individual MUBs (of a  $d$ -dimensional Hilbert space) be simply viewed as points of some abstract projective plane (of order  $d$ ) so that their basic combinatorial properties are qualitatively encoded in the geometry of  $k$ -arcs? A closer inspection of the algebraic geometrical properties of ovals suggests that this may indeed be the case.

To this end in view, we shall first show that every proper (non-composite) conic in  $PG(2, d)$ , a projective plane over the Galois field  $GF(d)$ , is an oval. A conic is the curve of second order

$$\mathcal{Q}: \sum_{i \leq j} c_{ij} z_i z_j = 0, \quad i, j = 1, 2, 3, \quad (1)$$

where  $c_{ij}$  are regarded as fixed quantities and  $z_i$  as variables, the so-called homogeneous coordinates of the projective plane. The conic is degenerate (composite) if there exists a change of the coordinate system reducing Eq. (1) into a form of fewer variables; otherwise, the conic is proper (non-degenerate). It is well-known [see, e.g., 8] that the equation of any *proper* conic in  $PG(2, d)$  can be brought into the canonical form

$$\tilde{\mathcal{Q}}: z_1 z_2 - z_3^2 = 0. \quad (2)$$

From the last equation it follows that the points of  $\tilde{\mathcal{Q}}$  can be parametrized as  $\varrho z_i = (\sigma^2, 1, \sigma)$ ,  $\varrho \neq 0$ , and this implies that a proper conic in  $PG(2, d)$  contains  $d+1$  points; the point  $(1, 0, 0)$  and  $d$  other

points specified by the sequences  $(\sigma^2, 1, \sigma)$  as the parameter  $\sigma$  runs through the  $d$  elements of  $GF(d = p^n)$ ,  $p$  being a prime and  $n$  a positive integer. Moreover, it can easily be verified that any triple of distinct points of  $\tilde{\mathcal{Q}}$  are linearly independent (i.e., not on the same line), as [10]

$$\det \begin{pmatrix} 1 & 0 & 0 \\ \sigma_1^2 & 1 & \sigma_1 \\ \sigma_2^2 & 1 & \sigma_2 \end{pmatrix} = \sigma_2 - \sigma_1 \neq 0 \quad (3)$$

and

$$\det \begin{pmatrix} \sigma_1^2 & 1 & \sigma_1 \\ \sigma_2^2 & 1 & \sigma_2 \\ \sigma_3^2 & 1 & \sigma_3 \end{pmatrix} = (\sigma_1 - \sigma_2)(\sigma_2 - \sigma_3)(\sigma_3 - \sigma_1) \neq 0. \quad (4)$$

Hence, a proper conic of  $PG(2, d)$  is indeed an oval. The converse statement is, however, true for  $d$  odd only; for  $d$  even and greater than four there also exist ovals which are *not* conics [8–11]. In order to see this explicitly, it suffices to recall that all the tangents to a proper conic  $\mathcal{Q}$  of  $PG(2, d = 2^n)$  are concurrent, i.e., pass via one and the same point, called the nucleus [8–11]. So, the conic  $\mathcal{Q}$  together with its nucleus form a  $(d+2)$ -arc. Deleting from this  $(d+2)$ -arc a point belonging to  $\mathcal{Q}$  leaves us with an oval which shares  $d = 2^n$  points with  $\mathcal{Q}$ . Taking into account that a proper conic is uniquely specified by *five* of its points, it then follows that such an oval cannot be a conic if  $n \geq 3$ ; for, indeed, if it were then it would have with  $\mathcal{Q}$  more than five points in common and would thus coincide with it, a contradiction.

Let us rephrase these findings in terms of the above-introduced MUBs– $k$ -arcs analogy. We see that whilst for any  $d = p^n$  there exist complete sets (c-sets for short) of MUBs having their counterparts in proper conics,  $d = 2^n$  with  $n \geq 3$  also feature c-sets whose analogues are ovals which are not conics. In other words, our analogy implies that MUBs do not behave the same way in odd and even (power-of-prime) dimensions. And this is, indeed, the property that at the *number theoretical* level has been known since the seminal work of Wootters and Fields [5, see also 7], being there intimately linked with the fact that so-called Weil sums

$$\left| \sum_{k \in GF(p^n)} e^{\frac{2\pi i}{p} \text{Tr}(mk^2+nk)} \right|, \quad (5)$$

with  $m, n \in GF(p^n)$  and the absolute trace operator “Tr” defined as

$$\text{Tr}(\eta) \equiv \eta + \eta^p + \eta^{p^2} + \dots + \eta^{p^{n-1}}, \quad \eta \in GF(p^n), \quad (6)$$

are non-zero (and equal to  $\sqrt{p^n}$ ) for all  $p > 2$ , playing thus a key role for proving the mutual unbiasedness in these cases, but vanish for  $p = 2$  [see, e.g., 12].<sup>1</sup> In the light of our analogy, this difference acquires a qualitatively new, and more refined, algebraic-geometrical contents/footing. Remarkably, this refinement concerns especially even  $(2^n)$  dimensions, as we shall demonstrate next.

In the example above, we constructed a particular kind of an oval by adjoining to a proper conic its nucleus and then removing a point of the conic; such an oval, called a pointed-conic, was shown to be inequivalent to a conic for  $n \geq 3$ . However, for  $n \geq 4$  there exists still another type of non-conic ovals, termed irregular ones, that cannot be constructed this way [see, e.g., 8,11,13]. This intriguing hierarchy of oval’s types is succinctly summarized in the following table:

$n$	1	2	3	$\geq 4$
ordinary conic	yes	yes	yes	yes
pointed-conic	no	no	yes	yes
irregular oval	no	no	no	yes

<sup>1</sup>It is important to stress here that in order to find sets of MUBs in the  $p=2$  case one has, following the pure number-theoretical approach, to employ the concept of Galois *rings* instead of Galois fields [4,7], which makes our analogy, resting fully on (projective planes defined over) Galois fields, even more intriguing. In this respect, see also our recent construction of a “lifted” Fano plane [4].

Pursuing our analogy to the extreme, one observes that whereas  $d=2$  and  $d=4$  can accommodate only one kind of c-sets of MUBs, viz. those present also in odd dimensions and having their counterparts in ordinary conics,  $d=8$  should already feature two different types and Hilbert spaces of  $d \geq 16$  should be endowed with as many as three qualitatively different kinds of such sets. So, if this analogy holds, a new MUBs' physics is to be expected to emerge at the three-qubit level and become fully manifested for four- and higher-order-qubit states/configurations. And this is perhaps the most serious implication of our approach and a big challenge for further geometrically-oriented explorations of MUBs.
