#### Abstract

Modular decomposition of graphs is a powerful tool with many applications in graph theory and optimization. There are efficient linear-time algorithms that compute the decomposition for undirected graphs. The best previously published time bound for directed graphs is  $O(n+m\log n)$ , where n is the number of vertices and m is the number of edges. We give an O(n+m)-time algorithm.

#### Keywords

modular decomposition, algorithm, tournaments, directed graphs, partitive families, tree-decomposable families, 2-structures

### 1 Introduction

A module in a graph G = (V, E) is a set X of vertices such that each vertex in  $V \setminus X$  has a uniform relationship to all members of X. That is, if  $y \in V \setminus X$ , then y has directed edges to all members of X or to none of them, and all members of X have directed edges to y or none of them do. (See Figure 1.) Different members y and y' of  $V \setminus X$  can have different relationships to members of X, however. For instance y can have directed edges to all members of X when y' has directed edges to none of them. The members of X can have arbitrary relationships to each other, as can the members of  $V \setminus X$ .

It is not hard to see that if X and Y are two disjoint modules, then if some vertex of Y is a neighbor of some vertex of X, then all vertices of Y are neighbors of all vertices of X. Therefore, Y can be considered unambiguously to be a neighbor of X or a non-neighbor of X. If  $\mathcal{P}$  is a nontrivial partition of Y such that each member of  $\mathcal{P}$  is a module, this observation gives rise to a quotient graph, which is the graph of adjacencies between members of  $\mathcal{P}$ . (See Figure 2.) The subgraphs induced by the members of  $\mathcal{P}$  record the relationships in G that are not captured by the quotient. Together, the quotient and factors give a representation of G.

Further simplification can often be obtained by decomposing the factors and the quotient recursively. The *modular decomposition* is a unique, canonical way to do this that implicitly represents all possible ways the decompose the graph into quotients and factors. It can be represented by a rooted tree.

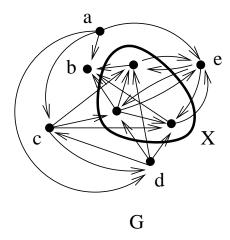

Figure 1: A module of an undirected graph is a set X of vertices such that each vertex  $y \in V \setminus X$  has a uniform relationship to all members of X. For instance, every member of X is a neighbor of d and no member of X has d as a neighbor, so they all have the same relationship to d.

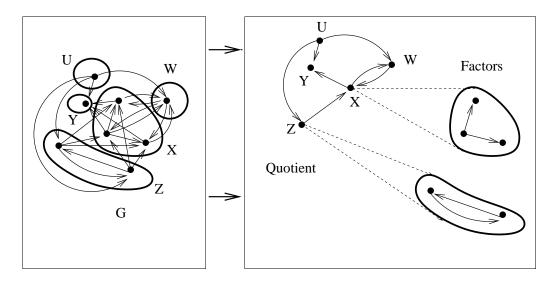

Figure 2: If A and B are disjoint modules, then if B contains a neighbor of a vertex in A, every member of B is a neighbor of every member of A. In this case, B is adjacent to A. A partition  $\mathcal P$  of G where each member of  $\mathcal P$  is a module defines a quotient graph, which describes the adjacencies among members of  $\mathcal P$ . The quotient, together with the subgraphs induced by the nontrivial members of  $\mathcal P$ , give a representation of G, since the edges of G can be recovered from them.

Modular decomposition theory originates from Gallai's work about transitive orientation [Gal67]. Möhring and Radermacher [MR84, Möh85] survey the topic.

The class of cographs (and some extensions like P<sub>4</sub>-sparse, P<sub>4</sub>-reducible, and P<sub>4</sub>-tidy) [CLS81, Hoà85, JO89, GRT97] are classes where a graph is uniquely defined by the properties of its modular decomposition. A great number of NP-hard optimization problems for graphs can be easily solved if a solution is known for every quotient graph in the modular decomposition. If every quotient is small, this gives an efficient solution. Its famous applications include transitive orientation [Gal67], weighted maximum clique, and coloring. Modular decomposition is also used in graph drawing. Many classes, such as interval graphs or permutation graphs have simple recognition algorithms using modular decomposition (see [Gol80, BLS99] for a survey). Fewer directed graph classes are known, but modular decomposition can help in their recognition (see [Mül97] for instance).

Some width parameters are also closely related to the modular decomposition. The clique-width of a graph is the maximum of clique-widths of quotient graphs in the modular decomposition tree. Classes with a finite number of possible quotients therefore have a bounded clique-width (2 for cographs, 3 for P<sub>4</sub>-sparse, P<sub>4</sub>-reducible, and P<sub>4</sub>-tidy).

Many algorithms of various complexities have appeared, beginning in the 1960's. The first linear-time algorithm was given by [MS94, MS99], which was quickly followed by other linear time algorithms that use quite different approaches to the problem [CH94, DGM01]. The best previous time bound for the directed case is  $O(n^2)$  [EGMS94, McC95] or  $O(m \log n)$ [DGM02]. Here we present an O(n+m)-time algorithm.

A graph G can be thought of as a coloring of the edges of the complete graph with two colors, one corresponding to edges that are contained in G and one corresponding to edges that are in its complement. This abstraction awards no special status to G over its complement; the modules are the same on both graphs. The 2-structures are a generalization of graphs: a 2-structure is a coloring of the complete digraph with k color, instead of two. This object was introduced by A. Ehrenfeucht and G. Rozenberg [ER90a, ER90b], who gave a generalization of modular decomposition to 2-structures.

Chein, Habib and Maurer [CHM81] characterized the properties that a family of sets, such as the modules of a graph, must have in order to have a decomposition tree such as the modular decomposition. Such families are called partitive set families. Our algorithm exploits the modular decomposition of a 2-structure, as well as the fact that the intersection of two partitive set families is a partitive set family. We develop a procedure for finding the tree decomposition of the intersection, given the tree decompositions of the two families.

The next section gives basic definitions and concepts. The third section presents the algorithm for finding the decomposition tree of the intersection of two partitive families. The fourth section gives a novel and simple algorithm for decomposition of tournaments that we use in the main algorithm. The fifth part of the paper gives the directed graph decomposition algorithm itself.

#### 2 Preliminaries

#### 2.1 Graphs and digraphs

Let G=(V,E) be a finite directed graph (or simply digraph) with vertexset V=V(G) and arc-set  $E=E(G)\subseteq V(G)\times V(G)$ . Here a digraph is loopless  $((u,u)\notin E)$ . Given  $H\subset V$ , the digraph induced by  $X\subseteq V$  is  $G[X]=(X,E\cap (X\times X))$ . The pair (u,v) a simple arc if  $(u,v)\in E$  and  $(v,u)\notin E$ , an edge if  $(u,v)\in E$  and  $(v,u)\in E$ , and a non-edge if  $(u,v)\notin E$  and  $(v,u)\notin E$ . Let n(G) denote the number of vertices of G and m(G) denote the number of arcs (with edges being counted twice). Let n and m denote these when G is understood.

Let  $N^+(v) = \{u|(v,u) \in E\}$  and let  $N^-(v) = \{u|(u,v) \in E\}$ . If X is a module, we may write  $N^+(X)$  and  $N^-(X)$ . A digraph can be stored in O(n+m) space using adjacency-list representation [CLRS01]. A digraph is connected if there is no partition of V in two non-empty sets with no arcs between them; a maximal connected subgraph is a component. An undirected graph (or simply graph) has no simple arc. A tree is a connected directed graph such that every vertex except one (the root) is the origin of one simple arc. A stable set is a digraph such that  $E = \emptyset$ , a clique (or complete digraph) is a digraph, such that  $E = \{(u,v)|u \neq v\}$ , and a tournament is a digraph where there is a simple arc between each pair of vertices. For our purposes, a linear order is an acyclic tournament. A linear order has a unique topological sort.

#### 2.2 Partitive families

The symmetric difference of two sets is  $A\Delta B = (A \cup B) \setminus (A \cap B)$ . Two sets X and Y overlap if they intersect, but neither is a subset of the other. That is, they overlap if  $X \setminus Y$ ,  $X \cap Y$ , and  $Y \setminus X$  are all nonempty.

Let V be a finite set and  $\mathcal{F}$  a family (set) of subsets of V. Let  $Size(\mathcal{F}) = \sum_{F \in \mathcal{F}} |F|$ .  $\mathcal{F}$  is tree-like if  $\emptyset \notin \mathcal{F}$ ,  $V \in \mathcal{F}$ ,  $\{x\} \in \mathcal{F}$  for all  $x \in V$ , and for all  $X, Y \in \mathcal{F}$ , X and Y do not overlap.

**Lemma 1** The Hasse diagram of the subset relation on a tree-like family is a tree.

Let us call the Hasse diagram of such a family the family's *inclusion tree*. This defines a parent relation on members of  $\mathcal{F}$ , and allows us to speak of the *siblings* and *children* of a member of  $\mathcal{F}$ .

The following is well-known:

**Lemma 2** If  $\mathcal{F}$  is a tree-like family on domain V and X is a nonempty subset of V that does not overlap any member of  $\mathcal{F}$ , then X is a union of one or more siblings in  $\mathcal{F}$ 's inclusion tree.

**Proof:** Let Y be the least common ancestor of X. If X is not a union of siblings, then X fails to contain some child A of Y that it intersects. Then Y overlaps A, a contradiction.

 $\mathcal{F}$  is a strongly partitive family [CHM81] (also called decomposable set family by [Möh85]) if:

- $V \in \mathcal{F}, \emptyset \notin \mathcal{F}, \text{ and } \forall v \in V, \{v\} \in \mathcal{F}$
- $\forall X,Y \in \mathcal{F}$ , if X and Y overlap, then  $X \cap Y \in \mathcal{F}$ ,  $X \cup Y \in \mathcal{F}$  and  $X \Delta Y \in \mathcal{F}$ .

In this paper we assume that the empty set is not a member of  $\mathcal{F}$ . A member of a partitive family  $\mathcal{F}$  is said to be *strong* if no other member of  $\mathcal{F}$  overlaps it, otherwise it is weak.  $\mathcal{S}(\mathcal{F})$  is the family of strong sets of  $\mathcal{F}$ . Though  $\mathcal{F}$  is not a tree-like family,  $S(\mathcal{F})$  is. Let  $T(\mathcal{F})$  denote the inclusion tree of  $\mathcal{S}(\mathcal{F})$ .

**Theorem 1** [CHM81, Möh85] Let  $\mathcal{F}$  be a strongly partitive family and let X be an internal node of  $T(\mathcal{F})$  with children  $S_1, S_2, ..., S_k$ . Then X is of one of the following two types:

- Complete: For every  $I \subset \{1, ... k\}$ , such that 1 < |I| < k,  $\bigcup_{i \in I} S_i \in \mathcal{F}$
- Prime: For every  $I \subset \{1, ... k\}$ , such that 1 < |I| < k,  $\bigcup_{i \in I} S_i \notin \mathcal{F}$

By Lemma 2, this implies that a set is a member of  $\mathcal{F}$  iff it is a node of  $T(\mathcal{F})$  or a union of children of a complete node in  $T(\mathcal{F})$ .

Notice that  $Size(\mathcal{F})$  can be exponential in |V| (the boolean family  $2^V$  is partitive) but that  $Size(S(\mathcal{F})) \leq |V|^2$ . Therefore  $T(\mathcal{F})$  is a polynomial-size representation of the family.

 $\mathcal{F}$  is a weakly partitive family if:

- $V \in \mathcal{F}, \emptyset \notin \mathcal{F}, \text{ and } \forall v \in V, \{v\} \in \mathcal{F}$
- $\forall X, Y \in \mathcal{F}$ , if X and Y overlap, then  $X \cap Y \in \mathcal{F}$ ,  $X \cup Y \in \mathcal{F}$ ,  $X \setminus Y \in \mathcal{F}$ , and  $Y \setminus X \in \mathcal{F}$ .

When X and Y are overlapping members of a strongly partitive family, then so is  $X\Delta Y$ , and this member overlaps X. Therefore,  $X\setminus Y=X\cap (X\Delta Y)$  is also a member of the family. Similarly,  $Y\setminus X$  is in the family. This implies that strongly partitive family is a weakly partitive family, but the converse is not true.

**Theorem 2** [Hab81] Let  $\mathcal{F}$  be a weakly partitive family, let X be an internal node of  $T(\mathcal{F})$ , and let  $S_1, S_2, ..., S_k$  be the children of X. Then X is of one of the following three types:

- Complete: For every  $I \subset \{1, ... k\}$ , such that  $1 < |I| < k, \bigcup_{i \in I} S_i \in \mathcal{F}$
- Prime: For every  $I \subset \{1, ... k\}$ , such that 1 < |I| < k,  $\bigcup_{i \in I} S_i \notin \mathcal{F}$
- Linear: There exists an ordering of  $\{1, 2, ..., k\}$  such that if  $I \subset \{1, ..., k\}$  and 1 < |I| < k, then  $\bigcup_{i \in I} S_i \in \mathcal{F}$  iff the members of I are consecutive in the ordering.

Conversely, by Lemma 2, if  $\mathcal{F}$  is a weak partitive family,  $Y \subseteq V$  is a member of  $\mathcal{F}$  iff it is either a node of  $T(\mathcal{F})$ , the union of a set of children children of a complete node of  $T(\mathcal{F})$ , or the union of a consecutive set of children in the ordering of a linear node.

#### 2.3 2-structures

A 2-structure [ER90a] is a triple G=(V,E,k), where V is a finite vertexset,  $k \in \mathbb{N}$ , and  $E:V \times V \mapsto \{1,\ldots k\}$  is a coloring function. A 2-structure is symmetric if E(x,y)=E(y,x). Notice that for k=2 a 2-structure is a digraph, and a symmetric 2-structure is a graph when one of the color classes is interpreted as the edges and the other as the non-edges. Furthermore, a loopless multigraph G=(V,E) where E is a multiset of pairs of vertices may be seen as a 2-structure G=(V,E',k), where E' counts the number of edges between two vertices and k is the maximum of E.

 $M \subseteq V$  is a module of a 2-structure (V, E, k) if it is nonempty and

$$\forall x, y \in M \ \forall z \notin M \ E(x, z) = E(y, z) \ and \ E(z, x) = E(z, y)$$

In other words, a module is a 2-structure is a set X of vertices that have a uniform relationship to each  $z \in V \setminus X$ . The *trivial modules* are V and its one-element (singleton) subsets.

#### Theorem 3 |ER90b|

The modules of a 2-structure form a weakly partitive family.

The modules of a symmetric 2-structure form a strongly partitive family.

The modular decomposition of a 2-structure H is the tree T(H) given by Theorem 3 and Theorem 2 or Theorem 1, depending on whether H is symmetric.

If X is a nonempty subset of V, and H is a 2-structure, let H[X] denote the substructure induced by X, that is, X and the coloring of  $X \times X$  given by H.

If X and Y are disjoint modules of H, then all members of  $X \times Y$  are colored with the same color, and all members of  $Y \times X$  are colored with the same color. If  $\mathcal{P}$  is a partition of V where every partition class is a module, the *quotient* induced by  $\mathcal{P}$  is the 2-structure with the members of  $\mathcal{P}$  as vertices, and where for  $X,Y \in \mathcal{P}$ , the color of (X,Y) is the color of the edges of  $X \times Y$  in H.

Let M be a node of T(H) and let Let  $M_1 
ldots M_k$  be its children. Since  $\{M_1, M_2, ..., M_k\}$  is a partition of the vertices of H[M] where every part is a module, it defines a quotient on H[M]. Let us call this M's quotient in T(H).

A 2-structure is *prime* if it has only trivial modules. It is a c-clique if E(x,y)=c for all x and y. It is a (c,c')-order if  $E(x,y)\in\{c,c'\}$  for all x and y, and the relation  $x\mathcal{R}y$  iff E(x,y)=c is a total order.

**Proposition 1** [ER90b] Let M be a strong module of a 2-structure G.

- If M is prime the quotient of M is a prime 2-structure.
- If M is complete, there exists c such that the quotient of M is a c-clique.
- If M is linear there exists c and c' such that the quotient of M is a (c,c')-order.

Let us say that a node is c-complete if its quotient is a c-clique, and (c, c')-linear if its quotient is a (c, c')-order.

#### 2.4 Modular decomposition of digraphs

The modules of a graph are obtained by treating it as a 2-structure on V with two colors, one for edges and one for non-edges. The properties of modules apply to graphs as a special case. By Proposition 1, if M is a a linear node of T(G), then its quotient is a total order, and if it is a complete node of T(G), then its quotient is a clique or a stable set. A complete node is a series node if its quotient is a clique and a parallel node if its quotient is a stable set.

Notice that a digraph has at most 2n-1 strong modules, while there can be  $2^n$  different modules in a digraph (e.g. a stable set).

A vertex v cuts a set  $S \subset V$  if  $v \notin S$  and S is not a module of  $G[S \cup \{v\}]$ . The vertices that cut S are its cutter-set. M is a module if and only if its cutter-set is empty.

# 3 Intersection of Strongly Partitive Set Families

Let V be a set and  $\mathcal{F}_a$ ,  $\mathcal{F}_b$  be two partitive families on V. The *intersection* of  $\mathcal{F}_a$  and  $\mathcal{F}_b$  is  $\mathcal{F} = \mathcal{F}_a \cap \mathcal{F}_b$ , the family of sets that are members of both families.

**Lemma 3** The intersection of two strongly partitive families is a strongly partitive family.

**Proof:** Let  $\mathcal{F}_a$  and  $\mathcal{F}_b$  be the two families. If X and Y are overlapping members of  $\mathcal{F}_a \cap \mathcal{F}_b$ , they are members of  $\mathcal{F}_a$ , so  $X \cup Y$ ,  $X \cap Y$ , and  $X \Delta Y$  are members of  $\mathcal{F}_a$ . The same is true of  $\mathcal{F}_b$ , so  $X \cup Y$ ,  $X \cap Y$ , and  $X \Delta Y$  are members of  $\mathcal{F}_a \cap \mathcal{F}_b$ .

This suggests a binary operator on decomposition trees over domain V. Given two decomposition trees  $T_a$  and  $T_b$  of strongly partitive families on domain V, let  $T_a \wedge T_b$  denote the partitive tree of  $\mathcal{F}(T_a) \cap \mathcal{F}(T_b)$ , which exists by Lemma 3.

In this section, we give an algorithm for computing  $T_a \wedge T_b$  efficiently, given partitive trees  $T_a$  and  $T_b$  on the same domain V. In the rest of this section, let  $\mathcal{F}_a$  and  $\mathcal{F}_b$  denote the partitive families represented by  $T_a$  and  $T_b$ , and let  $\mathcal{I} = \mathcal{F}_a \cap \mathcal{F}_b$ .

Given a partitive tree T, let  $\mathcal{F}(T)$  be the partitive set family that it represents. Let  $\mathcal{S}(T)$  denote the strong members of that family. That is,  $\mathcal{S}(T)$  is just the set of nodes of T.

If  $S \subset V$  is a union of one or more siblings in  $T_a$ , then let  $P_a(S)$  be their parent.  $P_a(S)$  is the smallest node of  $T_a$  that contains S as a proper subset. Let  $P_b(S)$  be defined in the same way on  $T_b$ .

Given an arbitrary set family S of subsets of domain V, let the *overlap graph* O(S) denote the graph whose vertices are the members of S and whose edges are the pairs  $\{(A,B)|A \text{ and } B \text{ are overlapping members of } S\}$ . The connected components of O(S) are known as the *overlap components*.

**Lemma 4** If C is an overlap component of S and X is a set that overlaps  $\bigcup C$ , then X overlaps some  $S \in C$ .

**Proof:** Since X overlaps  $\bigcup \mathcal{C}$ , it is not contained in any member of  $\mathcal{C}$ . Suppose X overlaps no member of  $\mathcal{C}$ . Let  $\{\mathcal{A}, \mathcal{B}\}$  be the partition of members of  $\mathcal{C}$  that

are disjoint from X and contained in X, respectively. Since X overlaps  $\bigcup \mathcal{C}$ , each of  $\mathcal{A}$  and  $\mathcal{B}$  is nonempty. No member of  $\mathcal{A}$  overlaps any member of  $\mathcal{B}$ , contradicting the assumption that  $\mathcal{C}$  is an overlap component.

Given strongly partitive trees  $T_a$  and  $T_b$ , let  $\mathcal{O}(T_a, T_b) = \{\bigcup \mathcal{C} | \mathcal{C} \text{ is an overlap component of } \mathcal{S}(T_a) \cup \mathcal{S}(T_b)\}$ . V and its singleton subsets are members of  $\mathcal{O}(T_a, T_b)$ . By Lemma 4, no members of  $\mathcal{O}(T_a, T_b)$  overlap, so it is a tree-like family, and no nodes of  $T_a$  or  $T_b$  overlap a member of  $\mathcal{O}(T_a, T_b)$ . No member of  $\mathcal{I}$  overlaps a node of  $T_a$  or of  $T_b$ , so by Lemma 4, no member of  $\mathcal{I}$  overlaps any member  $\mathcal{O}(T_a, T_b)$ . This gives the following by Lemma 2:

**Lemma 5** Every node of  $T_a$  and  $T_b$ , and every member of  $\mathcal{I}$ , is a union of siblings in inclusion tree of  $\mathcal{O}(T_a, T_b)$ .

Let  $\mathcal{A} = \{S | S \in \mathcal{O}(T_a, T_b) \text{ and } S \text{ is a node of } T_a \text{ or } P_a(S) \text{ is not prime in } T_a\}$ . Let  $\mathcal{B}$  be defined analogously on  $T_b$ . If  $T_a$  and  $T_b$  are strongly partitive trees, then let  $\mathcal{U}(T_a, T_b) = \mathcal{A} \cap \mathcal{B}$ .

Let  $R_U$  be the following relation on members of  $\mathcal{U}(T_a, T_b)$ : for  $X, Y \in \mathcal{U}(T_a, T_b)$ ,  $XR_UY$  iff  $P_a(X) = P_a(Y)$ ,  $P_b(X) = P_b(Y)$ , and neither of these nodes is prime.

Clearly,  $R_U$  is an equivalence relation. Let  $\mathcal{S}(T_a, T_b) = \mathcal{U}(T_a, T_b) \cup \{\bigcup \mathcal{D} | \mathcal{D}\}$  is an equivalence class in  $R_U$ .

**Theorem 4** If  $T_a$  and  $T_b$  are the decomposition trees of strongly partitive families, then  $S(T_a, T_b)$  is the set of nodes of  $T(\mathcal{I})$ .

**Proof:** Suppose  $X \in \mathcal{O}(T_a, T_b)$  is a member of  $\mathcal{I}$ . Then it must be a node of  $T_a$  or a union of children of a degenerate node in  $T_a$ , hence, by Lemma 5 it is a member of  $\mathcal{A}$ . Similarly, it is a member of  $\mathcal{B}$ , so it is a member of  $\mathcal{A} \cap \mathcal{B}$ . X overlaps with no member of  $\mathcal{I}$ , hence it is a node of  $T_{\mathcal{I}}$ .

If  $X \in \mathcal{I}$  is a node of  $T_a$  or of  $T_b$ , then, since X overlaps no other node of  $T_a$  or  $T_b$  it is the sole member of its equivalence class, hence a member of  $\mathcal{O}(T_a, T_b)$ . Any member Z of  $\mathcal{I}$  that is not a member of  $\mathcal{O}(T_a, T_b)$  must be a union of more than one and fewer than all children of some degenerate node  $Y_a$  in  $T_a$  and more than one and fewer than all children of some degenerate node  $Y_b$  in  $T_b$ , hence the union of some subfamily of the equivalence class of  $R_Y$  corresponding to  $Y_a$  and  $Y_b$ . Every union of members of this equivalence class is a member of  $\mathcal{I}$ , so if Z is a node of  $T(\mathcal{I})$ , it must be must be the union of the entire equivalence class to avoid overlapping other such unions. This is also sufficient: if Z is the union of the entire equivalence class, no member of  $\mathcal{I}$  overlaps  $Y_a$  or  $Y_b$ , and therefore no member of  $\mathcal{I}$  overlaps Z, hence Z is a node of  $T(\mathcal{I})$ .

We now describe some basic algorithmic tools.

**Lemma 6** Given a tree-like family  $\mathcal{F}$ , it takes  $O(Size(\mathcal{F}))$  time to construct its inclusion tree.

**Proof:** If V is the domain,  $Size(\mathcal{F}) = \Omega(|V|)$ , since  $V \in \mathcal{F}$ . Sort the members of  $\mathcal{F}$  by size. This takes  $O(Size(\mathcal{F}))$  time when using radix sort, since the sizes are in the ranges from 1 to |V| [CLRS01]. Then, create a list, for each  $x \in V$ , of the members of  $\mathcal{F}$  that contain x, in ascending order of size. This can be accomplished by visiting each  $Y \in \mathcal{F}$  in descending order of size, and for each  $x \in Y$ , inserting a pointer to Y to the front of x's list. This takes  $O(Size(\mathcal{F}))$ 

time. Then, visit each member x of V, putting a parent pointer from each member of x's list to its successor in x's list if there isn't already one, as these are the chain of ancestors of  $\{x\}$ .

Next, consider Algorithm 1 which is given in [Spi92], and which we reproduce here for completeness. Given an inclusion tree on a domain V and an arbitrary  $X \subseteq V$ , it finds the maximal members of  $\mathcal{F}$  that are subsets of X. The algorithm runs in O(|X|) time, with linear-time initializations performed once.

```
Input: An inclusion tree T on V and an arbitrary subset X of V

Output: The maximal nodes N_1, \ldots N_k of T such that N_i \subset X

begin

foreach leaf N = \{x\} of T, x \in X do

mark N

end

foreach node N of T such that all its children S_1, \ldots S_k are marked do

Unmark S_1, \ldots S_k

mark N

end
```

Algorithm 1: Mark the maximal nodes of an inclusion tree that are subsets of  $X \subseteq V$ 

Let an inclusion tree be *initialized* if each node carries a parent pointer, a list of pointers to its children, an initialized field for marking, a record of how many children it has, and an initialized field for recording how many of its children are marked. The next lemma follows easily from Algorithm 1.

**Lemma 7** [Spi92] Given an initialized inclusion tree of a tree-like set family  $\mathcal{F}$  on domain V and a set  $X \subseteq V$ , it takes O(|X|) time to find the maximal members of  $\mathcal{F}$  that are subsets of X, and then reinitialize the tree.

**Corollary 1** Given the decomposition tree of a strongly partitive family  $\mathcal{F}$  on domain V and  $X \subseteq V$ , it takes O(|X|) time to determine whether  $X \in \mathcal{F}$ .

**Proof:** X is a member of  $\mathcal{F}$  iff it is a node of the decomposition tree or a union of children of a complete node. By Lemma 7, we may find the maximal nodes of the decomposition tree that are subsets of X, and verify that if there is more than one of them, they share a complete parent.

**Theorem 5** [Dah00] Given a set family S on domain V, it takes O(|V| + Size(S)) time to find the overlap components of S.

The algorithm, which is straightforward to implement, finds the components without actually computing the overlap graph. Finding the union of each of these components using an initialized boolean array of size |V| gives  $\mathcal{O}(T_a, T_b)$ .

The following is the main result of this section.

**Theorem 6** Given decomposition trees  $T_a$  and  $T_b$  of strongly partitive families on domain V, it takes  $O(Size(S(\mathcal{F}_a)) + Size(S(\mathcal{F}_b)))$  time to find  $T(\mathcal{I}) = T_a \wedge T_b$ .

**Proof:** By Theorem 5, the bound is observed for finding the overlap components of the nodes  $\mathcal{S}(\mathcal{F}_a) \cup \mathcal{S}(\mathcal{F}_b)$  of  $T_a$  and  $T_b$ . The union of each component is easily found within the bound using a boolean array of size O(|V|) that is initialized once, and left in an initialized state after each union operation. This gives  $\mathcal{O}(T_a, T_b)$ . By Lemma 6, we may find the inclusion tree of  $\mathcal{O}(T_a, T_b)$  within the bound.

By Corollary 1, Algorithm 1 can be used to test each node in this tree for membership in  $\mathcal{A}$  and for membership in  $\mathcal{B}$  in time linear in  $Size(\mathcal{O}(T_a, T_b))$ , which gives  $\mathcal{U}(T_a, T_b)$ .

We may then number the members of  $\mathcal{U}(T_a, T_b)$  from 1 to O(n). Algorithm 1 can then be used to find  $P_a(X)$  and  $P_b(X)$  for each  $X \in \mathcal{U}(T_a, T_b)$  in  $O(Size(\mathcal{U}(T_a, T_b))$  time. The number labels of  $P_a(X)$  and  $P_b(X)$  give a pair of integers, each from 1 to O(n); radix sorting the members of  $\mathcal{U}(T_a, T_b)$  according to this number pair gives the equivalence classes of  $R_U$ . The union of each equivalence class can be found in linear time using an initialized boolean array of size O(|V|).

# 4 Modular decomposition of tournaments

A factorizing permutation  $\sigma$  of a graph G is a linear ordering of V(G) such that every strong module of G is a factor (interval) of  $\sigma$ . An embedding of T(G) gives a factorizing permutation, just by reading its leaves from left to right. Conversely, Capelle, Habib and Montgolfier [CHdM02] give an O(n+m) algorithm for retrieving T(G), given a factorizing permutation. The algorithm that we give in this section for finding the modular decomposition of a tournament does so by computing a factorizing permutation and then making use of this result.

Let say that a factorizing permutation is perfect if all modules of G, not just the strong modules, are intervals in the ordering.

A factorizing permutation exists for every graph, but a requirement for a perfect factorizing permutation to exist is that all nodes of the modular decomposition be prime or linear. All tournaments admit a perfect factorizing permutation. The factorizing permutation computed by the algorithm of this section is a perfect one, a fact that we make use of in a later section.

The algorithm uses ordered partition refinement algorithm [PT87]. An ordered partition is a list  $\mathcal{P}$  of non-empty and pairwise-disjoint subsets (classes) of a set V, whose union is V, with a total order on the classes.

At each step, up to three new classes are substituted for an old one. Empty classes are not inserted.

Correctness of the algorithm: The correctness of this algorithm is a consequence of the following three invariants:

**Invariant 1** For all  $0 \le i \le n$ ,  $\mathcal{P}_i$  is an ordered partition of V having at least i singleton classes.

**Invariant 2** Let i be the current step and C any class of  $\mathcal{P}_i$  having more than one vertex.

• If C is not the leftmost class of  $\mathcal{P}_i$ , then the class on the left of C is a singleton class  $\{v_j\}$ , j < i. Furthermore,  $C \subset N^+(v_j)$ .

```
Input: A tournament G = (V, E)

Output: A perfect factorizing permutation \mathcal{P}_n of G

begin

Let v_1 \dots v_n be any ordering of V

\mathcal{P}_0 \leftarrow \{V\}

for i from 1 to n do

Let C be the class of \mathcal{P}_{i-1} such that v_i \in C

\mathcal{P}_i = \mathcal{P}_{i-1} where C is replaced by C \cap N^-(v_i) \ \uplus \ \{v_i\} \ \uplus C \cap N^+(v_i)

end
end
```

Algorithm 2: A perfect factorizing permutation  $\mathcal{P}_n$  of G

• If C is not the rightmost class of  $\mathcal{P}_i$ , then the class on the right of C is a singleton class  $\{v_k\}$ , k < i. Furthermore,  $C \subset N^-(v_k)$ .

**Invariant 3** For all  $0 \le i \le n$ , the partial order  $\mathcal{P}_i$  has a linear extension that is a perfect factorizing permutation.

Invariant 3 is equivalent to the following: whenever M is a module of the tournament, the members of  $\mathcal{P}_i$  that intersect M are consecutive in the ordering on  $\mathcal{P}_i$ , and only the first and last of these can overlap with M.

The proof of the first two invariants is easy. Let us prove the third. Trivially  $\mathcal{P}_0$  can be extended to a perfect factorizing permutation. Let us suppose that  $\mathcal{P}_{i-1}$  also can. Let M be a module. Since  $\mathcal{P}_i$  differs from  $\mathcal{P}_{i-1}$  only in the class C that contains  $v_i$ , it is clear that our proof deals only with  $C \in \mathcal{P}_{i-1}$ . Let  $C_a$  be  $C \cap N^-(v_i)$  and  $C_b$  be  $C \cap N^+(v_i)$ . There are three cases:

- 1. If  $C \subseteq M$ , then the invariant is still true for M no matter how C is split.
- 2. If  $M \subset C$ , then
  - If  $v_i \in M$ , then M can overlap only the two classes  $C_a$  and  $C_b$ , and contains the class  $\{v_i\}$  between them, so the invariant is true.
  - If  $v_i \notin M$  then, since M is a module,  $M \subseteq C_a$  or  $M \subseteq C_b$  depending on whether  $M \subseteq N^+(v_i)$  or  $M \subseteq N^-(v_i)$ .
- 3. If M overlaps C, then M intersects either the class on the left of C, or the class on its right. According to Invariant 2, this class is a singleton class, say  $\{w\}$ . Suppose without loss of generality that w is to the right of C. Then  $C \subseteq N^-(w)$ .
  - If  $v_i \notin M$ , then  $M \subset N^+(v_i)$  (because M is a module containing  $w \in N^+(v_i)$ ). So  $M \cap C = M \cap C_b$ . Since  $C_b$  is located on the right of  $\{v_i\}$ , the invariant still holds.
  - If  $v_i \in M$  then  $\forall x \in C_b$ ,  $w \in N^+(x)$  and  $v_i \in N^-(x)$ . As  $\{v_i, w\} \subset M$ ,  $x \in M$  (it cannot cut a module), thus  $C_b \subset M$ . M can overlap only  $C_a$ , and contains  $\{v_i\}$  and  $C_b$ : the invariant still holds.

**Theorem 7** Algorithm 4 computes a perfect factorizing permutation of any tournament in O(n+m) time.

**Proof:** The correctness is directly given by Invariants 1 and 3. At the  $n^{th}$  step, all classes are singleton, so the order is total. Since every vertex  $v_i$  is used once, and since computing  $C_a$  and  $C_b$  takes O(n) time, the whole process takes  $O(n^2)$  time, which is linear since G has  $\Theta(n^2)$  arcs.

# 5 Modular decomposition of directed graphs

If G = (V, E) is a digraph. Let us define the following auxiliary objects:

The undirected graph  $G_s = (V, E_s)$  such that  $\{u, v\} \in E_s$  if and only if  $(u, v) \in E$  or  $(v, u) \in E$ 

The undirected graph  $G_d = (V, E_d)$ , such that  $\{u, v\} \in E_d$  if and only if  $(u, v) \in E$  and  $(v, u) \in E$ .

Let H and H' be two symmetric 2-structures on domain V. Let  $H \wedge H'$ , denote the two structure on domain V where two arcs have the same label iff they have the same label in both H and H'.

**Theorem 8** If H and H' are symmetric 2-structures on domain V, then

$$T(H \wedge H') = T(H) \wedge T(H')$$

**Proof:** Let  $\mathcal{F}$  be the modules of H and  $\mathcal{F}'$  be the modules of H'. By the definitions,  $M \subseteq V$  is a module of both H and H' iff for  $x \in V \setminus M$ , all edges between x and M have the same color in  $H \wedge H'$ . Therefore, the modules of  $H \wedge H'$  are  $\mathcal{F} \cap \mathcal{F}'$ , whose decomposition tree is  $T(H) \wedge T(H')$ .

Since undirected graphs are a special case of symmetric 2-structures, we may define the symmetric 2-structure  $H(V, E_H) = G_s \wedge G_d$ . Let us assume that the colors of edges of H are indicated with the following labels:

- $E_H(u,v) = 0$  if  $\{u,v\}$  is a non-edge ( $\{u,v\}$  is a non-edge in both  $G_s$  and  $G_d$ ).
- $E_H(u,v) = 1$  if  $\{u,v\}$  is an edge  $(\{u,v\})$  is an edge in both  $G_s$  and  $G_d$ .
- $E_H(u,v) = 2$  if (u,v) or (v,u) is a simple arc  $(\{u,v\})$  is an edge in  $G_s$  but not in  $G_d$ ).

Since the edges of  $G_d$  are a subset of the edges of  $G_s$ , there is no color for edges that are in  $G_d$  but not in  $G_s$ .

By Theorem 8, M is a module of H if and only if it is a module of both  $G_s$  and  $G_d$ .

**Lemma 8** Every module of G is a module of H.

**Proof:** Suppose  $X \subset V$  fails to be a module of  $G_d$  or  $G_s$ . Then there exist  $x_1, x_2 \in X$  and  $y \in V \setminus X$  such that, in  $G_d$  or  $G_s$ , y is a neighbor of  $x_1$  but not of  $x_2$ . If this happens in  $G_s$ , then  $(x_1, y)$  or  $(y, x_1)$  is an arc of G, but neither  $(x_2, y)$  nor  $(y, x_2)$  is an arc of G, and X fails to be a module of G. If it happens in  $G_d$ , then both of  $(x_1, y)$  and  $(y, x_1)$  are arcs of G, but one of  $(x_2, y)$  and  $(y, x_2)$  fails to be an arc, and X again fails to be a module of G.

**Corollary 2** There exists a way to order the children of each node in T(H) so that the resulting leaf order is a factorizing permutation of G.

**Proof:** Let X be a complete node of T(H), and let  $S = \{S_1, S_2, ..., S_k\}$  be its children. Let  $\mathcal{F}_X$  denote the tree-like family on domain S whose root is S, whose leaves are  $\{S_i|S_i \in S\}$ , and whose internal nodes are  $\{S'|\bigcup S'$  is a strong module of  $G\}$ . Since no members of  $\mathcal{F}_X$  overlap, it is a tree-like family on domain S. If  $\{S_1, S_2, ..., S_k\}$  is ordered according to their depth-first ordering of the inclusion tree of  $\mathcal{F}_X$ , all unions of children of X that are strong modules of G will be consecutive. By Lemma 8, every strong module of G is a node of G or a union of children of a degenerate node of G is a polying such an ordering at every degenerate node of G will impose a factorizing permutation of G on the leaves.

Our algorithm proceeds by ordering the children of nodes in T(H) to obtain a factorizing permutation of G in linear time. Combining this with the algorithm of [CHdM02] gives a linear-time algorithm for modular decomposition of G.

Let X be a 0-complete or 1-complete node of T(H), and let  $S_1, S_2, ..., S_k$  be its children that are modules of G. Let  $R_X$  be the relation on  $\{S_1, S_2, ..., S_k\}$  where  $S_i R_X S_j$  iff  $N^+(S_i) \cap (V \setminus X) = N^+(S_j) \cap (V \setminus X)$  and  $N^-(S_i) \cap (V \setminus S) = N^-(S_j) \cap (V \setminus X)$ . Clearly,  $R_X$  is an equivalence relation.

**Lemma 9** If X is a 0-complete or 1-complete node of T(H) and Y is a strong module of G that is a union of children of X and not strong in H, then Y is the union of all the members of an equivalence class of  $R_Y$ .

**Proof:** Suppose X is 0-complete, Y is a parallel node of the modular decomposition tree of G. The connected components  $C_1, \ldots C_k$  of G[Y] are modules of H. X is a parallel module of  $G_s$  and  $C_i$  is connected in  $G_s[Y]$ , so no module of  $G_s$  overlaps it.  $C_i$  is then a node of the modular decomposition of H, that is  $R_X$ -equivalent to  $C_j$ .

Therefore, Y must be a union of children of X that are modules of G, members of a single  $R_X$  equivalence class, and, since Y is not strong in H, it must be the union of more than one child. The union of every subfamily of members of an equivalence is a module of G[X] and has no cutters outside of X, so it is a module of G. Y must overlap such a union and thereby fail to be strong in G unless it is the union of all members of the equivalence class.

If X is 1-complete, then Y is a series module of G and of  $G_d$ . A child  $C_i$  of Y in the modular decomposition tree of G is not connected in  $G_d$ , therefore no module of  $G_d$  overlaps it. Then the same proof holds.

**Lemma 10** Let X be a 2-complete node of T(H), let  $S_1, S_2, ..., S_k$  be its children, and let  $S = \{s_1, s_2, ..., s_k\}$  be arbitrary representatives from  $S_1, S_2, ..., S_k$ , respectively. If  $(s_1, s_2, ..., s_k)$  is a perfect factorizing permutation of G[S], then every subfamily of  $\{S_1, S_2, ..., S_k\}$  whose union is a module of G must be consecutive in  $(S_1, S_2, ..., S_k)$ .

**Proof:** If M is a module of G that is a union of children of X, then  $M \cap S$  is a module of G[S]. Since  $(s_1, s_2, ..., s_k)$  is a perfect factorizing permutation of G[S],  $M \cap S$  is consecutive in this ordering, hence M is consecutive in  $(S_1, S_2, ..., S_k)$ .

This gives an algorithm for finding the modular decomposition of G:

- 1. Find  $G_s$  and  $G_d$  and H
- 2. Find the modular decompositions  $T(G_d)$  and  $T(G_s)$  of  $G_d$  and  $G_s$  using one of the algorithms of [MS99, CH94, DGM99].
- 3. Find  $T(H) = T(G_s) \wedge T(G_d)$
- 4. At each 0-complete and 1-complete node X, order the children so that each equivalence class of  $R_X$  is consecutive.
- 5. At each 2-complete node Y, select an arbitrary set S of representatives from the children. Order the children of Y according to a perfect factorizing permutation of G[S]
- 6. The resulting leaf order of T(H) is a factorizing permutation of G by Lemmas 9 and 10. Use the algorithm of [CHdM02] to find the modular decomposition of G.

Algorithm 3: Modular decomposition of a digraph

#### 5.1 Complexity analysis

A linear time bound for Step 1 is trivial and the linear time bounds for Steps 3 and 6 are immediate from the cited results. At each node Y of Step 5, we may charge the cost of finding the perfect factorizing permutation of G[S] to the corresponding edges of G at a cost of O(1) per edge, by Theorem 7. These edges all have Y as their least common ancestor in T(H), so no edge of G is charged more than once. It remains to derive the linear time bounds for steps 3 and 4.

#### 5.1.1 Step 3

**Theorem 9** Let G be a digraph and M the set of its strong modules.

$$\sum_{M \in \mathcal{M}} |M| \le 2m + 3n$$

Furthermore if G is connected, then

$$\sum_{M \in \mathcal{M}} |M| \le 2m + 2n$$

**Proof:** Let  $\rho(G)$  be the sum  $\sum_{M \in \mathcal{M}} |M|$ . Clearly for a one-vertex digraph  $\rho(G) = 1$ . Let us suppose the theorem holds for digraphs up to n-1 vertices, and let G be a digraph having n vertices.

If G is not connected, then G has  $k \geq 2$  connected components  $G_1 \dots G_k$ . Theorem 9 applies to each, so:

$$\forall 1 \leq i \leq k, \ \rho(G_i) \leq 2m_i + 2n_i$$

Moreover, a strong module of G is either a strong module of G,  $i \in \{1 ... k\}$ , or the vertex-set V(G). Each arc of G appears in exactly one G, so that  $\sum_i m_i = m$ .

$$\rho(G) = n + \rho(G_1) + \ldots + \rho(G_k) 
\leq n + 2m_1 + 2n_1 + \ldots + 2m_k + 2n_k 
< 2m + 3n$$

If G is connected, let  $G_i$   $1 \le i \le k$  be the maximal strong modules of G. Each one has less than n vertices, so

$$\forall 1 \leq i \leq k, \ \rho(G_i) \leq 2m_i + 3n_i$$

There are two kinds of arcs in G: the  $\sum m_i$  arcs that are internal to one  $G_i$ , and the  $m' = m - \sum m_i$  "external" arcs joining two  $G_i$ 's.

1. If every  $G_i$  has at least two vertices, then every vertex of G is adjacent to at least two external arcs, so  $m' \ge n$ .  $\sum m_i \le m - n$ .

$$\rho(G) = n + \rho(G_1) + \ldots + \rho(G_k) 
\leq n + 2m_1 + 3n_1 + \ldots + 2m_k + 3n_k 
\leq 4n + 2\sum_{i=1}^{n} m_i 
\leq 2n + 2m$$

2. Otherwise one  $G_i$  (say  $G_1$ ) has only one vertex. G is connected and, if its internal arcs are removed, G remains connected. Therefore  $m' \geq n-1$ .  $\sum m_i \leq m-n+1$ 

$$\rho(G) = n + \rho(G_1) + \rho(G_2) + \dots + \rho(G_k) 
\leq n + 1 + 2m_2 + 3n_2 + \dots + 2m_k + 3n_k 
\leq n + 1 + 2\sum_{i=1}^{n} m_i + 3(n - 1) 
\leq n + 1 + 2m - 2n + 2 + 3n - 3 
\leq 2n + 2m$$

Corollary 3 Step 3 takes O(n+m) time.

**Proof:** The sizes of  $G_d$  and  $G_s$  are O(n+m), so the result follows immediately from Theorems 6 and 9.

#### 5.1.2 Step 4

For Step 4, we must compute the equivalence classes of  $R_X$  at each 0-complete or 1-complete node X of T(H). For this, it suffices to identify those members of of the children  $\{S_1, S_2, ..., S_k\}$  of X that are modules of G, and to group these according to their adjacencies with vertices in  $V \setminus X$ .

A solution to this problem on undirected graphs was first given in [Spi92] and is a key step in the algorithms of [MS99, DGM99]. Its generalization to a directed graph G using the decomposition tree  $T_H$  of H is straightforward, as we show next. We present their a variation of the computation method.

The algorithm is general to any inclusion tree T, not just  $T_H$ . Number the elements of V from 1 to n in the order of left-to-right appearance in an arbitrary embedding of T. This gives a factorizing permutation  $\sigma$ . Each node of T occupies a factor of  $\sigma$ . Let le(X) be the first occurrence of a vertex of X in

 $\sigma$  and re(X) the last occurrence. If a node X of T has a cutter to its left in the ordering, let lc(X) denote the the number label of the leftmost of its cutters; otherwise let lc(X) = le(X). If it has a cutter to its right, let rc(X) denote the rightmost of its cutters; otherwise, let rc(X) = re(X). Note that X is a module iff lc(X) = le(X) and rc(X) = re(X).

**Lemma 11** le(X), re(X), lc(X) and rc(X) can be computed, for all nodes X of  $T_H$ , in O(n+m) time.

**Proof:** Computing re(X) and le(X) can be done bottom-up. If X is a leaf,  $lc(X) = rc(X) = \sigma(x)$ . Else, lc(X) and rc(X) can be computed using the following recurrence relations, where  $S_1, \ldots S_k$  are the children of X:

$$lc(X) = \min_{\sigma} (lc(S_1) \dots lc(S_k), lc(\{re(S_1), le(S_2)\}) \dots lc(\{re(S_{k-1}), le(S_k)\}))$$

$$rc(X) = \max_{\sigma} (rc(S_1) \dots rc(S_k), rc(\{re(S_1), le(S_2)\}) \dots rc(\{re(S_{k-1}), le(S_k)\}))$$

The proof for rc(X) is that  $lc(X) = \min_{\sigma} (rc(\{\sigma(i), \sigma(j)\}) \mid le(X) \leq i \neq j \leq re(X))$ . As a vertex cuts  $\{\sigma(i), \sigma(j)\}$  then it cuts  $\{\sigma(c), \sigma(c+1)\}, i \leq c < j$ , we have  $: lc(X) = \min_{\sigma} (rc(\{\sigma(i), \sigma(i+1)\}) \mid le(X) \leq i < re(X))$  Factorizing each  $S_i$  gives the result. Same proof for lc(X).

A vertex x, preceded by y and trailed by z in  $\sigma$ , is used twice: one time for the computation of the node that is the least common ancestor of x and y, and one time for the least common ancestor of x and z. The key point of the complexity analysis is to show that  $lc(\{x,y\})$  and  $rc(\{x,y\})$  can be computed in  $O(|N^+(x)| + |N^-(x)| + |N^+(y)| + |N^-(y)|)$  time.

To do this, radix sort the edges of G according to  $\sigma$ , with vertex of origin as the primary key and destination vertex as the secondary key, in order to get  $N^+(x)$  in sorted order of destination vertex at each vertex x. This takes O(n+m) time [CLRS01]. Reverse the roles of primary and secondary key and sort again to get  $N^-(x)$  in sorted order of vertex of origin in O(n+m) time.  $lc(\{x,y\})$  is the first vertex of  $(N^+(x)\Delta N^+(y)) \cup (N^-(x)\Delta N^-(y))$ . As these lists are sorted according to  $\sigma$ , it is easy to find.  $rc(\{x,y\})$  is the last vertex of these lists.

For a node Y that is a module of G and child of a 0-complete or 1-complete node X of  $T_H$ , let  $S^+(Y)$  be  $N^+(Y) \setminus X$  and a  $S^-(Y)$  be  $N^-(Y) \setminus X$ .  $S^+(Y)$  and  $S^-(Y)$  can be computed by taking any vertex  $y \in Y$  and pruning elements of X from its adjacency list. Two children of X are  $R_X$ -equivalent iff they have the same lists. Since the lists are sorted according to  $\sigma$ , a partition refining algorithm using their first element, then the second, and so on until the last, separates the children of a 0-complete or 1-complete node X into  $R_X$  classes.

**Lemma 12** Step 4 takes O(n+m) time.

**Proof:** Lemma 11 give the time bound for discrimination of modules. That the lengths of the  $S^+$  and  $S^-$  lists summed over all nodes of the tree is O(m) follows easily from the fact that the sum  $\sum_{x \in V} |S^+(\{x\})| + |S^-(\{x\})|$  of lengths of lists at the leaves is m, and at each internal node X, the lengths of its lists are at most half of the sum of lengths of the its children's lists. That is, if C(X) denotes the children of X,  $|S^+(X)| \leq (1/2) \sum_{S \in C(X)} |S^+(S)|$  and  $|S^-(X)| \leq (1/2) \sum_{S \in C(X)} |S^-(S)|$ .

The algorithm is linear in the lengths of the  $S^+$  and  $S^-$  lists, so it takes O(n+m) time to find the  $R_X$  classes.
