**Abstract** A new methodology is proposed to estimate displacement fields from pairs of images (reference and strained) that evaluates continuous displacement fields. This approach is specialized to a finite-element decomposition, therefore providing a natural interface with a numerical modeling of the mechanical behavior used for identification purposes. The method is illustrated with the analysis of Portevin-Le Châtelier bands in an aluminum alloy sample subjected to a tensile test. A significant progress with respect to classical digital image correlation techniques is observed in terms of spatial resolution and uncertainty.

## 1 Introduction and motivation

The analysis of displacement fields from mechanical tests is a key ingredient to bridge the gap between experiments and simulations. Different optical techniques are used to achieve this goal (1). Among them, digital image correlation (DIC) is appealing thanks to its versatility in terms of scale of observation ranging from nanoscopic to macroscopic observations with essentially the same type of analyses. Most developments based on correlation exploit mainly locally constant or linearly varying displacements (2).

In Solid Mechanics, the measurement stage is only the first part of the analysis. The most important application is the subsequent extraction of mechanical properties, or quantitative evaluations of constitutive law parameters (3). By having an *identical* description for the displacement field during the measurement stage and for the numerical simulation is the key for reducing the noise or uncertainty propagation in the identification chain. During the latter, there is usually a difference between the kinematic hypotheses made during the measurement and simulation stages. To avoid this source of noise, it is proposed to develop a DIC approach in which the measured displacement field is consistent with a finite element simulation. Consequently, the measurement *mesh* has also a mechanical meaning. Let us emphasize that in the present study, only the displacement field measurement is considered (*i.e.*, it is a DIC technique), and no (finite-element) mechanical computation is performed. No constitutive law has been chosen, nor any identification performed. However the displacement evaluation is

directly matched to a format ready to use for any further finite element modeling work.

In the following, it is proposed to develop a Q4-DIC technique in which the displacements are assumed to be described by Q4P1-shape functions relevant to finite element simulations (4). The pattern-matching algorithm is based upon the conservation of the optical flow. Variational formulations are derived to solve this ill-posed problem. A spatial regularization was introduced by Horn and Schunck (5) and consists in a looking for *smooth* displacement solutions. The quadratic penalization is replaced by “smoother” ones based upon robust statistics (6; 7; 8). In the present approach, the sought displacement field directly satisfies continuity. In its direct application, the conservation of the optical flow is a non-linear problem that is expressed in terms of the maximization of a correlation product when the sought displacement is piece-wise constant (9). Other kinematic hypotheses are possible and a perturbation technique of the minimization of a quadratic error leads to a linear system as in finite element problems. To increase the measurable displacement range, a multi-scale setting is used as was proposed for a standard DIC algorithm (10).

The paper is organized as follows. Section 2 presents the general principles of a DIC approach. It is particularized to Q4P1-shape functions and is referred to as Q4-DIC. Section 3 is devoted to a performance assessment of the Q4-DIC technique based on a picture of an aluminium alloy sample. This example constitutes a test case, discussed in Section 4, for the quantitative analysis of the kinematics as it offers a good illustration of an heterogeneous strain field (*i.e.*, a localized band is observed in a tensile test).

## 2 Q4-Digital Image Correlation (Q4-DIC)

In this section the principle of the perturbation approach is introduced. Let us underline that this approach applies to a wide class of functions, and is not confined to finite element shape functions. Other examples have been explored (11; 12), using mechanically based functions, or using spectral decompositions of the displacement field (14; 13). However, the discussion will be specialized to Q4P1-shape functions, which provide a versatile tool for the analysis of very different mechanical problems, ideally suited to finite element modeling.

### 2.1 Principle of DIC with an arbitrary displacement basis

Let us deal with two images, which characterize the original and deformed surface of a material subjected to a known loading. An image is a scalar function of the spatial coordinate that gives the gray level at each discrete point (or pixel) of coordinate  $\mathbf{x}$ . The images of the reference and deformed states are respectively called  $f(\mathbf{x})$  and  $g(\mathbf{x})$ . Let us introduce the displacement field  $\mathbf{u}(\mathbf{x})$ . This field allows one to relate the two images by requiring the conservation of the optical flow

$$g(\mathbf{x}) = f[\mathbf{x} + \mathbf{u}(\mathbf{x})] \quad (1)$$

Assuming that the reference image are differentiable, a Taylor expansion to the first order yields

$$g(\mathbf{x}) = f(\mathbf{x}) + \mathbf{u}(\mathbf{x}) \cdot \nabla f(\mathbf{x}) \quad (2)$$

Let us underline here that the differentiability of the original image is not simply a theoretical question, but we will come back to this point later on. The measurement of the displacement is an ill-posed problem. The displacement is only measurable along the direction of the intensity gradient. Consequently, additional hypotheses have to be proposed to solve the problem. If one assumes a locally constant displacement (or velocity), a block matching procedure is found. It consists in maximizing the cross-correlation function (15; 9). To estimate  $\mathbf{u}$ , the quadratic difference between right and left members of Eq. (2) is integrated over the studied domain  $\Omega$  and subsequently minimized

$$\eta^2 = \iint_{\Omega} [\mathbf{u}(\mathbf{x}) \cdot \nabla f(\mathbf{x}) + f(\mathbf{x}) - g(\mathbf{x})]^2 d\mathbf{x} \quad (3)$$

The displacement field is decomposed over a set of functions  $\Psi_n(\mathbf{x})$ . Each component of the displacement field is treated in a similar manner, and thus only *scalar* functions  $\psi_n(\mathbf{x})$  are introduced

$$\mathbf{u}(\mathbf{x}) = \sum_{\alpha,n} a_{\alpha n} \psi_n(\mathbf{x}) \mathbf{e}_{\alpha} \quad (4)$$

The objective function is thus expressed as

$$\eta^2 = \iint_{\Omega} \left[ \sum_{\alpha,n} a_{\alpha n} \psi_n(\mathbf{x}) \nabla f(\mathbf{x}) \cdot \mathbf{e}_{\alpha} + f(\mathbf{x}) - g(\mathbf{x}) \right]^2 d\mathbf{x} \quad (5)$$

and hence its minimization leads to a *linear* system

$$\sum_{\beta,m} a_{\beta m} \iint_{\Omega} [\psi_m(\mathbf{x}) \psi_n(\mathbf{x}) \partial_{\alpha} f(\mathbf{x}) \partial_{\beta} f(\mathbf{x})] d\mathbf{x} = \iint_{\Omega} [g(\mathbf{x}) - f(\mathbf{x})] \psi_n(\mathbf{x}) \partial_{\alpha} f(\mathbf{x}) d\mathbf{x} \quad (6)$$

that is written in a compact form as

$$\mathbf{M}\mathbf{a} = \mathbf{b} \quad (7)$$

where  $\partial_\alpha f = \nabla f \cdot \mathbf{e}_\alpha$  denotes the directional derivative, the matrix  $\mathbf{M}$  and the vector  $\mathbf{b}$  is directly read from Eq. (6)

$$M_{\alpha n, \beta m} = \iint_{\Omega} [\psi_m(\mathbf{x}) \psi_n(\mathbf{x}) \partial_\alpha f(\mathbf{x}) \partial_\beta f(\mathbf{x})] d\mathbf{x} \quad (8)$$

and

$$b_{\alpha n} = \iint_{\Omega} [g(\mathbf{x}) - f(\mathbf{x})] \psi_n(\mathbf{x}) \partial_\alpha f(\mathbf{x}) d\mathbf{x} \quad (9)$$

Let us note that the role played by  $f$  and  $g$  is symmetric, and up to second order terms, exchanging those two functions will lead to simply exchanging the sign of the displacement. Thus in order to compensate for variations of the texture and to cancel the induced first order error in  $\mathbf{u}$ , one substitutes  $f$  in the expression of the matrix  $\mathbf{M}$  by the arithmetic average  $(f + g)/2$ . This symmetrization turns out to make the estimate of  $\mathbf{a}$  much more stable and accurate, although it requires more computation time associated with the assembly of all elementary matrices and vectors.

Last, the present development is similar to a Rayleigh-Ritz procedure frequently used in elastic analyses (4). The only difference corresponds to the fact that the variational formulation is associated to the (linearized) conservation of the optical flow and not the principal of virtual work.

## 2.2 Particular case: Q4P1-shape functions

A large variety of function  $\Psi$  may be considered. Among them, finite element shape functions are particularly attractive because of the interface they

provide between the measurement of the displacement field and a numerical modeling of it based on a constitutive equation. Whatever the strategy chosen for the identification of the constitutive parameters, choosing an identical kinematic description suppresses spurious numerical noise at the comparison step. Moreover, since the image is naturally partitioned into pixels, it is appropriate to choose a square or rectangular shape for each element. This leads us to the choice of Q4-finite elements as the simplest basis. Each element is mapped onto the square  $[0, 1]^2$ , where the four basic functions are  $(1-x)(1-y)$ ,  $x(1-y)$ ,  $(1-x)y$  and  $xy$  in a local  $(x, y)$  frame. The displacement decomposition (4) is therefore particularized to account for the previous shape functions of a finite element discretization. Each component of the displacement field is treated in a similar manner, and thus only *scalar* shape functions  $N_n(\mathbf{x})$  are introduced to interpolate the displacement  $\mathbf{u}^e(\mathbf{x})$  in an element  $\Omega_e$

$$\mathbf{u}^e(\mathbf{x}) = \sum_{n=1}^{n_e} \sum_{\alpha} a_{\alpha n}^e N_n(\mathbf{x}) \mathbf{e}_{\alpha} \quad (10)$$

where  $n_e$  is the number of nodes (here  $n_e = 4$ ), and  $a_{\alpha n}^e$  the unknown nodal displacements. The objective function is recast as

$$\eta^2 = \sum_e \iint_{\Omega_e} \left[ \sum_{\alpha, n} a_{\alpha n}^e N_n(\mathbf{x}) \nabla f(\mathbf{x}) \cdot \mathbf{e}_{\alpha} + f(\mathbf{x}) - g(\mathbf{x}) \right]^2 d\mathbf{x} \quad (11)$$

and hence its minimization leads to a *linear* system (6) in which the matrix  $\mathbf{M}$  is obtained from the assembly of the elementary matrices  $\mathbf{M}^e$  whose components read

$$M_{\alpha n, \beta m}^e = \iint_{\Omega_e} [N_m(\mathbf{x}) N_n(\mathbf{x}) \partial_{\alpha} f(\mathbf{x}) \partial_{\beta} f(\mathbf{x})] d\mathbf{x} \quad (12)$$

and the vector  $\mathbf{b}$  corresponds to the assembly of the elementary vectors  $\mathbf{b}^e$  such that

$$b_{\alpha n}^e = \iint [g(\mathbf{x}) - f(\mathbf{x})] N_n(\mathbf{x}) \partial_\alpha f(\mathbf{x}) d\mathbf{x} \quad (13)$$

Thus it is straightforward to compute for each element  $e$  the elementary contributions to  $\mathbf{M}$  and  $\mathbf{b}$ . The latter is assembled to form the global “rigidity” matrix  $\mathbf{M}$  and “force” vector  $\mathbf{b}$ , as in standard finite element problems (4). The only difference is that the “rigidity” matrix and the “force” vector contain picture gradients in addition to the shape functions, and the “force” vector includes also picture differences. The matrix  $\mathbf{M}$  is symmetric, positive (when the system is invertible) and sparse. These properties are exploited to solve the linear system efficiently. Last, the domain integrals involved in the expression of  $\mathbf{M}^e$  and  $\mathbf{b}^e$  require imperatively a pixel summation. The classical quadrature formulas (*e.g.*, Gauss point) is *not* used because of the very irregular nature of the image texture. This latter property is crucial to obtain an accurate displacement evaluation.

### 2.3 Sub-pixel interpolation

In the previous subsection, the gradient  $\nabla f(\mathbf{x})$  is used freely in the Taylor expansion leading to Eq. (2). However,  $f$  represents the texture of the initial image, discretized at the pixel level. Therefore, the definition of a gradient requires a slight digression. Previous works have underlined the importance of sub-pixel interpolation. In Ref. (16) a cubic spline was argued to be very convenient and precise. Here a different route is proposed, namely, a Fourier decomposition. The latter provides a  $C_\infty$  function that passes by all known values of  $f$  at integer coordinates. From such a mapping one easily defines

an interpolated value of the gray level at any intermediate point. Moreover, one also exploits the same mapping for computing a gradient at any point. Finally, powerful Fast Fourier Transform (FFT) algorithms allow for a very rapid computation.

There is however a weakness in this procedure related to the treatment of edges. Fourier transforms over a finite interval implicitly assume periodicity. Thus left-right or up-down differences induce spurious oscillations close to edges. To reduce edge effects, each zone of interest (ZOI) is enlarged to an integer power of two size, including a frame around each element. This enlarged ZOI is only used for FFT purposes, and once gradients are estimated, the original ZOI is cut out the enlarged zone, and thus the region where most of spurious oscillations are concentrated is omitted. Moreover, at present, an “edge-blurring” procedure is implemented, *i.e.*, each border is replaced by the average of the pixel values of the original and opposite border ones. This again reduces the discontinuity across boundaries (10). There exist a few alternative routes to limit or circumvent part of this artefact, namely, *ad hoc* windowing (10), neutral padding (17), symmetrization, or linear trend removal. Such options have not been tested.

## 2.4 Multi-scale approach

Even though a way of interpolating between gray level values at a sub-pixel scale was introduced above, the very use of a Taylor expansion requires that the displacement be small when compared with the correlation length of the texture. For a fine texture and a large initial displacement, this requirement appears as inappropriate to converge to a meaningful solution. Thus one may devise a generalization to arbitrarily expand the correlation length of the

texture. This is achieved through a coarse-graining step. Again many ways may be considered, such as a low pass filtering in Fourier or Wavelet spaces. A rather crude, but efficient way, is to resort to a simple coarse-graining in real space (10) obtained by forming super-pixels of size  $2^n \times 2^n$  pixels, by averaging the gray levels of the pixels contained in each super-pixel.

First one generates a set of coarse-grained pictures of  $f$  and  $g$  for super-pixels of size  $2 \times 2$  pixels,  $4 \times 4$  pixels,  $8 \times 8$  pixels and  $16 \times 16$  pixels. Starting from the coarser scale, the displacement is evaluated using the above described procedure. This determination is iterated using a corrected image  $g$  where the previously determined displacement is used to correct for the image. These iterations are stopped when the total displacement no longer varies. At this point, one may estimate that a gross determination of the displacement has been obtained, and that only small displacement amplitudes remain unresolved. This lack of resolution is due to the fact that the small scale texture was filtered out. Thus finer scale images are used taking into account the previously estimated displacement to correct for the  $g$  image. Again the displacement evaluation is iterated up to convergence. This process is stopped once the displacement is stabilized at the finer scale resolution, *i.e.*, dealing with the original images.

Along the iterations, the “*correction*” of the deformed image by the previously determined displacement field are possible with different degrees of sophistication. For reasons of computation efficiency, only the most crude correction is performed in the present implementation, namely, each ZOI is simply translated by the average displacement in the element. Integer rounded displacements are taken into account by a mere shift of coordinates, and sub-pixel translation is performed by a phase shift in Fourier

space (18). This is a very low cost correction since Fourier transforms are already required to compute gradients.

At the present stage, the implementation is such that the same number of super-pixel is contained in each element. Thus as a finer resolution image is considered, the displacement is to be determined on a physically finer grid. The transfer of the displacement from one scale to the next one is performed using a linear interpolation, consistent with the Q4P1-shape functions that are used. This multi-resolution scheme is thus also a mesh refinement procedure which is performed *uniformly* (up to now) over the entire map.

This multi-resolution scheme was previously implemented using an FFT-correlation approach to estimate the displacement field (10). In this context, it leads to much more robust results. Large displacements and strains are measured using this algorithm, whereas a single scale procedure revealed to be severely limited. Similarly, using the present Q4-decomposition, this multi-resolution analysis revealed very precious to significantly increase the robustness and accuracy of the measurement.

### 3 A Priori Performance

The aim of the present section is to evaluate the a priori performances of the Q4-DIC technique applied to the picture that corresponds to the reference configuration of the experiment to be analyzed in Section 4. Figure 1 shows the texture used to measure displacement fields. It is obtained by spraying a white and black paint prior to the experiment.

### 3.1 Texture characteristics

The quality of the displacement measurement is primarily based on the quality of the image texture. Hence before discussing the result of the analysis, the characteristics of the texture are presented. The gray level was encoded on a 16-bit depth (even though the original depth was equal to 12 bits) in the image acquisition, and the true dynamics of gray level takes advantage of this encoding, as judged from the gray level histogram shown in Fig. 2. Such a histogram is a good indication of the global image quality to check for saturation problems.

However, such a global characterization of the image is only of limited interest. What is more significant is the average of texture properties as estimated from sampling of sub-images in ZOIs. The point is to evaluate whether these sub-images carry enough information to allow for a proper analysis. Each ZOI is characterized by its own gray level dynamics, or its standard deviation of gray level. The latter quantity, averaged over all ZOIs of a given size, and normalized by the maximum gray level used in the image, is shown in Fig. 3-a. Even for the smallest ZOI sizes, this ratio is already as large as 0.06, and increases to about 0.13 for large ZOI sizes. The higher the ratio, the smaller the detection threshold as shown in Eq. (2); the standard deviation being an indirect way of characterizing the sensitivity of the technique. One thus concludes that the gray level amplitude is large enough to allow for a good quality of the analysis even for ZOI sizes as small as 4 pixels.

Another significant criterion is the correlation radius of the image texture. The latter is computed from a parabolic interpolation of the auto-correlation function at the origin. The inverse of the two eigenvalues of the

curvature give an estimate of the two correlation radii,  $\xi_1$  and  $\xi_2$ , shown in Fig. 3-b when averaged over all ZOIs of a given size. The texture is rather isotropic (*i.e.*, similar eigenvalues), and remains small (varying from 1-2 to about 3 pixels) for all ZOI sizes. This indicates a very good texture quality that reveals small scale details even for small ZOI sizes. If one wants at least one disk and its complementary surrounding to get a good estimate, the correlation radii should be less than one fourth of the ZOI size. This is achieved for ZOI sizes greater than 6 pixels in the present case.

### 3.2 Displacement Measurement

Prior to any computation, it is important to estimate the a priori performance of the approach on the actual texture of the image. If one changes the picture, one may not get exactly the same performance since it is related to the local details of the gray level distribution as shown in Section 2. This is performed by using the original image  $f$  only, and generating a translated image  $g$  by a prescribed amount  $\mathbf{u}_{pre}$ . Such an image is generated in Fourier space using a simple phase shift for each amplitude. This procedure implies a specific interpolation procedure for inter-pixel gray levels, to which one resorts systematically (see Section 2.3). The algorithm is then run on the pair of images  $(f, g)$ , and the estimated displacement field  $\mathbf{u}_{est}(\mathbf{x})$  is measured. One is mainly interested in sub-pixel displacements, where the main origin of errors comes from inter-pixel interpolation. Therefore the prescribed displacement is chosen along the  $(1, 1)$  direction so as to maximize this interpolation sensitivity. To highlight this reference to the pixel scale, one refers to the  $x$ - (or  $y$ -) component of the displacement  $u_{pre} \equiv \mathbf{u}_{pre} \cdot \mathbf{e}_x$

varying from 0 to 1 pixel, rather than the Euclidian norm (varying from 0 to  $\sqrt{2}$  pixels).

The quality of the estimate is characterized by two indicators, namely, the systematic error,  $\delta_u = \|\langle \mathbf{u}_{est} \rangle - \mathbf{u}_{pre}\|$ , and the standard uncertainty  $\sigma_u = \langle \|\mathbf{u}_{est} - \langle \mathbf{u}_{est} \rangle\|^2 \rangle^{1/2}$ . The change of these two indicators is shown in Fig. 4 as functions of the prescribed displacement amplitude for different ZOI sizes  $\ell$  ranging from 4 to 128 pixels. Both quantities reach a maximum for one half pixel displacement,  $u_{pre} = 0.5$  pixel, and are approximately symmetric about this maximum. Integer valued displacements (in pixels) imply no interpolation and is exactly captured through the multi-scale procedure discussed above. This confirms that these errors are due to interpolation procedures. The results are shown in a semi-log scale to reveal the strong sensitivity to the ZOI size, however a linear scale would show that both  $\delta_u$  and  $\sigma_u$  follow a *linear* increase with  $u_{pre}$  from 0 to 0.5 pixel (and a symmetric decrease from 0.5 to 1 pixel).

To quantify the effect of the ZOI size, the error and standard uncertainty, are averaged over  $u_{pre}$  within the range  $[0, 1]$  as functions of the ZOI size  $\ell$ . These data are shown in Fig. 5. A power-law decrease

$$\begin{aligned} \langle \sigma_u \rangle &= A^{1+\zeta} \ell^{-\zeta} \\ \langle \delta_u \rangle &= B^{1+v} \ell^{-v} \end{aligned} \tag{14}$$

for  $8 \leq \ell \leq 128$  pixels is observed as shown by a line on the graph. Both amplitudes are close to 1 pixel (more precisely  $A = 1.15$  pixel and  $B = 1.07$  pixel). The exponents are measured to be  $\zeta = 1.96$  and  $v = 2.34$ . The data for  $\ell = 128$  pixels seem to depart from the power-law

For comparison purposes, the displacement uncertainties obtained with the present technique are compared with those of a standard FFT-DIC

technique (10). In that case, a weaker power-law decrease is observed with  $A = 1.00$  pixel and  $\zeta = 1.23$  (Fig. 5b). This result shows that by using a continuous description of the displacement field, it enables for a decrease of the displacement uncertainty when the same ZOI size is used. Conversely, for a given displacement uncertainty, the Q4-DIC algorithm allows one to reduce significantly the ZOI size, thereby increasing the number of measurement points when compared to a classical FFT-DIC technique.

### 3.3 Noise sensitivity

Last, the effect of noise associated to the image acquisition (*e.g.*, digitization, read-out noise, black current noise, photon noise (19)) on the displacement measurement is assessed. This analysis allows one to estimate the displacement resolution (20). The reference image is corrupted by a Gaussian noise of zero mean and standard variation  $\sigma_g$  ranging from 1 to 8 gray levels at each pixel with no spatial correlation. No displacement field is superimposed on the image, and the displacement field is then estimated. The standard deviation of the displacement field,  $\sigma_u$ , is shown in Fig. 6 as a function of the noise amplitude  $\sigma_g$  and for different ZOI sizes ranging from 4 to 128 pixels. The quantity  $\sigma_u$  is linear in the noise amplitude and inversely proportional to the ZOI size. The latter properties are derived from the central limit theorem.

A theoretical analysis of this problem is discussed in Ref. (11) and summarized in the Appendix, and leads to the following estimate of the standard deviation of the displacement field induced by a Gaussian white noise

$$\sigma_u = \frac{12\sqrt{2}\sigma_g p}{7\langle|\nabla f|^2\rangle^{1/2}\ell} \quad (15)$$

where  $p$  is the physical pixel size. For the present application, one computes  $\langle |\nabla f|^2 \rangle^{1/2} \approx 5340 \text{ pixel}^{-1}$ , hence  $\sigma_u \approx 4.5 \times 10^{-4} \sigma_g p / \ell$ . This theoretical expectation (neglecting the spatial correlation in the image texture) is consistent with the direct estimates shown in Fig. 6 (*e.g.*, for  $\ell = 4$  pixels and  $\sigma_g = 8$  gray levels, the direct estimate is  $1.2 \times 10^{-3}$  pixel to be compared with  $9 \times 10^{-4}$  pixel given by the above formula). In practice, with the used CCD camera, the noise level is given with a maximum range less than 3 gray levels. Consequently, the contribution of image noise is negligibly small when compared to that induced by the sub-pixel interpolation.

#### 4 Application to a tensile test

In this section, an application of the previously proposed algorithm is carried out to analyze a tensile test performed on an aluminum alloy sample. In the plastic regime, the formation of localization strain bands are observed. The fact that for a given the displacement uncertainty, smaller ZOI sizes can be chosen in the present case (Q4-DIC) when compared with those of a standard FFT-DIC technique (Fig. 5b), enables one to better capture kinematic details in the localization band.

##### 4.1 Material and method

The studied aluminum alloy is of type 5005 (*i.e.*, more than 99 wt% of Al content and a small amount of Mg; these values were determined by electron probe micro-analysis). As shown in Fig. 1, the sample is coated with sprayed black and white paints to create the random texture for the displacement field measurement. The sample size is  $140 \times 30 \times 2 \text{ mm}^3$ . It is

positioned within hydraulic grips of a 100 kN servo-hydraulic testing machine. Its alignment is checked with DIC measurements (*i.e.*, no significant rotation of the sample is observed in the elastic domain). To have a first strain evaluation, an extensometer was used. Its pins are observed on the right edge of the sample (Fig. 1).

An artificial light source is used to minimize gray level variations so that the conservation of the optical flow is considered as practically achieved. A CCD camera (12-bit digitization, noise less than 3 gray levels, resolution:  $1024 \times 1280$  pixels) with a conventional zoom is positioned in front of the sample. In the present case, the physical size of one pixel is  $25 \mu\text{m}$ . Two loading sequences are carried out. First, in the elastic domain, a controlled displacement rate of  $5 \mu\text{m/s}$  is applied and pictures are taken for  $12 \mu\text{m}$ -increments. Elastic properties may be identified (21). This will not be discussed herein. Second, a controlled displacement rate of  $10 \mu\text{m/s}$  is applied to study strain localization and pictures are taken for  $60 \mu\text{m}$ -increments. The following analysis of the displacement field is an increment between two image acquisitions in the “plastic” regime.

Figure 7 shows the change of the average longitudinal strain with the number of pictures (or equivalently with time). This result was obtained by using the Q4-DIC analysis. Until the extensometer pins slipped (at about a 5% strain), the average strain measured by DIC and that given by the extensometer were close, even though the same surface was not analyzed. This response is typical of a Portevin-Le Châtelier (PLC) phenomenon or jerky flow (22). From a microscopic point of view, PLC effects are related to dynamic interactions between mobile dislocations and diffusing solute atoms (23; 24). From a macroscopic perspective, it is related to a negative

strain rate sensitivity that leads to localized bands that are simulated (25). Many experimental studies (26) however are based upon average strain measurements. There are also full-field displacement measurements performed by using, for instance, laser speckle interferometry (27). Yet the spatial resolution did not allow for an analysis of the displacement field within the band. Additional insight is gained by using IR thermography (28).

## 4.2 Kinematic fields

Let us now analyze the displacement field in between two states (0.3% mean strain apart, see Fig. 7). The same region of interest of size  $1000 \times 700$  pixels is studied using the above method, with different ZOI sizes ranging from 16 down to 4 pixels. Figures 8 and 9 show the resulting displacement fields (component  $U_x$  and  $U_y$ , respectively). Although the test is pure tension, the analysis reveals without ambiguity the presence of a localization band whose width is about 150 pixels, and across which the displacement discontinuity is about 2 pixels along the tension axis, and about 1 pixel perpendicular to it. The mechanical analysis of this PLC localization phenomenon based on kinematic as well as thermographic images is deferred to a further publication. Let us concentrate here on this single pair of images to validate the algorithm on a real experimental test and evaluate its performances.

One notes that all ZOI sizes may be used. As expected, the smallest ZOI sizes are noisier, yet the agreement between all these determinations is excellent. Let us underline that FFT-DIC usually deals with ZOI sizes equal or larger than 32 pixels, exceptionally 16 pixels for very favorable cases are used when locally constant displacement fields are sought. Using the Q4-DIC technique allows one to reduce the ZOI size by a factor of 4,

which means that the number of pixels in the ZOI has been cut down by a factor of 16.

Let us however note that one should be cautious about the fact that displacements have a tendency to be attracted toward integer values, especially for small ZOI sizes. Therefore the direct evaluation of strains along the tension axis  $\varepsilon_{yy}$  as obtained by the Q4P1-shape functions or equivalently as a simple finite difference is expected to be artificially increased at half-integer displacement components. Figure 10 shows such strain fields for 4 different ZOI sizes from 16 down to 8 pixels. For a size of 16 pixels, the localization band appears as a genuine zone of increased strains as compared to a “silent” (or elastic) background. For smaller ZOI sizes, the edges of the shear band appear to concentrate still a higher strain. The same effect is apparent for ZOI sizes 12, 10 and 8 pixels. The strain maps obtained for smaller ZOI sizes are not shown, since the noise level becomes much higher and thus the measurement cannot be trusted. The same artefact of strain enhancement at the edges of the shear band is however observed.

### 4.3 Integer locking

One notes on the previous figure that the  $U_y$ -displacement is half-integer valued at the edge of the shear band. The larger strains at the edge of the band could therefore be interpreted as an artefact due to integer locking. Integer valued displacements being favored, an artificial gap is created for half-integer values displacement, and thus any gradient (finite difference operator) will underline this effect very markedly.

To test this interpretation, the following test is proposed. An artificially translated image by 0.5 pixel is computed from the original one, using a fast

Fourier transform, as the latter provides a simple and numerically efficient way of interpolating the image at any arbitrary sub-pixel value. A genuine strain enhancement is thus expected to be identified at a fixed position in the reference image frame of coordinates, whereas a numerical artefact would be moved to a different location. Figures 11a and b show the  $U_y$  displacement component starting from the original image or from the translated one (and where the 1/2 pixel translated has been corrected for). A good agreement is observed for the displacement field thus revealing a rather poor sensitivity to such a rigid translation. Figures 11c and d show the corresponding  $\varepsilon_{yy}$  strain maps. On the latter set of figures, although high strain values tend to concentrate along two lines in both figures, the precise location of these bands is not stable. This is a signature of the integer locking phenomenon. Therefore the strain enhancement at the edge of the shear band is to be considered as an artefact.

Let us underline that such a phenomenon results from the fact that the zones of interest are reduced to a very small size, and still provide a very accurate determination of the displacement field, without much noise. Such a success encourages the user to decrease the size of the zone of interest to very small values. By doing so, the determination of the displacement is much more prone to slight sub-pixel shifts (Fig. 5), here characterized as an attraction toward integer values, which appear as very significant upon differentiation (in the computation of the strain). This phenomenon should be identified before any further interpretation of the strain map to ensure its validity.

#### 4.4 Error maps

As mentioned earlier, a very important output of the displacement measurement obtained from a minimization procedure is that the optimization functional provides not only a global quality factor of the determined field, but more importantly a spatial map of residuals, so that one may appreciate a specific problem that may be spatially localized.

Figure 12 shows the different error maps obtained for different ZOI sizes. This error is the remanent difference in gray levels that is still unexplained by the estimated displacement field. The first observation is that the error level does not vary much with the ZOI size. This is consistent with the fact that the displacement field is quite comparable for different ZOI sizes. However, there is a slight increase in the error as the ZOI size decreases. This is explained by the fact that the performance of the correlation algorithm degrades as the spatial resolution improves. This observation is in good agreement with the results to be expected from the analysis of Fig. 5.

#### 5 Conclusion

A novel approach was developed to determine a displacement field based on the comparison of two digital images. The sought displacement field is decomposed onto a basis of continuous functions using Q4P1-shape functions as proposed in finite element methods. The latter corresponds to one of the simplest kinematic descriptions. It therefore allows for a compatibility of the kinematic hypotheses made during the measurement stage and the subsequent identification / validation stage, for instance, by using conventional finite element techniques.

The performance of the algorithm is tested on a reference image to evaluate the reliability of the estimation, which is shown to allow for either an excellent accuracy for homogeneous displacement fields, or for a very well resolved displacement field down to element sizes as small as  $4 \times 4$  pixels. When compared with a standard FFT-DIC technique, Q4-DIC enables for a significant decrease of the displacement uncertainty when the same size of the zone of interest is used.

Last, the displacement field is analyzed on an aluminium alloy sample where a localization band develops. In the present case, it corresponds to a Portevin-Le Châtelier effect. For element sizes ranging from 16 down to 4 pixels, the displacement field is shown to be reliably determined. As far as strains are concerned, spurious strain concentrations at the edge of the shear band is observed for small element sizes. This is attributed to integer locking of the displacement. Apart from this bias, the analysis has been shown to be operational and reliable, on a real experimental test with strain localization. The complete space-time kinematic analysis is now possible for the Portevin-Le Châtelier phenomenon even within the band thanks to the spatial resolution achieved by the Q4-DIC technique presented herein. It is deferred to a another publication.

### Appendix: Sensitivity to image noise

The sensitivity of the displacement evaluation to noise is addressed. It is assumed that the deformed image is corrupted by a random white noise  $\rho$ , of zero mean, and variance  $\sigma_g^2$ . The notations of Section 2 are used. The  $\mathbf{M}$  matrix is thus unaffected by this noise, but only the vector  $\mathbf{b}$  is modified by a quantity

$$\delta b_n = \iint \rho(\mathbf{x}) \cdot (\nabla f \cdot \Psi_n) d\mathbf{x} \quad (16)$$

On average,  $\langle \delta \mathbf{b} \rangle = 0$ , and

$$\langle \delta b_m \delta b_n \rangle = \sigma_g^2 M_{mn} \quad (17)$$

The impact of this noise on the determination of  $\mathbf{a}$ , which is not altered by a fluctuating part  $\delta \mathbf{a}$ , is sought. By linearity, one observes that  $\langle \delta \mathbf{a} \rangle = 0$ . Its variance is given by

$$\langle \delta a_m \delta a_n \rangle = \sigma_g^2 M_{mp}^{-1} M_{nq}^{-1} M_{pq} = \sigma_g^2 M_{mn}^{-1} \quad (18)$$

Rather than computing the exact above estimate of the variance of the displacement field (the  $\mathbf{M}^{-1}$  matrix is quite large), one further simplifies the computation, and only consider the spatial average of the covariance matrix  $\langle \delta a_m \delta a_n \rangle$ . This hypothesis ignores the edge effects where the variance will be larger than within the domain. It also exploits the assumption that the gradient of the image has only short distance correlations as compared to the Q4-element size. The average symbol  $\langle \dots \rangle$  is now understood as representing an ensemble average over the noise, and a spatial average. As a result the matrix  $\mathbf{M}$  has to be averaged, and reads

$$\langle M_{mn} \rangle = (1/2) \langle |\nabla f|^2 \rangle \iint \boldsymbol{\Psi}_m \cdot \boldsymbol{\Psi}_n d\mathbf{x} \quad (19)$$

The interesting feature of this equation is the fact that only the shape functions are involved in the integral. This results in a natural decoupling between the  $x$  and the  $y$  coordinates of the displacement, and a quasi-band diagonal of this function inherited from the classical finite-element formulation. For instance, the diagonal elements will have the following expression

$$\langle M_{nn} \rangle = (2/9) \langle |\nabla f|^2 \rangle \ell^2 \quad (20)$$

for a summation performed over the 4 elements attached to this node. For two adjacent nodes,  $\langle M_{mn} \rangle = (1/9) \langle |\nabla f|^2 \rangle \ell^2$ , and for two diagonally opposed nodes,  $\langle M_{nn} \rangle = (1/36) \langle |\nabla f|^2 \rangle \ell^2$ . This matrix is easily inverted. It has the same support as  $\mathbf{M}$ . The diagonal element is

$$\langle M \rangle_{nn}^{-1} = \frac{288}{49 \langle |\nabla f|^2 \rangle \ell^2} \quad (21)$$

The adjacent node matrix element is  $-(1/4)$  that value, and diagonally opposed nodes are  $1/16$  of it. By making a final additional hypothesis that the inverse of the spatial average is identified with the spatial average of the inverse (*i.e.*, valid for a homogeneous texture of the image), the final expression of the standard deviation  $\sigma_a$  of the Q4-displacement amplitude is expressed as

$$\sigma_a = \sqrt{\langle \delta a_n^2 \rangle} = \frac{12\sqrt{2}p\sigma_g}{7\sqrt{\langle |\nabla f|^2 \rangle} \ell} \quad (22)$$

It is to be noted that the fluctuating part of the  $\alpha$  field is anti-correlated. Thus part of the fluctuations at one node is compensated by the fluctuations on neighboring nodes.
