HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

GAUSSIAN LAWS FOR THE MAIN PARAMETERS OF THE EUCLID ALGORITHMS

LOÏCK LHOTE AND BRIGITTE VALLÉE

ABSTRACT. We provide sharp estimates for the probabilistic behaviour of the main parameters of the Euclid Algorithms, both on polynomials and on integer numbers. We study in particular the distribution of the bit-complexity which involves two main parameters : digit-costs and length of remainders. We first show here that an asymptotic gaussian law holds for the length of remainders at a fraction of the execution, which exhibits a deep regularity phenomenon. Then, we study in each framework –polynomials (P) and integer numbers (I)– two gcd algorithms, the standard one (S) which only computes the gcd, and the extended one (E) which also computes the Bezout pair, and is widely used for computing modular inverses.

The extended algorithm is more regular than the standard one, and this explains that our results are more precise for the Extended algorithm: we exhibit an asymptotic gaussian law for the bit-complexity of the extended algorithm, in both cases (P) and (I). We also prove that an asymptotic gaussian law for the bit-complexity of the standard gcd in case (P), but we do not succeed obtaining a similar result in case (I).

The integer study is more involved than the polynomial study, as it is usually the case. In the polynomial case, we deal with the central tools of the distributional analysis of algorithms, namely bivariate generating functions. In the integer case, we are led to dynamical methods, which heavily use the dynamical system underlying the number Euclidean algorithm, and its transfer operator. Baladi and Vallée [2] have recently designed a general framework for “distributional dynamical analysis”, where they have exhibited asymptotic gaussian laws for a large family of parameters. However, this family does not contain neither the bit-complexity cost nor the size of remainders, and we have to extend their methods for obtaining our results. Even if these dynamical methods are not necessary in case (P), we explain how the polynomial dynamical system can be also used for proving our results. This provides a common framework for both analyses, which well explains the similarities and the differences between the two cases (P) and (I), for the algorithms themselves, and also for their analysis. An extended abstract of this paper can be found in Proceedings of LATIN’06 [21].

1. INTRODUCTION

The Euclid algorithm is one of the most ancient algorithmic scheme. Designed by Euclid himself for computing the greatest common divisor [in shorthand notation, gcd] of two integer numbers, with a sequence of Euclidean divisions, this scheme can also be applied on polynomials with coefficients in a field K . There are two main algorithmic instances of the Euclid Algorithm: the first one works on the ring of polynomials $\mathbb{F}_q[X]$ (whose coefficients belong to the finite field \mathbb{F}_q with q elements), whereas the second one deals with the set \mathbb{N} of positive integers. The Euclid algorithm plays a central rôle in these two algorithmic domains. In polynomial case, this is a main step for factoring polynomials, and, in a sense, factorisation of polynomials can be seen as a sequence of gcd computations. And, polynomial factoring is widely used in computer algebra. Of course, the situation is a priori quite different for integers, since integer factoring is thought to be “difficult”: gcd computations, even if they are used in some important steps of factoring algorithms, are not sufficient here. However, the Euclid algorithm is also central in other domains of arithmetic: in the exact rational arithmetic, gcd computations are crucial, in order to keep the size of rationals small. However, the Euclid algorithm is not only useful for computing gcd. Together with the gcd, a second output of the Euclid algorithm is the continued fraction expansion [in both cases]. And it proves often more efficient to compute directly with this continued fraction than using the rational itself. And finally, the (extended) Euclidean algorithm computes modular inverses, and this type of computation is central in cryptography, for instance. See the book [30] for nice applications of the Euclidean scheme.

Date: 17th March 2007.

1.1. The Euclid Algorithms. In the sequel, the set \mathbb{A} will denote $\mathbb{F}_q[X]$ or \mathbb{N} . The degree of a non-zero polynomial u is denoted by $\deg u$. For $u = 0$, we let $\deg u := -\infty$. On positive integers, we consider the usual absolute value $\|v\| := v$, while, on polynomials, we consider the ultrametric absolute value, defined by $\|v\| := q^{\deg v}$, and $\|0\| = 0$. In the integer case, the size of a non-zero integer v , denoted by $\ell(v)$, is the binary length of the integer v ; it equals $\lfloor \lg v \rfloor + 1$, where \lg denotes the logarithm in base 2. For polynomials, the size $\ell(v)$ of a non-zero polynomial v equals the number of coefficients of the polynomial, i.e., $1 + \deg v$. In summary, for $v \neq 0$,

$$(1) \quad \text{Case (P): } \ell(v) := 1 + \deg v, \quad \text{Case (I): } \ell(v) := 1 + \lfloor \lg v \rfloor.$$

A polynomial v is monic if its dominant coefficient is equal to 1; in the integer case (by definition), the monic elements are just all the non-zero elements of \mathbb{N} . We will consider, as the set of possible inputs for the Euclid Algorithm, the set

$$(2) \quad \Omega := \{(u, v) \in \mathbb{A}^2; \ 0 \leq \|u\| < \|v\|, \ v \text{ monic}\}.$$

For any (u, v) of Ω , and by definition, the size of pair (u, v) is just the size $\ell(v)$ of v and the norm of this pair is just the norm $\|v\|$ of v .

The Euclid algorithm computes the greatest common divisor (in short gcd) by using Euclidean divisions $v = m \cdot u + r$ with $\|r\| < \|u\|$. On an input $(u, v) \in \Omega$, it lets $v_0 := v, v_1 := u$, performs a sequence of Euclidean divisions on the form,

$$(3) \quad v_0 = m_1 \cdot v_1 + v_2, \quad v_1 = m_2 \cdot v_2 + v_3, \quad \dots \quad v_i = m_{i+1} \cdot v_{i+1} + v_{i+2} \dots,$$

and stops when the remainder v_{p+1} is zero. The last division performed is just $v_{p-1} = m_p \cdot v_p$. Remark that, in the integer case, the digit m_p satisfies $m_p \neq 1$.

The sequences of the norms $\|v_i\|$ is strictly decreasing, and the last non-zero remainder v_p is a greatest common divisor of u and v . By definition, the gcd d of (u, v) is the unique monic polynomial d proportional to v_p . The set \mathcal{G} of possible digits in a non final step, the set \mathcal{F} of possible digits in the final step, and the set \mathcal{U} of possible gcd's are

$$(4) \quad \mathcal{G} := \{m \in \mathbb{A}; \ \|m\| \geq 1\}, \quad \mathcal{U} := \{d \in \mathbb{A}; \ d \text{ monic}\}, \quad \mathcal{F}_I := \{m \in \mathbb{N}; \ m \geq 2\}, \quad \mathcal{F}_P := \mathcal{G},$$

and the Euclid algorithm builds the fundamental bijection

$$(5) \quad \Omega \sim \mathcal{G}^* \times \mathcal{U} \quad [\text{Case (P)}] \quad \Omega \sim [\epsilon + \mathcal{F} \times \mathcal{G}^*] \times \mathcal{U} \quad [\text{Case (I)}].$$

In Case (I), it will be useful to deal with the set $\tilde{\Omega}$ of coprime inputs,

$$(6) \quad \tilde{\Omega} := \{(u, v) \in \mathbb{A}^2; \ u \neq 0, \ \gcd(u, v) = 1\} \sim \mathcal{F} \times \mathcal{G}^*.$$

1.2. Bit-complexities. We wish to study the bit-complexity of the Euclid algorithm; here the bit-complexity means the total number of binary operations for integers, and the total number of operations in the field \mathbb{F}_q for polynomials¹. The (naive) bit-complexity of the Euclidean division $v = m \cdot u + r$ is $\ell(u) \cdot \ell(m)$ so that, the total bit-complexity of the Euclid Algorithm on (u, v) is

$$(7) \quad B(u, v) = \sum_{i=1}^p \ell(m_i) \cdot \ell(v_i).$$

The Extended Euclid algorithm outputs, at the same time, the Bezout pair (r, s) for which $d = rv + su$. It computes the sequence \underline{s}_i defined by

$$\underline{s}_0 = 0, \quad \underline{s}_1 = 1, \quad \underline{s}_i = \underline{s}_{i-2} - \underline{s}_{i-1} \cdot m_{i-1}, \quad 2 \leq i \leq p.$$

The sequence s_i itself is defined by $s_i := \underline{s}_i$ for polynomials and $s_i := \lfloor \underline{s}_i \rfloor$ for integers. The last element s_p is the Bezout coefficient s . The bit-complexity D of Extended Euclid algorithm is then

$$(8) \quad D(u, v) = \ell(m_p) \cdot \ell(v_p) + \sum_{i=1}^{p-1} \ell(m_i) \cdot [\ell(v_i) + \ell(s_i)].$$

¹Since the cardinality q of $\mathbb{F}_q[X]$ is fixed, this is actually a bit-complexity, in the usual meaning

1.3. Other costs of interest. We observe that the previous costs of interest B, D can be expressed as a sum of terms, each of them being a product of two factors: the first one involves the size of digits m_i , and the second one involves the size of the so-called continuants, namely v_i and s_i . It is then useful to compare these costs to other costs defined on Ω , namely additive costs, associated to an elementary cost c on digits, under the form

$$(9) \quad C(u, v) := \sum_{i=1}^p c(m_i).$$

When $c(m)$ is $O(\log m)$, the cost c , and the cost C are said to be of moderate growth. This class of costs contains quite natural parameters, as the number of steps (for $c = 1$), the total encoding length (when c equals the binary length ℓ) or the number of occurrences of a given digit m_0 (for $c(m) := \llbracket m = m_0 \rrbracket$) [In the paper, we use Iverson's notation : $\llbracket X \rrbracket \in \{0, 1\}$ and equals 1 if and only X is true.].

We also consider a three costs, a cost $N^{(v)}$ which involves the size of remainders, its approximate version $\hat{N}^{(v)}$ and a cost $N^{(m)}$ which can be seen as the analog of a path-length in lists,

$$(10) \quad N^{(v)}(u, v) := \sum_{i=1}^p \ell(v_i), \quad \hat{N}^{(v)}(u, v) := \sum_{i=1}^p \lg v_i, \quad N^{(m)}(u, v) := \sum_{i=1}^{p+1} i \cdot \ell(m_i).$$

[We have let $m_{p+1} := v_p$]. In polynomial case, the two costs $N^{(v)}, N^{(m)}$ are equal, but this is no longer true in integer case.

We are interested here in precisely studying the probabilistic behaviour of both gcd algorithms, for polynomials and for integers. We consider that inputs (u, v) have a fixed size n , i.e., they belong to the subset

$$(11) \quad \Omega_n := \{(u, v) \in \Omega; \ell(v) = n\},$$

where Ω is defined in (2). We assume that Ω_n is endowed with the uniform probability \mathbb{P}_n . For a random variable R defined on Ω , its restriction to Ω_n is denoted by R_n , and we wish to analyse the asymptotic behaviour of R , i.e., the evolution of variables R_n when n becomes large.

1.4. Previous results for average-case analysis. The evolution of the mean values $\mathbb{E}[R_n]$ is of great interest and, more generally, the study of all moments $\mathbb{E}[R_n^\ell]$ provides a first understanding of the probabilistic behaviour of the algorithm: this is the aim of average-case analysis.

In the polynomial case, there are few analyses of this type. The works of Knopfmacher and Knopfmacher [18], or works of Friesen and Hensley [14] directly deal with the distribution. Since the analysis in the number case is more difficult, first analyses began with the study of the average-case, and there are now many well-known results of this type, even if the last ones have been obtained recently. The first results on probabilistic analysis of Euclid's Algorithm are due to Heilbronn and Dixon [8, 15], who have shown, around 1970, that the average number of iterations is linear with respect to the size. During the last ten years, the research team in Caen has designed a complete framework for analysing an entire class of Euclidean algorithms, with a large class of parameters [26, 27, 28]. It is possible to obtain precise results on the average behaviour of the main parameters of the algorithm : the digits m_i , and the size of continuants v_i and s_i . Akhavi and Vallée have also analysed the average bit-complexity [1]. These methods consider the underlying dynamical systems, and make a deep use of dynamical tools, like the transfer operator. They form what we now call the dynamical analysis methodology.

1.5. Distributional analysis and asymptotic gaussian laws. However, the distributional analysis, which describes the evolution of the distribution of variable R_n , provides a much more precise analysis of the algorithm: this is the ultimate purpose in analysis of algorithms. Very often, variables R_n have a distribution which tends to the Gaussian law: this phenomenon is easily proved as soon as cost R_n is the sum of n elementary costs, which are independent, and possess the same distribution. In the "real algorithmic life", and the "Euclidean world", the elementary costs are not independent, and their distribution may evolve with the evolution of the algorithm. This is why an asymptotic gaussian law, even if it is widely expected, is often difficult to prove, particularly in integer case.

We prove here that many variables R defined on Ω follow asymptotically a gaussian law. We first provide a precise definition of this notion:

Definition 1. [Asymptotic gaussian law.] *Consider a cost R defined on a set Ω and its restriction R_n to Ω_n . The cost R follows an asymptotic law if there exist three sequences a_n, b_n, r_n , with $r_n \rightarrow 0$, for which*

$$\mathbb{P} \left[(u, v) \in \Omega_n \mid \frac{R_n(u, v) - a_n}{\sqrt{b_n}} \leq y \right] = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^y e^{-t^2/2} dt + r_n(y), \quad r_n := \sup\{r_n(y); y \in \mathbb{R}\}.$$

The sequence r_n defines the speed of convergence, also denoted by $r[X_n]$. The expectation $\mathbb{E}[R_n]$ and the variance $\mathbb{V}[R_n]$ satisfy $\mathbb{E}[R_n] \sim a_n$, $\mathbb{V}[R_n] \sim b_n$. We say that the pair (a_n, b_n, r_n) is a characteristic triple for the gaussian asymptotic law of R .

1.6. Previous results for distributional analyses. All the analyses previously described in 1.3 are only ‘‘average–case analyses’’. Now, we review the main previous results for distributional analyses. In polynomial case, Knopfmacher and Knopfmacher studied in [18] the exact distribution of number of steps, and Friesen and Hensley [14] obtained large deviations in this context. For the number case, there were recently two breakthroughs; the first one, in 1994, when Hensley [16] performed the first distributional analysis, and proved that the number of steps has an asymptotic Gaussian behaviour. However, his proof is not easily extended to other parameters of the algorithm. Then, three years ago, Baladi and Vallée [2] have extended the dynamical analysis method for obtaining limit distributions, for a large class of costs, the so-called additive costs of moderate growth, defined in (9). They deal with the dynamical system underlying the algorithm and make a deep use of the weighted transfer operator, relative to an elementary cost c , which depends on two parameters (s, w) and is defined as

$$(12) \quad \mathbf{G}_{s,w,[c]}[f](x) := \sum_{m \geq 1} \frac{1}{(m+x)^{2s}} \cdot \exp[wc(m)] \cdot f\left(\frac{1}{m+x}\right).$$

For $w = 0$, the operator is just the plain transfer operator \mathbf{G}_s

$$(13) \quad \mathbf{G}_s[f](x) := \sum_{m \geq 1} \frac{1}{(m+x)^{2s}} \cdot f\left(\frac{1}{m+x}\right).$$

When c is of moderate growth, for (s, w) near $(1, 0)$, the operator $\mathbf{G}_{s,w,[c]}$ acts on $\mathcal{C}^1([0, 1])$ and admits a unique dominant eigenvalue denoted by $\lambda(s, w, [c])$. In the same vein, the dominant eigenvalue of \mathbf{G}_s is just denoted by $\lambda(s)$. These dominant eigenvalues play a central work in [2], and also in the present paper. The particular case when c equals the binary length ℓ is crucial in study of bit–complexities.

The result of [2] can be stated as follows.

Theorem A (I). [Asymptotic gaussian law for additive costs of moderate growth] (Baladi and Vallée). *Consider an additive cost C relative to an elementary cost c of moderate growth [i.e. $c(m) = O(\log m)$], defined in (9).*

(i) *On the set of integer inputs of size n , the cost C asymptotically follows a gaussian law, with mean, variance and speed of convergence given by*

$$\mathbb{E}[C_n] = \mu(c) \cdot n + \mu_1(c) + O(2^{-n\gamma}), \quad \mathbb{V}[C_n] = \rho(c) \cdot n + \rho_1(c) + O(2^{-n\gamma}), \quad r[C_n] = O(n^{-1/2}).$$

Here γ is a strictly positive constant which does not depend on cost c .

(ii) *The constants $\mu(c)$ and $\rho(c)$ [$\rho(c) > 0$] are mathematical objects closely related to the dominant eigenvalue $\lambda(s, w)$ of the transfer operator $\mathbf{G}_{s,w,[c]}$, defined in (12) and acting on $\mathcal{C}^1([0, 1])$. More precisely, they are expressed with the first five derivatives of order 1 and 2 of $\lambda(s, w)$ at $(s, w) = (1, 0)$,*

$$(14) \quad \mu(c) = \frac{2 \log 2}{|\lambda'_s(1, 0)|} \cdot \lambda'_w(1, 0),$$

$$(15) \quad \rho(c) = \frac{2 \log 2}{|\lambda'_s(1, 0)|^3} \cdot [\lambda_s'^2(1, 0) \cdot \lambda_w''(1, 0) - 2\lambda'_w(1, 0) \cdot \lambda'_s(1, 0) \cdot \lambda_{sw}''(1, 0) + \lambda_w'^2(1, 0) \cdot \lambda_s''(1, 0)].$$

The computational status of these two constants $\mu(c)$ and $\rho(c)$ is different. Very often, the first derivatives admit a closed form at $(1, 0)$. For instance, in the case when the cost c is the binary length ℓ ,

$$(16) \quad \lambda'_s(1, 0) = -\frac{\pi^2}{6 \log 2} \quad \lambda'_w(1, 0) = \frac{2}{\log 2} \log \prod_{i=0}^{\infty} \left(1 + \frac{1}{2^i}\right), \quad \mu(\ell) = \frac{12 \log 2}{\pi^2} \log \prod_{i=0}^{\infty} \left(1 + \frac{1}{2^i}\right).$$

It does not seem to be the same for the constant $\rho(c)$. In [20], Lhote performs a general study for the computational status for this type of “spectral constants” and proves that $\rho(c)$ is polynomial-time computable.

2. RESULTS AND OUTLINE OF THE METHOD.

Neither the bit-complexities nor the length of the remainders belong to the class of additive costs. These bit-complexity costs are more difficult to deal with, because they involve both continuants and digits, in a multiplicative way. Here, we aim to study the distribution of the bit-complexity, and we wish to extend both the results of Akhavi and Vallée, about the average bit-complexity, and the general distributional methods of Baladi and Vallée. We wish also to study the evolution of the size of remainders v_i .

2.1. Extended bit-complexity. The “extended” cost D defined in (8) is easier to analyse because it is, in a sense, more regular than cost B . We prove here that, on the set of inputs (u, v) of size n , and, in the two cases (polynomial case (P) , and integer case (I)), the cost D follows asymptotically a gaussian law.

Theorem 1 (P) . [Extended polynomial bit-complexity.] *On the set of polynomial inputs of size n , the bit complexity D of the extended Euclid algorithm follows asymptotically a gaussian law, with mean, variance and speed of convergence given by*

$$(17) \quad \mathbb{E}[D_n] = \frac{2q-1}{q} \cdot n^2 \cdot \left[1 + O\left(\frac{1}{n}\right)\right], \quad \mathbb{V}[D_n] = \frac{q-1}{q^2} \cdot n^3 \left[1 + O\left(\frac{1}{n}\right)\right], \quad r[D_n] = O(n^{-1/2}).$$

In fact, it is easy to obtain, in case (P) , the exact asymptotic expansion of both $\mathbb{E}[D_n]$ and $\mathbb{V}[D_n]$. In the integer case, the results are of the same spirit; however, the main constants that intervene in the mean and the variance are more involved, and the proven speed of convergence is not optimal.

Theorem 1 (I) . [Extended integer bit-complexity.] *(i) On the set of integer inputs of size n , the bit complexity D of the extended Euclid algorithm follows asymptotically a Gaussian law, with mean, variance and speed of convergence given by*

$$(18) \quad \mathbb{E}[D_n] = \mu(\ell) \cdot n^2 \cdot \left[1 + O\left(\frac{1}{n}\right)\right], \quad \mathbb{V}[D_n] = \rho(\ell) \cdot n^3 \left[1 + O\left(\frac{1}{n}\right)\right], \quad r[D_n] = O(n^{-1/3}),$$

where $\mu(\ell)$ and $\rho(\ell)$ are the constants which appear in Equations (14,15) of Theorem A, when the cost c is the binary length ℓ .

2.2. Standard bit-complexity. For the standard bit-cost B , defined in (7), we prove the following:

Theorem 2 (P) . [Standard polynomial bit-complexity.] *On the set of polynomial inputs of size n , the bit complexity B of the standard Euclid algorithm follows asymptotically a gaussian law, with mean, variance and speed of convergence given by*

$$(19) \quad \mathbb{E}[B_n] = \frac{2q-1}{2q} \cdot n^2 \cdot \left[1 + O\left(\frac{1}{n}\right)\right], \quad \mathbb{V}[B_n] = \frac{q-1}{3q^2} \cdot n^3 \left[1 + O\left(\frac{1}{n}\right)\right], \quad r[B_n] = O(n^{-1/2}).$$

As in Theorem 1 (P) , it is easy to obtain, in this case, the exact asymptotic expansions of both $\mathbb{E}[B_n]$ and $\mathbb{V}[B_n]$. For the integer case, we here obtain only partial results. Results of Akhavi and Vallée [1] already provide some information about the moments of cost B : the constant of the main asymptotic term in the mean value $\mathbb{E}[B_n]$ is already known, and the variance $\mathbb{V}[B_n]$ is of order $o(n^4)$. Here, we study more precisely the asymptotic behaviour of the variance $\mathbb{V}[B_n]$. Moreover, we will state in Section 4 two conjectures : a conjecture (C) which relates the variance $\mathbb{V}[B_n]$ and

the variance $\mathbb{V}[D_n]$, and a conjecture (G) which entails the plausibility of an asymptotic gaussian law for the standard bit-complexity B , even if it does not itself imply this asymptotic behaviour.

Theorem 2 (I). [Standard integer bit-complexity.] *On the set of integer inputs of size n , the mean and the variance of B_n satisfy*

$$(20) \quad \mathbb{E}[B_n] = \mu_0(\ell) \cdot n^2 \cdot \left[1 + O\left(\frac{1}{n}\right)\right], \quad \mathbb{V}[B_n] = \rho_0(\ell) \cdot n^3 \left[1 + O\left(\frac{1}{n}\right)\right],$$

The constants $\mu_0(\ell)$ and $\mu(\ell)$ are related via the equality $\mu_0(\ell) = (1/2)\mu(\ell)$ and the variance constant $\rho_0(\ell)$ is not zero.

Moreover, under the conjecture (C) the constant $\rho_0(\ell)$ is related to constant $\rho(\ell)$ of Theorem 1 (I) via the equality $\rho_0(\ell) = (1/3)\rho(\ell)$.

Remark. Conjecture (C) is motivated by the polynomial case and “copies” it.

2.3. Size of remainders. We are also interested in describing the evolution of the size of remainders v_i during the execution of the algorithm, and we consider the size of the remainder v_i at “a fraction of the depth”. For an input (u, v) , we denote by $P(u, v)$ the number of iterations of the Euclid Algorithm on the input (u, v) , that is also called the depth of (u, v) . Furthermore, for a real $\delta \in]0, 1[$, the random variable $L^{[\delta]}$ is the size of remainder v_i when i equals $\lfloor \delta P \rfloor$. It is defined as

$$(21) \quad L^{[\delta]}(u, v) := \ell(v_{\lfloor \delta P(u, v) \rfloor}).$$

The following result shows that the size of the remainders at a fraction δ of the depth asymptotically follows a gaussian law, at least when δ is rational. This proves that the evolution of the sizes of remainders is very regular during an execution of the algorithm. This result constitutes a “discrete version” of the well-known result of [22] (sharpened by Vallée in [29]) which shows that the n -th continuant of a real $x \in \mathcal{I}$ asymptotically follows a gaussian law, when \mathcal{I} is endowed with any density of class C^1 .

This result also plays a central rôle in the analysis of the so-called Interrupted Euclidean Algorithm which stops as soon as the size $\ell(v_i)$ of the remainder v_i is less than $\delta \cdot \ell(v_0)$. An average-case analysis of the Interrupted Algorithm is provided in [5], and the present results are a first [but crucial] step towards the distributional analysis of the algorithm. This type of results also plays a central rôle in the analysis of two important variants of the Euclid Algorithms: the Lehmer Euclid Algorithm [19, 5], and fast versions of Euclidean Algorithms [24, 6].

Theorem 3. [Gaussian limit law for sizes of remainders at a fraction of the depth.] *Consider a rational δ of $]0, 1[$. On the set of inputs of size n , the length $L^{[\delta]}$ defined in (21) follows asymptotically a Gaussian law. The speed of convergence is*

$$r_n = O(n^{-1/2}) \quad \text{in case (P)}, \quad r_n = O(n^{-1/3}) \quad \text{in case (I)},$$

and the following estimates hold for the mean and the variance,

$$\text{Case (I):} \quad \mathbb{E}[L_n^{[\delta]}] = \mu_{[\delta]} \cdot n + O(1), \quad \mathbb{V}[L_n^{[\delta]}] = \rho_{[\delta]} \cdot n + O(1),$$

$$\text{Case (P):} \quad \mathbb{E}[L_n^{[\delta]}] = \mu_{[\delta]} \cdot n + \mu_1(\delta) + O(2^{-n\gamma}), \quad \mathbb{V}[L_n^{[\delta]}] = \rho_{[\delta]} \cdot n + \rho_1(\delta) + O(2^{-n\gamma}).$$

Here γ is a strictly positive constant which depends on δ , and the constants $\mu_{[\delta]}$ and $\rho_{[\delta]}$ satisfy

$$\mu_{[\delta]} = (1 - \delta), \quad \rho_{[\delta]} = \frac{\delta(1 - \delta)}{q - 1} \quad \text{in case (P)}, \quad \rho_{[\delta]} = \delta(1 - \delta) \frac{|\Lambda''(1)|}{|\Lambda'(1)|} > 0 \quad \text{in case (I)},$$

where $\Lambda(s)$ is the logarithm of the dominant eigenvalue $\lambda(s)$ of the operator \mathbf{G}_s defined in (13).

Remark. Our methods only deal with the case when δ is rational.

We describe now the main principles of our method.

2.4. Generating Functions. We mainly use methods from analytic combinatorics, which deal with generating functions. See the book [12] for a complete treatment of this methodology. Our main tool is, as usual in analysis of algorithms, (bivariate) generating functions which depend on two parameters: the first one “marks” the input size, and the second one “marks” the cost of interest. For reasons which will appear clearer later, and unlike in classical use, we choose generating functions of Dirichlet type with respect to the size parameter s . The (bivariate) generating function of some cost R defined on the input set Ω will be²

$$(22) \quad S_R(s, w) := \sum_{(u, v) \in \Omega} \frac{1}{\|v\|^{2s}} \exp[wR(u, v)] = \sum_{k \geq 1} \frac{1}{k^{2s}} r_k(w)$$

where $r_k(w)$ is the cumulative value of $\exp[wR]$ on inputs for which $\|v\| = k$. We recall that $\|v\| = v$ in the integer case and $\|v\| = q^{\deg v}$ in the polynomial case. Then, in integer case, this series remains a (general) Dirichlet series, while, in polynomial case, this is in fact a power series in $z = q^{-2s}$ which will be alternatively denoted by $T_R(z, w)$,

$$(23) \quad T_R(z, w) := S_R\left(-\frac{1}{2} \log_q z, w\right) = \sum_{(u, v) \in \Omega} z^{\deg v} \exp[wR(u, v)].$$

We recognise in $T_R(z, w)$ the usual bivariate generating function, where variable z marks the degree, quite close to the polynomial input size. These bivariate series are used for analysing the distribution of cost R .

If we restrict our study to the moment of order k , we deal with a Dirichlet Series $S_R^{[k]}(s)$ with respect to the unique variable s , which is the k -th derivative of $w \mapsto S_R(s, w)$ at $w = 0$,

$$(24) \quad S_R^{[k]}(s) := \frac{\partial^k}{\partial w^k} S_R(s, w)|_{w=0} = \sum_{(u, v) \in \Omega} \frac{1}{\|v\|^{2s}} R^k(u, v).$$

This is also a power series $T_R^{[k]}(z)$ in the polynomial case, namely

$$T_R^{[k]}(z) = \sum_{(u, v) \in \Omega} R^k(u, v) \cdot z^{\deg v}.$$

We first look for an alternative expression for these series $S_R(s, w)$ from which the position and the nature of the dominant singularity of $S_R(s, w)$ become apparent. Then, with taking derivatives, we also obtain alternative expressions for $S_R^{[k]}(s)$. Then, we transfer these informations on the coefficients of $S_R(s, w)$ or $S_R^{[k]}(s)$, which are our prime subject of interest.

How can we obtain an alternative expression for series $S_R(s, w)$? In the case of the polynomial gcd, it is possible to directly deal with the bijection (5), because it keeps track of the size; for instance, for an additive cost C related to some step-cost c , we easily obtain an alternative form for $T_C(z, w)$ which involves the quasi inverse $1/(1 - G_{[c]}(z, w))$ of the generating function $G_c(z, w)$ relative to cost c ,

$$(25) \quad G_c(z, w) = \sum_{m \in \mathcal{G}} \exp[wc(m)] \cdot z^{\deg m}.$$

And, now, for integers? The bijection is no longer of use, since it does not deal properly with the integer size, and the series $S_R(s, w)$ cannot be directly expressed with the quasi-inverse of $1/(1 - A_c(s, w))$ of the generating function $A_c(s, w)$ relative to cost c ,

$$(26) \quad A_c(s, w) = \sum_{m \in \mathcal{G}} \frac{1}{\|m\|^{2s}} \exp[wc(m)].$$

We will use the transfer operator $\mathbf{G}_{s, w, [c]}$ relative to the underlying dynamical system, defined in (12), as a “generating” operator, and we will deal with the more elaborated bijection (44) : now, the bivariate series $S_C(s, w)$ can be expressed with the quasi-inverse $(I - \mathbf{G}_{s, w, [c]})^{-1}$ of $\mathbf{G}_{s, w, [c]}$ [see for instance Equation (65)].

²We also consider in integer case the “tilde” generating functions relative to the subset $\tilde{\Omega}$ of coprime inputs defined in (6).

It will be possible to transfer these informations on the coefficients of series, as soon as we dispose of a convenient “extractor” which expresses coefficients of series as a function of the series itself. Of course, the common extractor is the Cauchy formula. For power series, the usual integration contour is a (compact) circle, whereas it is an (unbounded) vertical line for Dirichlet series; this explains why it is more difficult to deal with Dirichlet series than usual (power) series. The main “extractors” for Dirichlet series are Tauberian Theorems [which do not provide remainder terms]³, or the Perron Formula [which may provide remainder terms]. Tauberian theorems are well-adapted for average-case analysis, but Perron’s formulae are essential in distributional analysis. However, they need a more precise information on the quasi-inverse of $(I - \mathbf{G}_{s,w,[c]})^{-1}$, namely the existence of a vertical strip free of poles (as in the Prime Number Theorem...)

2.5. Decomposition of bit-complexity costs. Our first step is quite natural. Since the expression of the bit-complexities is quite involved, we “split” each cost of interest [namely the cost B , and the extended cost D] into two parts: a “main” cost X , which will be (asymptotically) gaussian, and a “remainder” cost Y , which will be (asymptotically) more concentrated than the main cost. The following result proves that, in this general framework, the total cost $Z = X + Y$ is (asymptotically) gaussian, and its characteristics –mean value, variance, and speed of convergence– are expressed with characteristics of X and Y .

Definition 2. [Variance-equivalence] Consider two costs X and Z , defined on Ω and their restrictions X_n, Z_n to Ω_n . We say that X and Z are variance-equivalent if $\mathbb{V}[X_n - Z_n] = o(\mathbb{V}[X_n])$ for $n \rightarrow \infty$. They are called equivalent⁴ with order α_n [with $\alpha_n \rightarrow 0$] if $\mathbb{V}[X_n - Z_n] = \alpha_n \cdot \mathbb{V}[X_n]$. We denote by $X \asymp_{\alpha} Z$ such a situation.

Proposition 1. Consider two costs X and Z , defined on Ω and their restrictions X_n, Z_n to Ω_n . Suppose that X and Z are variance-equivalent (with order α_n) and that X admits an asymptotic gaussian limit law with a speed of convergence $r[X_n]$. Then Z admits an asymptotic gaussian limit law, with a variance and a speed of convergence which satisfy

$$\mathbb{V}[Z_n] = \mathbb{V}[X_n] \cdot [1 + O(\alpha_n^{1/2})], \quad r[Z_n] = r[X_n] + O(\alpha_n^{1/3}).$$

Proof. Consider $Y := Z - X$ and the two variables $\bar{X}_n = (X_n - \mathbb{E}[X_n]) \cdot (\mathbb{V}[X_n])^{-1/2}$ and $\bar{Y}_n = (Y_n - \mathbb{E}[Y_n]) \cdot (\mathbb{V}[X_n])^{-1/2}$. Then, the random variable $\bar{X}_n + \bar{Y}_n$ satisfies

$$\mathbb{P}[\bar{X}_n + \bar{Y}_n \leq a] = \mathbb{P}[(\bar{X}_n + \bar{Y}_n \leq a) \cap (|\bar{Y}_n| \leq \epsilon_n)] + \mathbb{P}[(\bar{X}_n + \bar{Y}_n \leq a) \cap (|\bar{Y}_n| > \epsilon_n)].$$

The second term is less than $\mathbb{P}[|\bar{Y}_n| > \epsilon_n]$, and, with the Markov inequality, it is $O(\alpha_n \cdot \epsilon_n^{-2})$. Now, for the first term, one has

$$\mathbb{P}[\bar{X}_n \leq a - \epsilon_n] \leq \mathbb{P}[(\bar{X}_n + \bar{Y}_n \leq a) \cap (|\bar{Y}_n| \leq \epsilon_n)] \leq \mathbb{P}[\bar{X}_n \leq a + \epsilon_n],$$

and both lower and upper bounds are of the form

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{a \pm \epsilon_n} e^{-t^2/2} dt + O(r_n) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^a e^{-t^2/2} dt + O(r_n + \epsilon_n),$$

with $r_n = r[X_n]$. Finally, the speed of convergence is $O(r_n + \epsilon_n + \alpha_n \cdot \epsilon_n^{-2})$ and the optimal choice $\epsilon_n^3 = \alpha_n$ provides the result. ■

Remark. In case (P), we deal with an order $\alpha_n = O(n^{-2})$ [which will entail an optimal speed of convergence of order $n^{-1/2}$], whereas in case (I) we only obtain an order $\alpha_n = O(n^{-1})$ [which will entail a speed of convergence of order $n^{-1/3}$]. In both cases, the variances studied are of order n^3 and are proven to admit an asymptotic expansion, which is polynomial with respect to n . Then the estimates about the variances can be improved and become $\mathbb{V}[Z_n] = \mathbb{V}[X_n] + O(n^2)$.

³There are Tauberian Theorems which provide errors terms, but we do not use them in our context.

⁴This is actually an equivalence, since in this case the two variance satisfy $\mathbb{V}[X_n] \sim \mathbb{V}[Z_n]$.

2.6. Quasi-Powers Theorem. This theorem provides sufficient conditions on the moment generating function under which the parameter R is proven to follow an asymptotic gaussian law.

Theorem B. [Hwang] [17] *Consider a cost R defined on a set Ω and its restriction R_n to Ω_n , and suppose that the moment generating function $\mathbb{E}[\exp(wR_n)]$ of R_n is an analytic function on a neighbourhood \mathcal{W} of $w = 0$ and satisfies on \mathcal{W}*

$$\mathbb{E}[\exp(wR_n)] = \exp[\beta_n A(w) + B(w)] \cdot (1 + O(\kappa_n^{-1})) \quad (\beta_n, \kappa_n \rightarrow \infty),$$

with $A(w)$, $B(w)$ analytic on \mathcal{W} and a O -term uniform on \mathcal{W} . Then, the expectation and the variance of R_n satisfy

$$\mathbb{E}[R_n] = A'(0) \cdot \beta_n + B'(0) + O(\kappa_n^{-1}), \quad \mathbb{V}[R_n] = A''(0) \cdot \beta_n + B''(0) + O(\kappa_n^{-1}).$$

Moreover, if $A''(0)$ is not zero, then R_n asymptotically a Gaussian law with speed of convergence $r_n = O(\kappa_n^{-1} + \beta_n^{-1/2})$.

2.7. Various types of costs. The analyses of the bit complexities B, D and of the size of the continuant $L^{[\delta]}$ are based on decompositions that satisfy Proposition 1. In addition to the costs N [see (10)], these decompositions involve various other costs, and in particular, the so-called additive costs and end-costs, whose generating functions will be easy to deal with.

Definition 3. [Types of cost] (i) *An elementary cost c and its associated additive cost C are of intermediate growth if $c(m) = O(\ell(m)^\beta)$ with $\beta > 0$. An elementary cost c and its associated additive cost C are of moderate growth if $c(m) = O(\ell(m))$.*

(ii) *An end-cost R is a cost which only depends on $\gcd v_p$ and quotients m_2 and m_p in a polynomial way, namely $R = O((\ell(v_p) + \ell(m_p) + \ell(m_2))^k)$ for some integer $k \geq 1$.*

The general philosophy of our work is now summarised by the following theorem, which is one of the basic results of our paper.

Theorem 4. *The following holds:*

(a) *In case (I), any additive cost C of moderate growth is asymptotically gaussian with a characteristic triple of the form $[O(n), \Theta(n), O(n^{-1/2})]$. In case (P), any additive cost C of moderate growth, whose elementary cost is not proportional to $c = \deg$, is asymptotically gaussian with a characteristic triple of the form $[O(n), \Theta(n), O(n^{-1/2})]$.*

(b) *In case (P), the costs N defined in (10) are asymptotically gaussian with a characteristic triple of the form $[O(n^2), \Theta(n^3), O(n^{-1/2})]$.*

(c) *Any additive cost C of intermediate growth satisfies the concentration property, i.e., the expectation $\mathbb{E}[C_n]$ and the variance $\mathbb{V}[C_n]$ are $O(n)$.*

(d) *Any end-cost has all its moments of order $O(1)$.*

Remark. We did not succeed proving Assertion (b) in case (I) whereas it is an essential result for studying the bit-complexity B in case (P). This is why we conjecture the following.

Conjecture (G). *In case (I), the costs N defined in (10) are asymptotically gaussian with a characteristic triple of the form $[O(n^2), O(n^3), O(n^{-1/2})]$.*

2.8. Plan of the paper. The general architecture of the paper is summarized in Figure 1. Section 3 is devoted to the polynomial case, and deals with (bivariate) generating functions. Sections 4 and 5 deal with the number case: Section 4 describes the dynamical system underlying the Euclid algorithm, introduces the transfer operator and provides alternative expressions of the generating functions which involve the transfer operator. Then, in Section 5, we perform the analytic study, and obtain the main results in the number case. In Section 6, we describe an unified framework for the two cases (P) and (I).

3. THE EUCLID ALGORITHM ON POLYNOMIALS.

We perform the analysis of the Euclid algorithm on $\mathbb{F}_q[X]$, and we wish to prove Theorems 1-4 with their (P) version. We first decompose the bit-complexities cost, and show that these decompositions involve the costs which are studied in Theorem 4. Then, the remainder of this section is devoted to the proof of the version (P) of Theorem 4 and Theorem 3. The main tool here for studying the behaviour of these costs is the generating function, univariate (in the case

FIGURE 1. The general architecture of the paper. (Alg) means Algebraic study while (Ana) means Analytic study.

where only moments are analysed) or bivariate, when we expect a gaussian limit law. When all the assertions of Theorem 4 are proven, we obtain Theorem 1 (P) and Theorem 2 (P) with an application of Proposition 1.

3.1. Decomposition of costs. For simplicity, we denote by m_{p+1} the monic gcd v_p . The polynomial case (P) will be easier because both bit-complexities B and D are only expressed with the sequence $\ell(m_i)$ (with $1 \leq i \leq p+1$). Since the degrees of polynomials v_i and s_i are both related to degrees $\deg m_i$ of quotients m_i , one has, for any i , with $0 \leq i \leq p$,

$$(27) \quad \deg v_i = \sum_{j=i+1}^{p+1} \deg m_j, \quad \deg s_i = \sum_{j=1}^{i-1} \deg m_j, \quad \ell(v_i) + \ell(s_i) = 2 + \ell(v_0) - \ell(m_i).$$

This provides the following decompositions for the bit-complexities:

Proposition 2(P). *On Ω_n , the extended bit-complexity $D = D_n$ decomposes as*

$$D_n = \left[n \cdot \sum_{i=1}^{p-1} \ell(m_i) \right] + \left[2 \cdot \sum_{i=1}^{p-1} \ell(m_i) - \sum_{i=1}^{p-1} \ell^2(m_i) \right] + [\ell(m_p) \cdot \ell(m_{p+1})]$$

On Ω_n , the plain bit-complexity $B = B_n$ decomposes as

$$B_n = \left[\frac{1}{2}(n-1)^2 - 1 + \sum_{i=1}^{p+1} i \cdot \deg m_i \right] + \left[\sum_{i=1}^{p+1} \left(1 - \frac{1}{2} \deg^2 m_i\right) \right].$$

With Theorem 4 (P), both decompositions satisfy Proposition 1 and with Definition 2, the following holds on Ω_n ,

$$D \underset{(n-2)}{\asymp} n \cdot L, \quad \text{with } L = \sum_{i=1}^{p-1} \ell(m_i) \quad B \underset{(n-2)}{\asymp} N + \frac{n^2}{2}, \quad \text{with } N = \sum_{i=1}^{p+1} i \deg m_i,$$

where the costs $n \cdot L$ and N are both asymptotically gaussian with a characteristic triple of the type $[O(n^2), O(n^3), O(n^{-1/2})]$.

Proof. Each decomposition exhibits three possible blocks delimited by square brackets (the third block is possibly empty). The first block will provide the ‘‘main’’ part, which will be proven to be

(asymptotically) gaussian. The cost L is an additive cost of moderate growth and will be proven to be asymptotically gaussian with characteristic triple $[O(n), \Theta(n), O(n^{-1/2})]$ in Section 3.3. Hence, the cost $n \cdot L$ is asymptotically gaussian with characteristic triple $[O(n^2), O(n^3), O(n^{-1/2})]$. The gaussian behaviour of cost N will be proven in Section 3.5. The possible third block is formed with end costs (studied in Section 3.8) whose variance is $O(1)$. The second block is formed with additive costs of intermediate growth, whose variance will be proven of order $O(n)$ in Section 3.7. ■

Admitting Theorem 4(P), Proposition 1 and Proposition 2 entail that the bit-complexities B and D follow asymptotic gaussian laws [Theorem 1(P), Theorem 2(P)]. The remainder of this section is then devoted to the proof of Theorem 4(P) as well as the proof of Theorem 3(P) (concerning the size of the remainders).

3.2. Generating functions. Here, our main tools are *generating functions*, since it will be easy to transfer operations on polynomials into operations on generating functions. We will always deal with generating functions which will be fractional fractions with respect to z and $t = e^w$. The reference size for generating functions is the degree. We recall that the Euclidean algorithm builds a bijection between Ω and the Cartesian product $\mathcal{G}^* \times \mathcal{U}$ with

$$\Omega := \{(u, v); v \text{ monic and } [u = 0 \text{ or } \deg u < \deg v]\},$$

$$\mathcal{G} := \{m \in \mathbb{F}_q[X]; \deg m \geq 1\}, \quad \mathcal{U} := \{v \in \mathbb{F}_q[X]; v \text{ monic}\}.$$

The generating functions $T(z)$ of Ω , $G(z)$ of \mathcal{G} , $U(z)$ of \mathcal{U} are then equal to

$$T(z) = \frac{1}{1 - q^2 z} \quad G(z) = \frac{(q-1)qz}{1 - qz} = (q-1) \left[\frac{1}{1 - qz} - 1 \right], \quad U(z) = \frac{1}{1 - qz}.$$

The fundamental bijection, which is compatible with the notion of size, can be translated into an equality between generating functions. Since the generating function of \mathcal{G}^* is just the quasi-inverse $1/(1 - G(z))$, we finally obtain

$$T(z) = \frac{1}{1 - G(z)} \cdot U(z).$$

Of course, this equality is trivial in this case. However, we will see how useful it will be when we refine it when considering some *additive cost*. Flajolet adopts this point of view in [11], and obtains a concise and elegant proof of results previously obtained in [18] [with counting arguments] on the distributional analysis of the number of iterations.

In the remainder of this section, we make a constant use of bivariate generating functions relative to some parameter R , namely the series $T_R(z, w)$ or $\hat{T}_R(z, t)$

$$T_R(z, w) := \sum_{(u,v) \in \Omega} e^{wR(u,v)} \cdot z^{\deg v}, \quad \hat{T}_R(z, t) := \sum_{(u,v) \in \Omega} t^{R(u,v)} \cdot z^{\deg v}.$$

We first analyse costs for which we expect an asymptotic gaussian law, namely

- additive costs of moderate growth, in 3.3 and 3.4,
- cost N in 3.5,
- degree of the remainder v_i at a fraction of the execution in 3.6.

3.3. Gaussian law for additive costs of moderate growth. [Proof of Theorem 4(P)(a)] Consider a cost c defined on $\mathbb{F}_q[X]$. The total cost C relative to c is defined on the set Ω as

$$C(u, v) := \sum_{i=1}^p c(m_i).$$

Consider also the bivariate generating functions $G_{[c]}(z, w), T_C(z, w)$

$$(28) \quad G_{[c]}(z, w) := \sum_{m \in \mathcal{G}} e^{wc(m)} \cdot z^{\deg m}, \quad T_C(z, w) := \sum_{(u,v) \in \Omega} e^{wC(u,v)} \cdot z^{\deg v}.$$

Now, the bijection (5), together with the additivity of cost (9) provide a relation between the bivariate generating functions $G_{[c]}(z, w), U(z), T_C(z, w)$, namely

$$(29) \quad T_C(z, w) = \frac{U(z)}{1 - G_{[c]}(z, w)}.$$

Now, we omit the reference to the cost c . The moment generating function $\mathbb{E}[\exp(wC_n)]$ is expressed with coefficients of $T_C(z, w)$ and $T(z) = T_C(z, 0)$ as

$$\mathbb{E}[\exp(wC_n)] = \frac{[z^{n-1}]T_C(z, w)}{[z^{n-1}]T_C(z, 0)}.$$

With the particular form of T_C , it is clear that the dominant singularity is brought by the denominator; it is located at $z = \sigma(w)$, where $\sigma(w)$ is defined by the equation $G(\sigma(w), w) = 1$. At $w = 0$, one has $\sigma(w) = q^{-2}$ and the two derivatives

$$(30) \quad G'_z(q^{-2}, 0) = G'_z(q^{-2}) = \frac{q^3}{q-1}, \quad G'_w(q^{-2}, 0) = \sum_{m \in \mathcal{G}} c(m) \cdot q^{-2 \deg m} = \sum_{m \in \mathcal{G}} \frac{c(m)}{\|m\|^2},$$

are not zero. From the Implicit Function Theorem, and the moderate growth condition, such a function σ is well-defined and analytic on a neighbourhood of $w = 0$ and satisfies $\sigma(0) = 1/q^2$. Since G is analytic, the denominator $1 - G(z, w)$ possesses a simple pôle at $s = \sigma(w)$. And finally, on a neighbourhood of $w = 0$,

$$[z^n]T_C(z, w) = \exp[-n\Sigma(w) + V(w)] \cdot [1 + O(\theta^n)], \quad \text{with } \Sigma(w) = \log \sigma(w), \quad \theta < 1.$$

Moreover V is analytic on \mathcal{W} , and the O -term is uniform on \mathcal{W} . Then, the Quasi-Powers Theorem applies, with

$$A(w) = -\Sigma(w) + \Sigma(0), \quad B(w) = V(w) - V(0), \quad \kappa_n = \theta^{-n},$$

and provides the estimates for the mean and the variance,

$$\mathbb{E}[C_n] = -\Sigma'(0) \cdot n + V'(0) + O(\theta^n), \quad \mathbb{V}_n = -\Sigma''(0) \cdot n + V''(0) + O(\theta^n).$$

Provided that the condition $\Sigma''(0) \neq 0$ holds, this entails an asymptotic gaussian law with a speed of convergence $r_n = O(n^{-1/2})$.

We now study in the next lemma the condition $\Sigma''(0) \neq 0$.

Lemma 1. *For a cost c defined on $\mathbb{F}_q[X]$, consider the function σ defined on a neighbourhood of $w = 0$ by the equality $G(\sigma(w), w) = 1$, and denote by Σ the function defined by $\Sigma = \log \sigma$. Then, the two conditions are equivalent*

- (i) $\Sigma''(0) = 0$,
- (ii) *The cost c is proportional to cost deg.*

Proof. At $z = \sigma(w)$, the series $G(z, w)$ satisfies

$$(31) \quad 1 = G(\sigma(w), w) = \sum_{m \in \mathcal{G}} e^{f_m(w)} \quad \text{with } f_m(w) := wc(m) + \Sigma(w) \deg m.$$

We already know from (30) that the two derivatives $G'_z(q^{-2}, 0)$ and $G'_w(q^{-2}, 0)$ are not zero. Taking the derivative of (31) shows that $\sigma'(0) \neq 0$, and entails that $\Sigma'(0) = \sigma'(0)/\sigma(0) \neq 0$. With two derivations of (31) with respect to w , at $w = 0$, we obtain

$$(32) \quad 0 = \sum_{m \in \mathcal{G}} [f_m''(w) + f_m'^2(w)] \cdot e^{f_m(w)}.$$

If $\Sigma''(0) = 0$, then the equality $f_m''(0) = \Sigma''(0) \cdot \deg m = 0$ holds for all $m \in \mathcal{G}$. Then, Relation (32) proves the equality $f_m'(0) = 0 = c(m) + \Sigma'(0) \cdot \deg m$, valid for all $m \in \mathcal{G}$. Since $\Sigma'(0) \neq 0$, this entails that $c(m)$ is a linear function of $\deg m$.

Conversely, if c is of the form $c(m) = d \cdot \deg m$, then $G_{[c]}(z, w)$ can be written as

$$(33) \quad G_{[c]}(z, w) = \frac{(q-1)qze^{dw}}{1 - qze^{dw}} = G(ze^{dw}),$$

and the function $\sigma(w)$ is defined by the relation $\sigma(w) = q^{-2} \cdot e^{-dw}$. Then Σ is a linear function of w and $\Sigma''(0) = 0$. This ends the proof of the lemma. ■

With Lemma 1, Theorem 4(P)(a) is now proven.

Remark. If we are interested in an additive cost defined by $C(u, v) := \sum_{i=1}^p c(m_i) + d(v_p)$, the bivariate series is now

$$(34) \quad T_C(z, w) = \frac{U_d(z, w)}{1 - G_{[c]}(z, w)},$$

and the analysis is almost the same [compare (29) and (34)].

3.4. Some particular costs of moderate growth. We consider the cases when c is constant, and then the case when $c = \ell$. The total costs C associated are of main algorithmic interest since the cost relative to $c = 1$ is the number P of iterations and the cost relative to $c = \ell$ is the total space necessary for storing the sequence of the digits. This is also equal to the total encoding length of the continued fraction relative to the input u/v (see Introduction and Section 6).

Case $c = 1$. Here, the series $G_{[c]}(z, w)$ satisfies $G_{[c]}(z, w) = e^w G(z)$, so that the function σ is defined by the relation

$$\frac{1}{\sigma(w)} = q[1 + (q-1)e^w].$$

Then, the two first derivatives of $\Sigma = \log \sigma$ satisfy : $-\Sigma'(0) = \frac{q-1}{q}$, $\Sigma''(0) = \frac{q-1}{q^2}$.

Case $c = \ell$. Here, the series $G_{[c]}(z, w)$ satisfies

$$G_{[c]}(z, w) = e^w \cdot \sum_{m \in \mathcal{G}} (ze^w)^{\deg m} = \frac{(q-1)qze^{2w}}{1 - qze^w} = e^w G(ze^w)$$

so that the function σ is defined by the relation: $\frac{1}{\sigma(w)} = qe^w \cdot [1 + (q-1)e^w]$.

Then, the two first derivatives of $\Sigma = \log \sigma$ satisfy: $-\Sigma'(0) = \frac{2q-1}{q}$, $-\Sigma''(0) = \frac{q-1}{q^2}$.

This entails that the mean value $\mathbb{E}[L_n]$ of the total encoding length of the continued fraction is asymptotic to $n \cdot [2 - (1/q)]$.

3.5. Gaussian law for Cost N . [Proof of Theorem 4(P)(b).] The main cost in the decomposition of the cost B involves the cost N defined as

$$N(u, v) := \sum_{i=1}^{p+1} i \cdot \deg m_i,$$

and we now show that N asymptotically follows a gaussian law. The bivariate generating function $T_N(z, w)$ admits the alternative expression

$$T_N(z, w) = U(z, w) + \sum_{p \geq 1} G(z, w) \cdot G(z, 2w) \cdot \dots \cdot G(z, pw) \cdot U(z, (p+1)w)$$

which involves the bivariate generating functions $U(z, w)$ and $G(z, w)$ relative to cost $c = \deg$. In this case, letting $t = e^w$, the equalities $G(z, w) = G(zt)$, $U(z, w) = U(zt)$ hold and we deal in this subsection with the bivariate generating function $\hat{T}_N(z, t)$. This series satisfies

$$(35) \quad \hat{T}_N(z, t) = U(zt) + \sum_{p \geq 1} G(zt) \cdot G(zt^2) \cdot \dots \cdot G(zt^p) \cdot U(zt^{p+1}),$$

and then satisfies the following functional equation

$$(36) \quad \hat{T}_N(z, t) = U(zt) + G(zt) \cdot \hat{T}_N(zt, t),$$

which appears in other studies related to analyses of path-lengths. Using the explicit formulae for G, U , we obtain

$$\hat{T}_N(z, t) = \sum_{p \geq 0} [(q-1)qz]^p \cdot t^{p(p+1)/2} \cdot \prod_{j=1}^{p+1} \frac{1}{1 - qzt^j}$$

The last sum is of the form $\Phi(-(q-1), -qz, t)$ with

$$\Phi(u, \xi, t) := \sum_{p \geq 0} \xi^p u^p \cdot t^{p(p+1)/2} \prod_{j=1}^{p+1} \frac{1}{1 + \xi t^j}.$$

Since Φ satisfies the identity $\Phi(u, \xi, t) = 1 - t\xi(1-u)\Phi(tu, \xi, t)$, the following q -identity, which resorts to q -calculus⁵ (see [12] page 292),

$$\Phi(u, \xi, t) = 1 + \sum_{n \geq 1} (-1)^n (t\xi)^n \prod_{j=0}^{n-1} (1 - ut^j)$$

entails an alternative expression for $\hat{T}_N(z, t)$, namely

$$\hat{T}_N(z, t) = 1 + \sum_{n \geq 1} (qzt)^n \prod_{j=0}^{n-1} (1 + (q-1)t^j).$$

The moment generating function of the cost N on Ω_{n+1} is then equal to

$$\mathbb{E}[\exp(wN_{n+1})] = \frac{[z^n]T_N(z, w)}{|\Omega_{n+1}|} = e^{nw} \prod_{j=0}^{n-1} \left[\frac{1 + (q-1)e^{jw}}{q} \right].$$

We now study the parameter \tilde{N} which is defined by

$$\tilde{N}(u, v) = \frac{N(u, v)}{\ell(v) - 1}, \quad \text{i.e.,} \quad \tilde{N}_{n+1} := \frac{N_{n+1}}{n},$$

and we prove that it follows an asymptotic gaussian law. The moment generating function of \tilde{N} on Ω_{n+1} is of the form $\exp \delta_n(w)$ with

$$\delta_n(w) = w + \sum_{j=0}^{n-1} F_w\left(\frac{j}{n}\right), \quad \text{with} \quad F_w(y) := \log \frac{1 + (q-1)e^{wy}}{q}.$$

We remark that the function F_w can be expressed with the function Σ relative to cost $c = 1$, via the relation $F_w(y) = \Sigma(0) - \Sigma(wy)$. We transform the previous sum into an integral with the Euler-Mac Laurin formula, and now

$$\delta_n(w) = n \cdot A(w) + B(w) + O\left(\frac{1}{n}\right), \quad \text{with} \quad A(w) = \int_0^1 [\Sigma(0) - \Sigma(wy)] dy,$$

with an analytic function B on a complex neighbourhood of 0. Then

$$\mathbb{E}_n[\exp(w\tilde{N}_n)] = \exp[(n-1) \cdot A(w) + B(w)] \cdot \left(1 + O\left(\frac{1}{n}\right)\right).$$

Then, the Quasi-Powers Theorem entails the following estimates for the expectation and the variance of parameter \tilde{N} ,

$$\mathbb{E}[\tilde{N}_n] = A'(0) \cdot n + O(1) = \frac{q-1}{2q} \cdot n + O(1), \quad \mathbb{V}[\tilde{N}_n] = A''(0) \cdot n + O(1) = \frac{q-1}{3q^2} \cdot n + O(1).$$

Moreover, $A''(0) \neq -\Sigma''(0)/3 = (q-1)/(3q^2)$, then the cost \tilde{N} follows an asymptotic normal law, with a speed of convergence $r_n = O(n^{-1/2})$. The parameter N (our prime subject of interest) then follows an asymptotic normal law with parameters

$$\mathbb{E}_n[N] = \frac{q-1}{2q} \cdot n^2 + O(n), \quad \mathbb{V}_n[N] = \frac{q-1}{3q^2} \cdot n^3 + O(n^2), \quad r_n = O(n^{-1/2}).$$

This concludes the proof of Theorem 4(P)(b).

Remark. This proof seems to be completely specific to the case where the cost \deg intervenes. The cost $N^{[c]}$ associated to another cost c of moderate growth does not seem to be analysed with the same tool of q -calculus.

⁵The term q in the q -calculus is unrelated to the cardinality q of the field \mathbb{F}_q .

3.6. Gaussian law for $L^{[\delta]}$. [Proof of Theorem 3(P).] The bivariate generating function for $L^{[\delta]}$ is just denoted by $T_{[\delta]}(z, w)$. With the bijection (5), relation (27), and the special form of the bivariate generating function $G(z, w)$ relative to $c = \deg$ [see (33)], it admits a nice alternative form

$$(37) \quad T_{[\delta]}(z, w) = U(ze^w) \cdot \sum_{p \geq 0} G(z)^{\lfloor \delta p \rfloor} G(ze^w)^{p - \lfloor \delta p \rfloor}.$$

Now, if δ is a rational of the form $\delta = c/(c + d)$, then

$$(38) \quad T_{[\delta]}(z, w) = U(ze^w) \cdot \left[\sum_{j=0}^{c+d-1} G(ze^w)^{j - \lfloor \delta j \rfloor} G(z)^{\lfloor \delta j \rfloor} \right] \cdot \left[\sum_{k \geq 0} G(ze^w)^{dk} \cdot G(z)^{ck} \right],$$

$$(38) \quad T_{[\delta]}(z, w) = U(ze^w) \cdot \left[\sum_{j=0}^{c+d-1} G(ze^w)^{j - \lfloor \delta j \rfloor} G(z)^{\lfloor \delta j \rfloor} \right] \cdot \frac{1}{1 - G(z)^c G(ze^w)^d}$$

The last expression is a rational fraction with respect to two variables $G(z)$ and $G(ze^w)$, and the dominant pôles are only brought by the denominator. The denominator $z \rightarrow 1 - [G(z)^\delta G(ze^w)^{1-\delta}]^D$, with $D = c + d$, admits as zeroes all the values of z for which

$$\psi(z, w) := G(z)^\delta G(ze^w)^{1-\delta} = \exp[2iL\pi/D] \quad \text{with } 0 \leq L < D.$$

The Implicit Functions Theorem can be applied: there is a sufficiently small neighbourhood of w on which a curve of the form $z = \sigma_L(w)$ is well defined and satisfies $\psi(\sigma_L(w), w) = \exp[2iL\pi/D]$. For $w = 0$, the equality $\psi(z, 0) = G(z)$ entails that the relation $G(\sigma_L(0)) = \exp[2iL\pi/D]$ holds. Then,

$$\sigma_L(0) = \left(\frac{1}{q} \right) \frac{1}{1 + (q-1) \exp[2iL\pi/D]}, \quad \text{so that, for } 0 < L < D, \quad |\sigma_L(0)| > q^{-2} = |\sigma_0(0)|.$$

There exist a (complex) neighbourhood \mathcal{W} of $w = 0$ and a positive number $\theta < 1$ for which $|\sigma_0(w)| \leq \theta |\sigma_L(w)|$, for any L , with $0 < L < D$. Furthermore, when $w = 0$, the residue of $T_{[\delta]}(z, w)$ at $z = \sigma_0(w)$ is the residue of $T(z)$ at $z = q^{-2}$. It is non zero, since q^{-2} is actually a simple pôle for T . Then, there exists a small neighbourhood of $w = 0$ for which the residue of $T_{[\delta]}(z, w)$ at $z = \sigma_0(w)$ is non zero. Finally, $T_{[\delta]}(z, w)$ admits as dominant singularity an unique (simple) pôle at $z = \sigma_0(w)$, and

$$[z^n]T_{[\delta]}(z, w) = \left(\frac{1}{\sigma_0(w)} \right)^n \cdot V(w) \cdot [1 + O(\theta^n)],$$

with a non-zero analytic function $V(w)$ and a O -term uniform on \mathcal{W} . The quasi-powers theorem can be applied with $A(w) = -\log \sigma_0(w) + \log \sigma_0(0)$. Now, if we let $\Lambda(z) := \log G(q^{-2}e^{-z})$, the relation $\psi(\sigma_0(w), w) = 1$ which defines $\sigma_0(w)$ can be written as

$$\delta \Lambda(A(w)) + (1 - \delta) \Lambda(A(w) - w) = 0.$$

Now, with two derivations, we obtain:

$$A'(0) = 1 - \delta, \quad A''(0) = \delta(1 - \delta) \frac{\Lambda''(0)}{|\Lambda'(0)|} = \frac{1}{q-1} \cdot \delta(1 - \delta) > 0.$$

This completes the proof of Theorem 3 (P).

Remark. It is important to remark that, in the case when δ is not rational, the singularity q^{-2} is no longer a pôle. Consider the case where $z = q^{-2}$. Then

$$T(q^{-2}, w) := U(q^{-2}e^w) \sum_{p \geq 0} G(q^{-2}e^w)^{p - \lfloor \delta p \rfloor}$$

is a power series with respect to $G(q^{-2}e^w)$ which possesses integer coefficients and is not a rational fraction. Then, we can apply a Theorem due to Polya:

Theorem C. [Polya] *If a power series with integer coefficients converges inside the unit disc, then the function it represents is either a rational function or a function that admits the unit circle as a natural boundary.*

This proves that $w \mapsto T(q^{-2}, w)$ admits as singularities all the points of the curve

$$\mathcal{C} = \{w \in \mathcal{W}; G(q^{-2}e^w) = 1\}$$

.

We have now analysed costs for which we expect an asymptotic gaussian law, namely

- additive costs of moderate growth, in 3.3 and 3.4,
- cost N in 3.5,
- degree of the remainder v_i at a fraction of the execution in 3.6.

Now, at the end of this section, we study costs, for which we only expect results on moments, namely, additive costs of intermediate growth, end-costs.

3.7. Additive costs of intermediate growth. [Proof of Theorem 4(P)(c).] We recall that the series $T_C(z, w)$ relative to any additive cost C can be expressed as

$$T_C(z, w) = \frac{U(z)}{1 - G_{[c]}(z, w)},$$

where $G_{[c]}(z, w)$ is the bivariate series relative to cost c [see equation (28)]. Now, if c is of intermediate growth, the generating function $G_{[c]}(z, w)$ is no longer analytic at $w = 0$. However, it admits derivatives of any order, and it is the same for $T_C(z, w)$. The derivative of order k of $T_C(z, w)$ (with respect to w , at $w = 0$), denoted by $T_C^{[k]}(z)$, will provide informations on the moment of order k of C , via the relation

$$(39) \quad \mathbb{E}[C_n^k] = \frac{[z^{n-1}]T_C^{[k]}(z)}{[z^{n-1}]T(z)}.$$

The first two series $T_C^{[k]}(z)$ (for $k = 1, 2$) are equal to

$$T_C^{[1]} = \frac{U \cdot G_{[c]}}{(1 - G)^2}, \quad T_C^{[2]} = \frac{U \cdot G_{[c^2]}}{(1 - G)^2} + 2 \frac{U \cdot G_{[c]}^2}{(1 - G)^3}$$

where the “weighted” series $G_{[d]}$ relative to some cost d is defined as

$$G_{[d]}(z) = \sum_{m \in \mathcal{G}} d(m) \cdot z^{\deg m}.$$

Since c is of intermediate growth, the two series $G_{[c]}, G_{[c^2]}$ are analytic on a disk of center 0 and radius strictly larger than q^{-2} . The explicit expressions of G and U entail precise expressions for $T_C^{[k]}(z)$ (for $k = 1, 2$), namely

$$T_C^{[1]}(z) = G_{[c]}(z) \cdot \frac{(q-1)qz}{(1-q^2z)^2}, \quad T_C^{[2]}(z) = G_{[c^2]}(z) \cdot \frac{(q-1)qz}{(1-q^2z)^2} + 2G_{[c]}^2(z) \cdot \frac{(q-1)qz(1-qz)}{(1-q^2z)^3},$$

which show that $T_C^{[1]}$ has a dominant pôle of order 2 at $z = q^{-2}$, $T_C^{[2]}$ has a dominant pôle of order 3 at $z = q^{-2}$. Then, with the Cauchy Formula,

$$[z^n]S_C^{[1]}(z) = q^{2n} \cdot \left[\frac{q-1}{q} \cdot G_{[c]}(q^{-2}) \right] \cdot n + O(1),$$

$$[z^n]S_C^{[2]}(z) = q^{2n} \cdot \left[\frac{q-1}{q} G_{[c]}(q^{-2}) \right]^2 \cdot n^2 + O(n).$$

Now, the equality $[z^n]T(z) = q^{2n}$ proves that the first two moments of C_n admit the following estimates

$$(40) \quad \mathbb{E}[C_n^i] = \left[\frac{q-1}{q} G_{[c]}(q^{-2}) \right]^i \cdot n^i \left(1 + O\left(\frac{1}{n}\right) \right).$$

This exhibits a cancellation in the dominant term of the variance, so that $\mathbb{V}[C_n] = \mathbb{E}[C_n^2] - \mathbb{E}[C_n]^2 = O(n)$. This proves the assertion (c) of Theorem 4 (P).

3.8. End costs. [Proof of Theorem 4 (P)(d).] The end costs are all the costs of the form $O(\ell(m_2) + \ell(m_p) + \ell(v_p))^k$ for some integer fixed k . If E denotes the end-cost defined by $E(u, v) = \ell(m_2) + \ell(m_p) + \ell(v_p)$, it is sufficient to show that all the moments of E_n (of any order k) are $O(1)$. The bivariate generating function T_E of E , can be written, with additivity of cost E as

$$T_E(z, w) = U_\ell(z, w) \cdot \left(1 + \frac{G_{[\ell]}^2(z, w)}{1 - G(z)} \right).$$

Now, we omit the index ℓ , and the k -th derivative of $T_E(z, w)$ [with respect to w , at $w = 0$] is

$$T_E^{[k]}(z) = \frac{\partial^k}{\partial w^k} U(z, w)|_{w=0} + \frac{1}{1 - G(z)} \left(\frac{\partial^k}{\partial w^k} (UG_{[\ell]}^2)(z, w) \right)|_{w=0}.$$

Since the function $(UG_{[\ell]}^2)(z, w)$, and all its derivatives (with respect to w , at $w = 0$), are analytic in a disk of center 0 and radius strictly larger than q^{-2} , the series $T_E^{[k]}(z)$ possess a unique dominant pôle at $z = q^{-2}$, of order 1. Then, with the Cauchy Formula,

$$[z^n]T_E^{[k]}(z) = q^{2n} \cdot \frac{\partial^k}{\partial w^k} (UG_{[\ell]}^2)\left(\frac{1}{q^2}, 0\right) \cdot (1 + O(n^{-1})).$$

With (39) and relation $[z^n]T(z) = q^{2n}$, this proves assertion (d) of Theorem 4(P).

3.9. Conclusion of the polynomial study. The analysis of the polynomial case is now complete, since we have proven all the versions (P) of Theorem 3 and Theorem 4. With Proposition 1 and the decompositions in Proposition 2, this proves the gaussian limit laws of the bit-complexities B and D [Theorem 1(P) and Theorem 2(P)]. We now consider the integer case.

4. THE EUCLID ALGORITHM ON INTEGERS. ALGEBRAIC STUDY

We now perform the analysis of the Euclid algorithm on integers, and we wish to prove the four Theorems with their (I) version. We first decompose the bit-complexities costs, and show that these decompositions involve the costs which are studied in Theorem 4. Since the integer study is more involved, there are two sections devoted to the analysis in case (I). The present section introduces the main tool of the analysis: the transfer operator. Then, it performs an ‘‘algebraic’’ study: it provides, for each cost of interest, an alternative expression of the generating function which involves the transfer operator. These alternative expressions will be used in Section 5 for the analytical study.

4.1. Continued fraction expansion. Each division-step of the Euclid algorithm $v = m \cdot u + r$ uses a digit m and changes the old pair (u, v) into a new pair (r, u) . Instead of integers, we consider rationals [the old rational $x = u/v$, and the new rational $y = r/u$] which both belong to the unit interval, and we look for a relation between y and x . One has

$$y = \frac{r}{u} = \frac{v - mu}{u} = \frac{v}{u} - \left\lfloor \frac{v}{u} \right\rfloor = \frac{1}{x} - \left\lfloor \frac{1}{x} \right\rfloor.$$

The map $T : \mathcal{I} \rightarrow \mathcal{I}$, defined as

$$(41) \quad T(x) = \frac{1}{x} - \left\lfloor \frac{1}{x} \right\rfloor \quad \text{for } x \neq 0, \quad T(0) = 0,$$

is called the Gauss map and plays a fundamental rôle in the study of the Euclid Algorithm. When the quotient is m , there exists also a linear fractional transformation (LFT) $h_{[m]}$ for which

$$x = h_{[m]}(y) \quad \text{with} \quad h_{[m]}(y) = \frac{1}{m + y}.$$

Of course, the LFT's $h_{[m]}$ are the inverse branches of T . On an input (u, v) with $u \neq 0$, the execution (3) creates a (unique) continued fraction expansion (CFE) of the form

$$(42) \quad \frac{u}{v} = \frac{1}{m_1 + \frac{1}{m_2 + \frac{1}{\ddots + \frac{1}{m_{p-1} + \frac{1}{m_p}}}}} = h_{[m_1]} \circ h_{[m_2]} \circ \dots \circ h_{[m_p]} = h(0),$$

and the Euclid algorithm “writes” the result $u/v = h(0)$. We remark that the last step of the Euclid algorithm is particular, since the last digit m_p satisfies $m_p > 1$. Then, with the sets $\mathcal{H}, \mathcal{F}, \mathcal{U}$ defined as

$$(43) \quad \mathcal{H} = \{h_{[m]}, m \geq 1\}, \quad \mathcal{F} = \{h_{[m]}, m \geq 2\}, \quad \mathcal{U} := \{d \in \mathbb{N}; d \geq 1\},$$

and already defined in (5), the Euclid Algorithm builds the bijection

$$(44) \quad \tilde{\Omega} := \{(u, v); 0 < u < v, \gcd(u, v) = 1\} \sim \mathcal{H}^* \times \mathcal{F},$$

together with the decomposition

$$\Omega \sim \mathcal{U} + \tilde{\Omega} \times \mathcal{U}.$$

4.2. Expression for continuants. When the algorithm performs p iterations, it gives rise to a continued fraction of depth p . Here, we show that the main parameters of the Euclid Algorithm on the input (u, v) (quotients m_i , remainders v_i and continuants s_i) can be read on the continued fraction of the rational u/v . When the CFE of u/v is splitted at depth i , the LFT h defines three LFT's, the beginning LFT b_i , the middle LFT h_i and the ending LFT e_i , respectively defined as

$$b_i := h_{[m_1]} \circ h_{[m_2]} \circ \dots \circ h_{[m_{i-1}]}, \quad h_i := h_{[m_i]} \quad e_i := h_{[m_{i+1}]} \circ \dots \circ h_{[m_p]},$$

so that h decomposes as $h = b_i \circ e_{i-1} = b_i \circ h_i \circ e_i$. The continuant s_i (which intervenes in the extended gcd algorithm) is the denominator of the beginning rational $b_i(0)$, while the remainder v_i is related to the denominator w_i of the ending rational $e_i(0)$ via the equality $v_i = v_p \cdot w_i$. For any LFT h of the form

$$(45) \quad h(x) = (\alpha x + \beta)/(\gamma x + \delta) \quad \text{with } \alpha, \beta, \gamma, \delta \text{ coprime integers,}$$

there exists a simple (but important) relation between the denominator $D[h]$ of the LFT h , defined by $D[h](x) := |\gamma x + \delta|$, and the derivative $h'(x)$, namely

$$|h'(x)| = \frac{|\det h|}{D[h](x)^2}.$$

Here, all the LFT's h used by the Euclid algorithm have their determinant that satisfy $|\det h| = 1$. Then, $v_0^{-2} = v_p^{-2} \cdot |h'(0)|$, and, more generally, the i -th continuants admit expressions which involve the beginning LFT e_i and the ending LFT b_i under the form

$$(46) \quad s_i^{-2} = |b'_i(0)|, \quad v_i^{-2} = v_p^{-2} \cdot |e'_i(0)|.$$

We also deal with “approximate” versions t_i, w_i of parameters s_i, v_i ,

$$(47) \quad w_i = v_i/v_p, \quad t_i := |b'_i(e_{i-1}(0))^{-1/2}| \quad \text{with } w_p = 1, s_1 = 1, \text{ and } t_1 := 1.$$

4.3. Decomposition of the bit-complexities. We consider three costs which involve the continuants s_i and their approximate versions t_i, w_i ,

$$A(u, v) := \sum_{i=1}^p \ell(m_i) \cdot \lg w_i, \quad \bar{A}(u, v) := \sum_{i=1}^p \ell(m_i) \cdot \lg t_i, \quad \underline{A}(u, v) := \sum_{i=1}^p \ell(m_i) \cdot \lg s_i,$$

via their logarithms instead of their integer size. The costs A, \bar{A} are useful because their generating functions will be easily generated by our transfer operators [See Propositions 4 and 5, Section 4.11 and 4.12].

The following proposition first relates the approximate bit-costs $A + \bar{A}, A$ to the bit-complexities costs D, B . Then, it provides decompositions for costs $A, A + \bar{A}$, in the same vein as in polynomial case. The present decompositions will be more involved than in the polynomial case. This is due

to the fact that it is no longer possible to express the bit-complexities, with only the parameters $\ell(m_i)$. We then introduce new parameters, the cost r and the sequence θ_i . In particular, the sequence θ_i plays in the number case a similar rôle as the constant sequence equal to -1 in the polynomial case. Finally, the proposition relates the three costs $A, \bar{A}, \underline{A}$.

Proposition 2 (I). (a) On Ω_n , the bit-complexity D decomposes as

$$(48) \quad D = [A + \bar{A}] + \left[\sum_{i=1}^p d_i \ell(m_i) \right] - [\ell(m_p)\ell(s_p)]$$

where d_i is defined as $d_i := 2 - \{\lg t_i\} - \{\lg v_i\} + \lg s_i - \lg t_i + \lg v_p$ and is a $O(\ell(v_p))$.

On Ω_n , the plain bit-complexity B decomposes as

$$(49) \quad B = [A] + \left[\sum_{i=1}^p f_i \ell(m_i) \right]$$

where f_i is defined as $f_i := 1 - \{\lg v_i\} + \lg v_p$ and is $O(\ell(v_p))$.

(b) On Ω_n , the approximate bit-complexity cost $A + \bar{A}$ of the Extended Euclidean Algorithm decomposes as

$$(50) \quad \bar{A} + A = \left[n \cdot \sum_{i=1}^p \ell(m_i) \right] - \left[\sum_{i=1}^p \ell^2(m_i) \right] - \left[\sum_{i=1}^p \ell(m_i)(r + \theta_i) \right].$$

The approximate complexity A of the standard algorithm decomposes as

$$(51) \quad A = \left[\frac{1}{2}(n-r)^2 - \sum_{i=1}^p \theta_i \lg w_i \right] - \frac{1}{2}(n-r).$$

Here, parameters r and θ_i are defined as $r = \lg v_p - \lg v_0 + \ell(v_0)$, $\theta_i := \lg w_{i-1} - \lg w_i - \ell(m_i)$ and satisfy $r = O(\ell(v_p))$, $-1 \leq \theta_i \leq 1$.

(c) On Ω_n , the three costs $A, \bar{A}, \underline{A}$ are related with the help of an auxilliary cost \hat{A} defined in (57) which has exactly the same distribution as \underline{A} . They satisfy

$$(52) \quad \bar{A} = \underline{A} + \sum_{i=1}^p a_i \ell(m_i), \quad |A - \hat{A}| \leq \lg w_2 \cdot |\ell(m_2 + 1) - \ell(m_2) - 1|,$$

where a_i is defined as $a_i := \lg t_i - \log s_i$ and satisfies $0 \leq a_i \leq 1$.

Proof.

Assertion (a). We first use the definitions of w_i, t_i in (47) together with the relation $\ell(x) = \lg x - \{\lg x\} + 1$ that holds for any $x \in \mathbb{N}$. Second, since any LFT h used by the Euclid Algorithm is of the form (45) with $0 < \gamma \leq \delta$, the relation $|h'(x)| \leq 4|h'(y)|$ holds, for all $x, y \in \mathcal{I}$, for any $h \in \mathcal{H}^*$ and entails the relation $-1 \leq \lg s_i - \lg t_i \leq 0$.

Assertion (b). We first define the sequence θ_i as follows: Denote by x_i the rational v_{i+1}/v_i [which is equal to the rational w_{i+1}/w_i]. The relation $w_{i-1} = m_i \cdot w_i + w_{i+1}$ entails that, for any i , with $1 \leq i \leq p$,

$$(53) \quad \lg w_{i-1} - \lg w_i = \lg(m_i + x_i) = \ell(m_i) + \theta_i, \quad \text{with } \theta_i = \lg \frac{m_i + x_i}{\tilde{m}_i}, \quad x_i := T^i\left(\frac{u}{v}\right),$$

and \tilde{m}_i the smallest power of two strictly greater than m_i . Remark that θ_i satisfies $-1 \leq \theta_i \leq 1$. Relation (53) replaces the polynomial relation $\ell(v_{i-1}) - \ell(v_i) = \ell(m_i) - 1$, and, in the number case, the sequence θ_i plays a similar rôle as the constant sequence equal to -1 in the polynomial case. Then, for any $i, 0 \leq i \leq p-1$, one has

$$(54) \quad \lg w_i = \sum_{j=i+1}^p [\ell(m_j) + \theta_j],$$

and, with the parameter r defined as

$$(55) \quad r = \lg v_p - \lg v_0 + \ell(v_0)$$

the previous relation for $i = 0$ entails on Ω_n the decomposition:

$$(56) \quad \sum_{i=1}^p [\ell(m_i) + \theta_i] = \lg w_0 = n - r.$$

Then, on Ω_n , the cost A can be written as

$$A_n = \sum_{i=1}^p ([\ell(m_i) + \theta_i] - \theta_i) \left(\sum_{j>i}^p [\ell(m_j) + \theta_j] \right) = \frac{1}{2}(n-r)^2 - \frac{1}{2}(n-r) - \sum_{i=1}^p \theta_i \lg w_i.$$

In the study of cost $A_n + \bar{A}_n$, the relation $\lg t_i + \lg(m_i + x_i) + \lg w_i = \lg w_0 = n - r$ holds and entails the equality $\lg s_i + \lg w_i + \ell(m_i) = n - r - \theta_i$. Then, the cost $A_n + \bar{A}_n$ can be written as

$$A(u, v) + \bar{A}(u, v) = \sum_{i=1}^p \ell(m_i) [n - r - \theta_i - \ell(m_i)] = n \cdot \sum_{i=1}^p \ell(m_i) - \sum_{i=1}^p \ell^2(m_i) - \sum_{i=1}^p \ell(m_i)(r + \theta_i).$$

Assertion (c). The first equality is clear.

For the remainder of Assertion (c), we mainly use the mirror mapping on continued fraction expansions, which associates to a CFE its mirror, formed of the same sequence of digits, in the reverse order. However, the existence of two different CFE's for the same rational makes the central idea a little bit technical. We first recall that any non zero rational admits two continued fraction expansions: – the proper CFE, built by the Euclid Algorithm, whose sequence of digits is of the form (m_1, m_2, \dots, m_p) with $m_p \neq 1$ – the improper CFE, of the form $(m_1, m_2, \dots, m_p - 1, 1)$.

We introduce the mirror mapping τ (on integer pairs) which associates to a pair $(u, v) \in \tilde{\Omega}$ a pair $\tau(u, v) = (u', v)$ which is characterized as follows: the rational u'/v is defined via (one of) its CFE, which is the mirror of the proper CFE of u/v . Then the restriction of τ to $[0, 1/2]$ is a bijection of the interval $[0, 1/2]$ (whose inverse is denoted by ρ_0) whereas the restriction of τ to $[1/2, 1]$ is a bijection from $[1/2, 1]$ onto $[0, 1/2]$ (whose inverse is denoted by ρ_1). We define the map α as the bijection from $[1/2, 1]$ onto $[0, 1/2]$ which transforms a rational whose proper CFE is of the form $(1, m_2, m_3, \dots, m_p)$ to the rational whose (proper) expansion is $(m_2 + 1, m_3, \dots, m_p)$ (The two rationals $\alpha(u/v)$ and (u/v) are not “close”, but their CFE's are “close”). Then the map $\rho_1 \circ \alpha$ is a bijection of the interval $[1/2, 1]$. Finally, since ρ_0 and $\rho_1 \circ \alpha$ are bijections which fix the size, the map \hat{A} defined by

$$(57) \quad \hat{A}(u, v) := \underline{A}(\rho_0(u, v)), \quad \text{if } u/v \leq 1/2, \quad \hat{A}(u, v) = \underline{A}(\rho_1 \circ \alpha(u, v)) \quad \text{if } u/v \geq 1/2$$

has exactly the same distribution as \underline{A} on each Ω_n .

We compare now \hat{A} and A . On $[0, 1/2]$, it is clear that $\hat{A} = A$. On $[1/2, 1]$, the two costs are slightly different, and their difference is exactly the difference between the bit-complexity when the quotients are $(1, m_2, m_3, \dots, m_p)$ and when the quotients are $(m_2 + 1, m_3, \dots, m_p)$. This difference equals $\lg w_2 \cdot [\ell(m_2 + 1) - \ell(m_2) - 1]$. This ends the proof. ■

4.4. Variance-equivalence. The previous decompositions of Proposition 2 (I), together with Theorem 4 (I) entail various variance equivalence (see Definition 2) between costs of interest. Then, applying Proposition 2 provides asymptotic gaussian laws.

Proposition 3 (I). (a) On Ω_n , various variance equivalences involve the bit-complexity costs D and the cost Θ equal to the sum of the terms of the sequence θ_i :

$$D \asymp_{(n-1)} A + \bar{A} \asymp_{(n-1)} n \cdot L, \quad \text{with } L = \sum_{i=1}^{p-1} \ell(m_i), \quad \Theta := \sum_{i=1}^p \theta_i \asymp_{(n-2)} n - L,$$

(b) The bit-complexity D , the approximate bit-complexity $\bar{A} + A$ and the cost Θ are asymptotically gaussian, with the respective characteristic triples $[O(n^2), \Theta(n^3), O(n^{-1/2})]$ (for the first two ones) and $[O(n), \Theta(n), O(n^{-1/2})]$ (for the last one).

(c) The variance $\mathbb{V}[B_n]$ is of exact order $\Theta(n^3)$.

$$B \asymp_{(n-1)} A \asymp_{(n-1)} \frac{n^2}{2} - \underline{N}, \quad \text{with } \underline{N} := \sum_{i=1}^p \theta_i \lg w_i.$$

(d) Conjecture (C) holds if and only if the two terms $3\mathbb{E}[(A_n - \bar{A}_n)^2]$ and $\mathbb{V}[D_n]$ have the same dominant terms of order n^3 .

(e) The conjecture (G_+) which states the Gaussian behaviour of \underline{N} can be viewed as a strong form of conjecture (G).

Proof.

Assertion (a). Except the case of cost \underline{N} , there are three kinds of “remainder” costs in the various decompositions of Proposition 2(I).

– First, there is an occurrence of a cost of intermediate growth [second block in (50)] whose variance is $O(n)$ [Theorem 4(I)(c)].

– A second kind is formed by costs of the form $O(n)\ell(m_p)$ or $O(n) \cdot \ell(m_2)$ (case of the third block in (48), or the second decomposition in (52)). With Theorem 4(P)(d) their variance is of order $O(n^2)$.

– Finally, the other remainders costs are of the form $O(L) \cdot \ell(v_p)$ and involve the additive cost L defined in Proposition 3: this is the case of the second block of (48), the second block of (49), the third block of (50), the block of the first decomposition of (52). Since P_n is $O(n)$, relation (56) entails that L_n is $O(n)$. Then, with Theorem 4(P)(d) the variance of all the costs of the third kind is of order $O(n^2)$.

Assertion (b). Since L is of moderate growth, Theorem 4(I)(a) proves that it is asymptotically gaussian with characteristic triple $[O(n), \Theta(n), O(n^{-1/2})]$. Now, $n \cdot L$ is clearly gaussian with characteristic triple $[O(n^2), \Theta(n^3), O(n^{-1/2})]$. This proves assertion (b) for costs $A + \bar{A}, D, \Theta$.

Assertion (c). Previous assertion (a) proves

$$(58) \quad E[\bar{A}_n - A_n] = O(n), \quad |\sigma[A_n] - \sigma[\bar{A}_n]| \leq \sigma[A_n - \bar{A}_n] = O(n).$$

With (b), the standard deviation $\sigma[A_n + \bar{A}_n]$ is of order $\Theta(n^{3/2})$, and the triangular inequality entails that $\sigma[A_n] + \sigma[\bar{A}_n]$ is $\Omega(n^{3/2})$. Now, Relation (58) proves that $\mathbb{V}[A_n], \mathbb{V}[\bar{A}_n], \mathbb{V}[A_n + \bar{A}_n]$ are of order $\Theta(n^3)$.

Assertion (d). Now, with (c), the equality

$$2\mathbb{V}[A_n] + 2\mathbb{V}[\bar{A}_n] = \mathbb{V}[A_n + \bar{A}_n] + \mathbb{V}[A_n - \bar{A}_n]$$

together with relations

$$\mathbb{V}[B_n] = \mathbb{V}[A_n] + O(n^{5/2}), \quad \mathbb{V}[A_n] = \mathbb{V}[\bar{A}_n] + O(n^{5/2}), \quad \mathbb{V}[D_n] = \mathbb{V}[A_n + \bar{A}_n] + O(n^2),$$

entail the equality

$$12(\mathbb{V}[B_n] - \frac{1}{3}\mathbb{V}[D_n]) = 3\mathbb{V}[A_n - \bar{A}_n] - \mathbb{V}[D_n] + O(n^{5/2}).$$

On the other side, since $\mathbb{E}[A_n - \bar{A}_n]$ is $O(n)$, we deduce $\mathbb{V}[A_n - \bar{A}_n] = \mathbb{E}[(A_n - \bar{A}_n)^2] + O(n^2)$. Then the conjecture (C), which says $\mathbb{V}[B_n] = (1/3)\mathbb{V}[D_n] + O(n^2)$ is equivalent to

$$3\mathbb{E}[(A_n - \bar{A}_n)^2] - \mathbb{V}[D_n] = O(n^{5/2}).$$

Assertion (e). Another expression of cost \underline{N} ,

$$\underline{N} = \sum_{i=1}^p \left(\sum_{j<i} \theta_j \right) \cdot \lg(m_i + x_i),$$

exhibits the similarity of cost \underline{N} with the cost N defined in (10) which has been studied in case (P): since the cost Θ is gaussian with the characteristic triple $[O(n), O(n), O(n^{-1/2})]$, the factor $(\sum_{j<i} \theta_j)$ in the previous sum is close to its mean, of order i . Then, a first step in order to prove that \underline{N} is gaussian, is to prove that its smoothed versions, obtained when the sequence θ_i is replaced by a constant, namely

$$(59) \quad \hat{N}^{(v)} = \sum_{i=1}^p \lg v_i \quad \bar{N}^{(v)} = \sum_{i=1}^p \lg w_i, \quad \text{or} \quad N^{(m)} = \sum_{i=1}^p i \cdot \ell(m_i)$$

are asymptotically gaussian. Since Theorem 4(I)(d) implies that

$$\hat{N}^{(v)} \underset{(n-1)}{\asymp} \bar{N}^{(v)},$$

it is sufficient to study $\hat{N}^{(v)}$ and $N^{(m)}$. We do not know how to prove their (asymptotic) gaussian behaviours, but we have access to an alternative expression for the bivariate generating functions of these costs. Then, conjecture (G_+) which states the asymptotic behaviour of \underline{N} can be viewed as a strong form of our conjecture (G) , stated as follows:

Conjecture (G) . *The costs $\bar{N}^{(v)}$ and $N^{(m)}$ are asymptotically gaussian. ■*

Remark. Then, proving Theorem 4 (I) will lead to the analysis of integer bit-complexities B and D [Theorem 1 (I) and Theorem 2 (I)]. The only point that remains to be checked will be the order of remainder terms, which are of order $O(n^{5/2})$ whereas they are announced to be of order $O(n^2)$. We will prove in the following that the asymptotic expansions of $\mathbb{V}[A_n]$ and $\mathbb{V}[\bar{A}_n]$ are polynomial with respect to n , which will complete the proof of Theorem 1 (I) and Theorem 2 (I) .

In order to prove Theorem 4 (I) , we now study the main costs of interest. Remind that the bijection (5) is no longer use, since it does not properly deal with the integer size. We mainly use the bijection $\tilde{\Omega} \sim \mathcal{H}^* \times \mathcal{F}$ and explain how it is possible to generate this set with the help of transfer operators.

4.5. Dynamical systems and transfer operator. A continuous extension of one step of the Euclid algorithm to real numbers x of $\mathcal{I} := [0, 1]$ is provided by the Gauss map $T : \mathcal{I} \rightarrow \mathcal{I}$, defined in (41). The pair (\mathcal{I}, T) defines a dynamical system. The set \mathcal{H} defined in (43) is just the set of branches of the inverse function T^{-1} that are also naturally numbered by the digit set \mathcal{G} . The set \mathcal{H}^k is the set of the inverse branches of the iterate T^k , and the set $\mathcal{H}^* := \cup_k \mathcal{H}^k$ is the semi-group generated by \mathcal{H} .

The main purpose in Dynamical Systems is the study of trajectories of a point x under the action of T . Here, we are interested in studying particular trajectories, relative to rational numbers x , which meet 0. A priori, they are not at all typical, but we aim to compare them to generic trajectories. The behaviour of generic trajectories of dynamical systems, is more easily explained by examining the flow of densities. The set \mathcal{I} is endowed with some initial density $f = f_0$, and the time evolution governed by the map T modifies the density. The successive densities $f_1, f_2, \dots, f_n, \dots$ describe the global evolution of the system at time $t = 0, 1, 2, \dots$. There exists an operator \mathbf{G} for which $f_1 = \mathbf{G}[f_0]$, $f_2 = \mathbf{G}[f_1]$, and more generally $f_n = \mathbf{G}[f_{n-1}] = \mathbf{G}^n[f_0]$ for all n . This operator, called the density transformer, or the Perron-Frobenius operator, can be defined as

$$(60) \quad \mathbf{G}[f](x) = \sum_{h \in \mathcal{H}} |h'(x)| \cdot f \circ h(x) = \sum_{m \geq 1} \frac{1}{(m+x)^2} \cdot f\left(\frac{1}{m+x}\right),$$

and involves the set \mathcal{H} defined in (43). It proves quite useful to add an extra parameter s in order to define the transfer operator \mathbf{G}_s (or Ruelle operator [23]), already defined in (13)

$$(61) \quad \mathbf{G}_s[f](x) = \sum_{h \in \mathcal{H}} |h'(x)|^s \cdot f \circ h(x) = \sum_{m \geq 1} \frac{1}{(m+x)^{2s}} \cdot f\left(\frac{1}{m+x}\right).$$

The “final” operator relative to the last step of the Euclid Algorithm which only uses quotients $m > 1$ is

$$(62) \quad \mathbf{F}_s[f](x) = \sum_{h \in \mathcal{F}} |h'(x)|^s \cdot f \circ h(x) = \sum_{m \geq 2} \frac{1}{(m+x)^{2s}} \cdot f\left(\frac{1}{m+x}\right).$$

Such operators are well-defined for $\Re s > 1/2$ and act on $\mathcal{C}^1(\mathcal{I})$. Note that the n -th iterate \mathbf{G}_s^n of \mathbf{G}_s has exactly the same form as \mathbf{G}_s , with a sum now taken over the set \mathcal{H}^n . The analog also holds for the quasi-inverse $(I - \mathbf{G}_s)^{-1}$, for which the sum is taken over \mathcal{H}^* . Then, with transfer operator, we have at hand a dictionary which replaces the dictionary on (usual) generating functions. The operator \mathbf{G}_s will play exactly the same rôle as $G(z)$ in Section 3 on polynomials.

We will deal with two kinds of generating functions, the plain relative generating functions, relative to the whole set Ω , and the tilde generating functions relative to the subset $\tilde{\Omega}$ formed with coprime pairs. Let us begin with an easy case, when the cost is the zero cost. Then,

$$(63) \quad \tilde{S}_0(s, w) := \sum_{(u,v) \in \tilde{\Omega}} \frac{1}{v^{2s}} = \sum_{h \in \mathcal{H}^* \mathcal{F}} |h'(0)|^s = \mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1}[1](0).$$

Furthermore, the classical Riemann Zeta function, defined as

$$\zeta(2s) := \sum_{d \geq 1} \frac{1}{d^{2s}},$$

allows to “returning” in Ω , via the relation

$$S_0(s, w) := \sum_{(u,v) \in \Omega} \frac{1}{v^{2s}} = \zeta(2s)[1 + \tilde{S}_0(s, w)].$$

As in Section 3, we deal with modifications of \mathbf{G}_s , where we introduce another parameter w in order to mark our parameters of interest. These transfer operators will provide alternative expressions for the generating functions of interest. As in Section 3, we begin with studying costs, for which we wish to establish an asymptotic gaussian law, namely

– additive costs of moderate growth (already proven in [2]) for Theorem 4(I)(a), also used for proving Theorem 1(I),

– size of the remainder at a fraction of the execution, for Theorem 3(I),

– parameters $N^{(v)}$ and $N^{(m)}$, in relation with Conjecture (G), useful for Theorem 2(I).

We consider all the bivariate generating functions $S_R(s, w)$, defined in (22) and we aim to express them with a convenient transfer operator, which depends also on these two parameters s and w .

4.6. Additive costs. Consider an additive cost C relative to a step-cost c . We first define the cost c on \mathcal{H} by letting $c(h_{[m]}) := c(m)$, then we extend cost c on \mathcal{H}^* by additivity, namely

$$c(h) := \sum_{i=1}^p c(h_i), \quad \text{for } h = h_1 \circ h_2 \circ \dots \circ h_p.$$

Then, for any input (u, v) with a CFE of the form $u/v = h(0)$, the cost $C(u, v)$ equals $c(h)$.

Consider the weighted transfer operator $\mathbf{G}_{s,w,[c]}$ relative to the digit cost c , already defined in (12),

$$(64) \quad \mathbf{G}_{s,w,[c]}[f](x) = \sum_{h \in \mathcal{H}} \exp[wc(h)] \cdot |h'(x)|^s \cdot f \circ h(x) = \sum_{m \geq 1} \exp[wc(m)] \cdot \frac{1}{(m+x)^{2s}} \cdot f\left(\frac{1}{m+x}\right),$$

and the “final” weighted transfer operator $\mathbf{F}_{s,w,[c]}$. Now, the n -th iterate of $\mathbf{G}_{s,w,[c]}$ has exactly the same expression as $\mathbf{G}_{s,w,[c]}$, with \mathcal{H} replaced by its n -th power \mathcal{H}^n . And, the quasi-inverse of the operator, of the form

$$\mathbf{F}_{s,w,[c]} \circ (I - \mathbf{G}_{s,w,[c]})^{-1}[f](x) = \sum_{h \in \mathcal{H}^* \mathcal{F}} \exp[wc(h)] \cdot |h'(x)|^s \cdot f \circ h(x),$$

“generates” the bivariate generating function $\tilde{S}_C(s, w)$ of cost C (relative to coprime inputs). With the bijection (44), the bivariate generating function \tilde{S}_C satisfies

$$(65) \quad \tilde{S}_C(s, w) = \sum_{(u,v) \in \tilde{\Omega}} \frac{1}{v^{2s}} \exp[C(u, v)] = \sum_{h \in \mathcal{H}^* \mathcal{F}} \exp[wc(h)] \cdot |h'(0)|^s = \mathbf{F}_{s,w,[c]} \circ (I - \mathbf{G}_{s,w,[c]})^{-1}[1](0),$$

whereas the plain generating function $S_C(s, w)$ is related to $\tilde{S}_C(s, w)$ via the equality

$$S_C(s, w) = \zeta(2s)[1 + \tilde{S}_C(s, w)].$$

4.7. Remainder at a fraction of the depth. As for the bit-complexities, the exact size of a continuant is difficult to generate with the transfer operators. This is why we first study the parameter $\widehat{L}^{[\delta]}$ which equals the logarithm of remainder v_i for $i = \lfloor \delta P \rfloor$, and we will return to the parameter $L^{[\delta]}$ with Proposition 1 and relation

$$(66) \quad L^{[\delta]}(u, v) = \ell(v_{\lfloor \delta p \rfloor}) = \frac{1}{\log 2} (\log v_{\lfloor \delta p \rfloor} - \{v_{\lfloor \delta p \rfloor}\} + 1) = \frac{1}{\log 2} \widehat{L}^{[\delta]} + O(1).$$

We denote by $\tilde{S}_{[\delta]}(s, w)$ the (tilde) bivariate generating function relative to the parameter $2\widehat{L}^{[\delta]}$,

$$\tilde{S}_{[\delta]}(s, w) := \sum_{(u,v) \in \tilde{\Omega}} \frac{1}{v^{2s}} \exp[2w \log v_{\lfloor \delta p \rfloor}] = \sum_{(u,v) \in \tilde{\Omega}} \frac{1}{v^{2s}} v_{\lfloor \delta p \rfloor}^{2w}$$

Consider an input (u, v) of Ω on which the algorithm performs p iterations. There exists a unique LFT h of depth p such that $u/v = h(0)$. We decompose h into two LFT's g and r of depth $\lfloor \delta p \rfloor$ and $p - \lfloor \delta p \rfloor$ such that $h = g \circ r$. With the relations

$$|(g \circ r)'(0)| = v_0^{-2} \cdot v_p^2, \quad |r'(0)| = w_{\lfloor \delta p \rfloor}^{-2} = v_{\lfloor \delta p \rfloor}^{-2} \cdot v_p^2,$$

the general term of the series $S_{\lfloor \delta \rfloor}(s, w)$ decomposes as

$$\frac{1}{v_{2s}^{2w}} v_{\lfloor \delta p \rfloor}^{2w} = v_p^{2w-2s} \cdot |r'(0)|^{-w} \cdot |(g \circ r)'(0)|^s = v_p^{2w-2s} \cdot |r'(0)|^{s-w} \cdot |g'(r(0))|^s.$$

Now, when (u, v) varies in $\tilde{\Omega}$ with a given height $p+1$ (with $p \geq 0$), we obtain

$$(67) \quad \sum_{\substack{(u,v) \in \tilde{\Omega} \\ P(u,v)=p+1}} \frac{1}{v_{2s}^{2w}} v_{\lfloor \delta p \rfloor}^{2w} = \mathbf{F}_{s-w} \circ \mathbf{G}_{s-w}^{p-\lfloor \delta p \rfloor} \circ \mathbf{G}_s^{\lfloor \delta p \rfloor} [1](0),$$

and finally, the tilde generating function satisfies

$$(68) \quad \tilde{S}_{\lfloor \delta \rfloor}(s, w) = \sum_{p \geq 0} \sum_{\substack{(u,v) \in \tilde{\Omega} \\ P(u,v)=p+1}} \frac{v_{\lfloor \delta p \rfloor}^{2w}}{v_{2s}^{2w}} = \mathbf{F}_{s-w} \circ \left(\sum_{p \geq 0} \mathbf{G}_{s-w}^{p-\lfloor \delta p \rfloor} \circ \mathbf{G}_s^{\lfloor \delta p \rfloor} \right) [1](0),$$

with the relation $S_{\lfloor \delta \rfloor}(s, w) = \zeta(2s-2w)[1 + \tilde{S}_{\lfloor \delta \rfloor}(s, w)]$. The central part of (68) defines the so-called pseudo-quasi-inverse $\mathbb{G}_{s,w}$, namely

$$(69) \quad \mathbb{G}_{s,w} := \sum_{p \geq 0} \mathbf{G}_{s-w}^{p-\lfloor \delta p \rfloor} \circ \mathbf{G}_s^{\lfloor \delta p \rfloor}.$$

Of course, since \mathbf{G}_s and \mathbf{G}_{s-w} do not commute, this is not a “true” quasi-inverse. However, we study this operator when w is near to 0, and we can hope that the properties of $\mathbb{G}_{s,w}$ will be close to properties of a true quasi-inverse.

4.8. Costs N . In case (I) , the two parameters defined in (10) are no longer equal, and we consider two bivariate generating functions, $\tilde{S}_{(v)}(s, w)$ [for cost $\bar{N}^{(v)}$] and $\tilde{S}_{(m)}(s, w)$ [for cost $N^{(m)}$]. We express these series with two operators $\mathbb{S}_{(v)}(s, w)$ and $\mathbb{S}_{(m)}(s, w)$ as

$$\tilde{S}_{(v)}(s, w) = \mathbb{S}_{(v)}(s, w)[1](0) \quad \tilde{S}_{(m)}(s, w) = \mathbb{S}_{(m)}(s, w)[1](0).$$

With the same principles as previously, the two operators are defined as follows:

$$(70) \quad \mathbb{S}_{(v)}(s, w) = \sum_{p \geq 1} \mathbf{F}_{s-pw} \circ \mathbf{G}_{s-(p-1)w} \circ \dots \circ \mathbf{G}_{s-w},$$

$$\mathbb{S}_{(m)}(s, w) = \sum_{p \geq 1} \mathbf{F}_{s,pw} \circ \mathbf{G}_{s,(p-1)w} \circ \dots \circ \mathbf{G}_{s,w}.$$

Here, the weighted operator $\mathbf{G}_{s,w} := \mathbf{G}_{s,w, \ell}$ is relative to the binary cost ℓ . Note that the first generating operator satisfies the functional equation

$$(71) \quad \mathbb{S}_{(v)}(s, w) = \mathbb{S}_{(v)}(s-w, w) \circ \mathbf{G}_{s-w},$$

whereas a similar equation does not seem to hold for the second generating operator.

In both cases, the operators look like quasi-inverses; however, there is an important difference with our previous pseudo-quasi-inverse (69). Previously, the operator $\mathbb{G}_{s,w}$ can be viewed as a small perturbation of the quasi-inverse $(I - \mathbf{G}_s)^{-1}$, since for a small w , each term of $\mathbb{G}_{s,w}$ is close to the corresponding term of $(I - \mathbf{G}_s)^{-1}$. Here, this is no longer true, since the terms which define $\mathbb{S}(s, w)$ contain operators of the form \mathbf{G}_{s-jw} where j tends to ∞ .

We now study other costs R , for which we only expect results for the expectation and the variance. We then deal with univariate generating functions, denoted by $S_R^{[1]}(s)$ for the mean, and $S_R^{[2]}(s)$ for the moment of order 2. We wish to study

- end-costs for Theorem 4(d)
- additive costs of intermediate growth for Theorem 4(c),
- costs A, \bar{A} for Theorem 2(I), whose study is also crucial for Conjecture (C).

4.9. Square brackets and angle brackets. We now introduce an object which will be quite useful in the sequel.

We first consider the set $\mathcal{T} \subset \mathcal{L}(\mathcal{C}^1(I))$ of operators \mathbf{H}_s of the form

$$\mathbf{H}_s[f](x) = \sum_{m \geq 1} \frac{R_m(x)}{(m+x)^{2s}} \cdot f\left(\frac{1}{m+x}\right), \quad \text{for } \Re s > 1/2,$$

for which there exists a positive number k and a constant K , such that, for any m , one has $|R_m(x)| \leq K \cdot (\log m)^k$. Now, there are two operators which operate on the set \mathcal{T} : the derivation with respect to s , denoted by Δ [which multiplies each term $R_m(x)$ by the factor $-2 \log(m+x)$], and, for a cost c of intermediate growth, the weighting operator $W_{[c]}$ which weights each component R_m by the factor $c(m)$ [i.e. R_m is replaced by $c(m)R_m$]. Of course, our transfer operator \mathbf{G}_s is an element of \mathcal{T} . Moreover, the weighted operator $\mathbf{G}_{s,w,[c]}$ (relative to any cost c of intermediate growth), together with its derivatives of any order with respect to s and w (at $w = 0$) belongs to the set \mathcal{T} .

Definition 4. [Square brackets and Angle brackets.] *Consider the algebra \mathcal{A} generated by the operator Δ , and all the weighting operators $W_{[c]}$ relative to costs c of intermediate growth. Consider k elements of \mathcal{A} , denoted by A_1, A_2, \dots, A_k . The square bracket $[A_1, A_2, \dots, A_k](s)$ is the Dirichlet series equal to*

$$\mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1} \circ A_1 \mathbf{G}_s \circ (I - \mathbf{G}_s)^{-1} \circ A_2 \mathbf{G}_s \circ \dots \circ A_k \mathbf{G}_s \circ (I - \mathbf{G}_s)^{-1} [1](0),$$

and the angle bracket $\langle A_1, A_2, \dots, A_k \rangle(s)$ is the Dirichlet series equal to

$$\Delta \mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1} \circ A_1 \mathbf{G}_s \circ (I - \mathbf{G}_s)^{-1} \circ A_2 \mathbf{G}_s \circ \dots \circ A_k \mathbf{G}_s \circ (I - \mathbf{G}_s)^{-1} [1](0),$$

We now see many examples of occurrences of these objects.

4.10. Additive costs C of intermediate growth. It will not be possible to deal directly with the transfer operator $\mathbf{G}_{s,w,[c]}$ as with additive costs of moderate growth, since it is no longer analytic at $(1, 0)$ [with respect to w]; however, when c is of intermediate growth, $\mathbf{G}_{s,w,[c]}$ admits derivatives at any order with respect to w , at $w = 0$, and we work with univariate series $\tilde{S}_C^{[j]}(s)$ [defined as in (24)] but relative to the tilde generating functions. Since the derivative of the quasi-inverse satisfies

$$\frac{\partial}{\partial w} (I - \mathbf{G}_{s,w,[c]})^{-1} = (I - \mathbf{G}_{s,w,[c]})^{-1} \circ \left(\frac{\partial}{\partial w} \mathbf{G}_{s,w,[c]} \right) \circ (I - \mathbf{G}_{s,w,[c]})^{-1},$$

these series for $j = 1, 2$ can be expressed with brackets. We only consider the part of these Dirichlet series which gathers the brackets of maximal order, which we denote with an underline. Then:

$$(72) \quad \underline{\tilde{S}}_C^{[1]} = [W_{[c]}], \quad \underline{\tilde{S}}_C^{[2]} = 2[W_{[c]}, W_{[c]}].$$

4.11. Bit-complexities A and \bar{A} . In this subsection and the next one, the reference to the cost c is omitted in W since c is always the binary length ℓ . The objective is to study the Dirichlet series relative to the first two moments of A and \bar{A} .

Proposition 4. *The parts $\underline{\tilde{S}}_A^{[1]}$ and $\underline{\tilde{S}}_{\bar{A}}^{[1]}$ of the series $\tilde{S}_A^{[1]}$ and $\tilde{S}_{\bar{A}}^{[1]}$ which only gather the brackets of order at least 2 satisfy*

$$(73) \quad (2 \log 2) \cdot \underline{\tilde{S}}_A^{[1]} = [\Delta, W], \quad (2 \log 2) \cdot \underline{\tilde{S}}_{\bar{A}}^{[1]} = [W, \Delta].$$

The parts $\underline{\tilde{S}}_A^{[2]}$ and $\underline{\tilde{S}}_{\bar{A}}^{[2]}$ of the series $\tilde{S}_A^{[2]}$ and $\tilde{S}_{\bar{A}}^{[2]}$ which only gather the brackets of order at least 3 satisfy

$$(74) \quad (2 \log^2 2) \cdot \underline{\tilde{S}}_A^{[2]} = 2[\Delta, \Delta, W, W] + [\Delta, W, \Delta, W] + [\Delta^2, W, W] + [\Delta, \Delta W, W] + [\Delta, \Delta, W^2] + 2\langle \Delta, W, W \rangle + \langle W, \Delta, W \rangle$$

$$(75) \quad (2 \log^2 2) \cdot \underline{\tilde{S}}_{\bar{A}}^{[2]} = 2[W, W, \Delta, \Delta] + [W, \Delta, W, \Delta] + [W, W, \Delta^2] + [W, \Delta W, \Delta] + [W^2, \Delta, \Delta].$$

Proof. We begin with the moments of order 1, then we deal with the moments of order 2.

Moments of order 1. We first deal with the elementary costs $[\ell(m_i) \cdot w_i^{2w}]$, $[\ell(m_i) \cdot t_i^{2w}]$ for some (small) w . The corresponding Dirichlet generating functions are

$$\mathbf{F}_{s-w} \circ \sum_{p \geq i} \mathbf{G}_{s-w}^{p-i} \circ \mathbf{G}_{s, [\ell]} \circ \mathbf{G}_s^{i-1} [1](0), \quad \mathbf{F}_s \circ \sum_{p \geq i} \mathbf{G}_s^{p-i} \circ \mathbf{G}_{s, [\ell]} \circ \mathbf{G}_{s-w}^{i-1} [1](0).$$

Now, the Dirichlet series $(2 \log 2) S_A^{[1]}(s)$, $(2 \log 2) S_{\bar{A}}^{[1]}(s)$, are just obtained with taking the sum over all the indices i between 1 and p , and taking the derivative with respect to w (at $w = 0$). We obtain, after the first step [i.e., taking the sum over indices i]

$$\mathbf{F}_{s-w} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_s)^{-1} [1](0), \quad \mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_{s-w})^{-1} [1](0),$$

and, after the second step, the Dirichlet series which only takes into account square brackets of order at least 2, denoted with a underline, are

$$(2 \log 2) \cdot \underline{\tilde{S}}_A^{[1]} = [\Delta, W], \quad (2 \log 2) \cdot \underline{\tilde{S}}_{\bar{A}}^{[1]} = [W, \Delta].$$

Moments of order 2. For the two moments of order 2, namely $\mathbb{E}[A_n^2]$, $\mathbb{E}[\bar{A}_n^2]$, we first deal with the elementary costs $[\ell(m_i) \cdot \ell(m_j) \cdot w_i^{2w} \cdot w_j^{2t}]$ and $[\ell(m_i) \cdot \ell(m_j) \cdot t_i^{2w} \cdot t_j^{2t}]$, for fixed index i, j with $1 \leq i, j \leq p$. There are two cases, $i = j$ and $i \neq j$. Then, we take the sum over all the pairs i, j with i, j between 1 and p and any possible p . We first obtain an alternative expression for the corresponding Dirichlet series (first step) and then, we take the derivative with respect to t, w , at $w = 0, t = 0$ (second step). We obtain the Dirichlet series with a multiplicative factor equal to $(2 \log 2)^2$. Since we deal with the two main terms in the asymptotics, we do not need terms which involve only three quasi-inverses. The Dirichlet series which only takes into account square brackets of order at least 3 will be denoted with a underline.

Cost A^2 . We deal with the elementary cost $[\ell(m_i) \cdot \ell(m_j) \cdot w_i^{2w} \cdot w_j^{2t}]$, and we obtain for $j > i$

$$\mathbf{F}_{s-w-t} \circ \sum_{p \geq j} \mathbf{G}_{s-w-t}^{p-j} \circ \mathbf{G}_{s-w}^{[\ell]} \circ \mathbf{G}_{s-w}^{j-i-1} \circ \mathbf{G}_s^{[\ell]} \circ \mathbf{G}_s^{i-1} [1](0),$$

and after the first step for any $i \neq j$,

$$2\mathbf{F}_{s-w-t} \circ (I - \mathbf{G}_{s-w-t})^{-1} \circ \mathbf{G}_{s-w}^{[\ell]} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_s)^{-1},$$

and finally after the second step

$$4[\Delta, \Delta, W, W] + 2[\Delta, W, \Delta, W] + 2[\Delta^2, W, W] + 2[\Delta, \Delta W, W] + \langle W, \Delta, W \rangle + \langle \Delta, W, W \rangle.$$

Second, for $i = j$, the same ideas apply with the operator

$$\mathbf{F}_{s-w} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_s^{[\ell^2]} \circ (I - \mathbf{G}_s)^{-1}$$

and two successive derivations with respect to w (at $w = 0$). This provides the term $2[\Delta, \Delta, W^2] + \langle \Delta, W, W \rangle$. Finally,

$$(2 \log^2 2) \cdot \underline{\tilde{S}}_A^{[2]} = 2[\Delta, \Delta, W, W] + [\Delta, W, \Delta, W] + [\Delta^2, W, W] + [\Delta, \Delta W, W] + [\Delta, \Delta, W^2] + 2\langle \Delta, W, W \rangle + \langle W, \Delta, W \rangle$$

Cost \bar{A}^2 . We deal with the elementary cost $[\ell(m_i) \cdot \ell(m_j) \cdot t_i^{2w} \cdot t_j^{2t}]$, and, for $j > i$, we obtain

$$\mathbf{F}_s \circ \sum_{p \geq j} \mathbf{G}_s^{p-j} \circ \mathbf{G}_s^{[\ell]} \circ \mathbf{G}_{s-w}^{j-i-1} \circ \mathbf{G}_s^{[\ell]} \circ \mathbf{G}_{s-w-t}^{i-1} [1](0).$$

Then, we take the sum over all the pairs i, j with $i \neq j$ and i, j between 1 and p , and take the derivative with respect to t, w (at $w = 0, t = 0$). We obtain after the first step [for cost A^2]

$$2\mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_{s-w}^{[\ell]} \circ (I - \mathbf{G}_{s-w-t})^{-1},$$

and, after the second step,

$$4[W, W, \Delta, \Delta] + 2[W, \Delta, W, \Delta] + 2[W, W, \Delta^2] + 2[W, \Delta W, \Delta].$$

Second, for $i = j$, the same ideas apply with the operator

$$\mathbf{F}_s \circ (I - \mathbf{G}_s)^{-1} \circ \mathbf{G}_s^{[\ell^2]} \circ (I - \mathbf{G}_{s-w})^{-1},$$

and two successive derivations with respect to w (at $w = 0$). This provides the term $2[W^2, \Delta, \Delta]$. Finally, for cost \bar{A}^2 ,

$$(2 \log^2 2) \cdot \tilde{\underline{S}}_{\bar{A}}^{[2]} = 2[W, W, \Delta, \Delta] + [W, \Delta, W, \Delta] + [W, W, \Delta^2] + [W, \Delta W, \Delta] + [W^2, \Delta, \Delta].$$

This completes the proof of Proposition 4. ■

We will see in the sequel that, when a generating Dirichlet series involves square brackets, the associated moments on Ω_n admit an asymptotic expansion which is a polynomial with respect to n .

4.12. Conjecture (C). We recall that our Conjecture (C) says that $\mathbb{V}[B_n] = (1/3)\mathbb{V}[D_n] + O(n^2)$. An equivalent form obtained in Proposition 3 (I) (d) is

The two moments $3\mathbb{E}[(A_n - \bar{A}_n)^2]$ and $\mathbb{V}[D_n]$ have the same terms of order n^3 .

We are then led to study the Dirichlet series $S_{A-\bar{A}}^{[2]}$.

Proposition 5. *The part $\tilde{\underline{S}}_{A-\bar{A}}^{[2]}$ of the series $\tilde{S}_{A-\bar{A}}^{[2]}$ which only gathers all the brackets of order at least 3 can be written as the sum of two series, $\Gamma_1(s)$ (which gathers all the brackets of order 4), and $\Gamma_2(s)$ (which gathers all the brackets of order 3), namely*

$$(\log^2 2) \cdot \Gamma_1(s) := [\Delta, \Delta, W, W] + [W, W, \Delta, \Delta] - [W, \Delta, \Delta, W] - [\Delta, W, W, \Delta],$$

and

$$\begin{aligned} (2 \log^2 2) \cdot \Gamma_2(s) = & [\Delta, \Delta, W^2] + [W^2, \Delta, \Delta] - [\Delta, W^2, \Delta] + [\Delta^2, W, W] + [W, W, \Delta^2] - [W, \Delta^2, W] + \\ & + [\Delta, \Delta W, W] + [W, \Delta W, \Delta] - [\Delta, W, \Delta W] - [W, \Delta, \Delta W] - [\Delta W, \Delta, W] - [\Delta W, W, \Delta] \\ & + 2\langle \Delta, W, W \rangle - 2\langle W, W, \Delta \rangle. \end{aligned}$$

Proof. Since the Dirichlet generating function of costs A^2 and \bar{A}^2 have already been obtained in Proposition 4, it remains to study the mean $\mathbb{E}[A_n \cdot \bar{A}_n]$. The cost $A \cdot \bar{A}$ deals with the elementary cost $[\ell(m_i) \cdot \ell(m_j) \cdot w_i^{2w} \cdot t_j^{2t}]$, and there are three different cases $j > i$, $j < i$ and $j = i$. For $j > i$, we obtain,

$$\mathbf{F}_{s-w} \circ \sum_{p \geq j} \mathbf{G}_{s-w}^{p-i} \circ \mathbf{G}_{s-w}^{[\ell]} \circ \mathbf{G}_{s-w-t}^{j-i-1} \circ \mathbf{G}_{s-t}^{[\ell]} \circ \mathbf{G}_{s-t}^{j-1}[1](\eta),$$

and after the first step

$$\mathbf{F}_{s-w} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_{s-w}^{[\ell]} \circ (I - \mathbf{G}_{s-w-t})^{-1} \circ \mathbf{G}_{s-t}^{[\ell]} \circ (I - \mathbf{G}_{s-t})^{-1}[1](0).$$

For $j < i$, we obtain,

$$\mathbf{F}_{s-w} \circ \sum_{p \geq i} \mathbf{G}_{s-w}^{p-i} \circ \mathbf{G}_s^{[\ell]} \circ \mathbf{G}_s^{i-j-1} \circ \mathbf{G}_s^{[\ell]} \circ \mathbf{G}_{s-t}^{i-1}[1](\eta),$$

and after the first step,

$$\mathbf{F}_{s-w} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_s)^{-1} \circ \mathbf{G}_s^{[\ell]} \circ (I - \mathbf{G}_{s-t})^{-1}[1](0).$$

Finally, for $i = j$, the same ideas apply with the operator

$$\mathbf{F}_{s-w} \circ (I - \mathbf{G}_{s-w})^{-1} \circ \mathbf{G}_s^{[\ell^2]} \circ (I - \mathbf{G}_{s-t})^{-1},$$

and two successive derivations with respect to w and t (at $w = 0, t = 0$). This provides the term $[\Delta, W^2, \Delta]$. Finally, for cost $A\bar{A}$,

$$\begin{aligned} (4 \log^2 2) \cdot \tilde{\underline{S}}_{A\bar{A}}^{[1]} = & 2[W, \Delta, \Delta, W] + 2[\Delta, W, W, \Delta] + [W, \Delta, W, \Delta] + [\Delta, W, \Delta, W] + \\ & + [W, \Delta^2, W] + [\Delta, W, \Delta W] + [W, \Delta, \Delta W] + [\Delta W, \Delta, W] + [\Delta W, W, \Delta] + [\Delta, W^2, \Delta] \\ & + 2\langle W, W, \Delta \rangle + \langle W, \Delta, W \rangle. \end{aligned}$$

Combining the previous expression with the expressions (74), (75) relative to cost A^2 and \bar{A}^2 leads to the result. ■

4.13. End-costs. We end the algebraic part with the expression of the Dirichlet series relative to an end-cost. The end costs are all the costs of the form $O((\ell(m_2) + \ell(m_p) + \lg v_p)^k)$ for some integer fixed k . As in polynomial case, if E denotes the end-cost defined by $E(u, v) = \ell(m_2) + \ell(m_p) + 2 \lg v_p$, it is sufficient to show that all the moments of E_n (of any order k) are $O(1)$.

The bivariate generating function $S_E(s, w)$ of E can be written as

$$S_E(s, w) = \zeta(2s - 2w) \cdot (1 + \mathbf{F}_{s,w} \circ (I - \mathbf{G}_s)^{-1} \circ \mathbf{G}_{s,w} \circ \mathbf{G}_s[1])(0)$$

Now, the Dirichlet series relative to the k -th moment of E is

$$(76) \quad S_E^{[k]}(s) = \frac{\partial^k}{\partial w^k} S_E(s, w)$$

and contains only one quasi-inverse.

4.14. Conclusion of this section. We have obtained an alternative expression for each generating function related to each cost of interest. Each expression involves a “generating operator” whose analytic properties are now studied.

5. THE EUCLID ALGORITHM ON INTEGERS. ANALYTIC STUDY.

With alternative expressions of Dirichlet series provided in the previous section at hand, it is now possible to perform the second step: we wish to find the dominant singularities of these Dirichlet series and their nature, and then transfer these informations towards coefficients and obtain asymptotic expressions for their coefficients.

5.1. First spectral properties of the transfer operator. As we previously saw, all the generating functions (bivariate or univariate) admit alternative expressions which involve the quasi-inverse [or the pseudo quasi-inverse] of a transfer operator (weighted or not). The dominant singularities of this type of operator (QI or PQI) and their nature are closely related to *spectral properties* of the plain operator, on a convenient functional space, which will be here $\mathcal{C}^1(I)$ (see [2] for more information). When w is near 0, and for an elementary cost c , the transfer operator $\mathbf{G}_{s,w,[c]}$ is just a perturbation of the plain operator \mathbf{G}_s .

For $\Re(s) > 1/2$, the operator \mathbf{G}_s acts on $\mathcal{C}^1(I)$ and the map $s \mapsto \mathbf{G}_s$ is analytic. For $s = 1$, the operator is quasi-compact: there exists a spectral gap between the unique dominant eigenvalue (that equals 1, since the operator is a density transformer) and the remainder of the spectrum. By perturbation theory, these facts —existence of a unique dominant eigenvalue $\lambda(s)$ and of a spectral gap— remain true in a complex neighbourhood \mathcal{V} of $s = 1$. There, the operator splits into two parts: the projection onto the dominant eigensubspace, denoted \mathbf{P}_s , and the part relative to the remainder of the spectrum, denoted \mathbf{N}_s , whose spectral radius is strictly less than $\eta|\lambda(s)|$ (with $\eta < 1$). This leads to the following spectral decomposition

$$\mathbf{G}_s = \lambda(s)\mathbf{P}_s + \mathbf{N}_s,$$

which extends to the powers of the operator

$$(77) \quad \mathbf{G}_s^n = \lambda^n(s)\mathbf{P}_s + \mathbf{N}_s^n,$$

and finally to the quasi-inverse $(\mathbf{I} - \mathbf{G}_s)^{-1}$

$$(78) \quad (I - \mathbf{G}_s)^{-1} = \frac{\lambda(s)}{1 - \lambda(s)}\mathbf{P}_s + (\mathbf{I} - \mathbf{N}_s)^{-1}.$$

The first term on the right admits a pole (of order 1) at $s = 1$, while the second term is analytic on the half-plane $\{\Re(s) \geq 1\}$. We further need a precise expression of the expansion of the quasi-inverse near $s = 1$.

Dominant spectral objects at $s = 1$. All the dominant spectral objects of \mathbf{G} are explicit

$$(79) \quad \lambda(1) = 1, \quad \mathbf{P}[f](x) = \varphi(x) \cdot \int_I f(t) dt, \quad \text{with } \varphi(x) = \frac{1}{\log 2} \frac{1}{1+x}.$$

Moreover at $s = 1$, the first two derivatives of $\Lambda(s) := \log \lambda(s)$ satisfy

$$(80) \quad B := -\Lambda'(1) > 0, \quad A := \Lambda''(1) > 0.$$

Finally, the expansion of $(I - \mathbf{G}_s)^{-1}$ at $s = 1$, of the form
(81)

$$(I - \mathbf{G}_s)^{-1} = \frac{1}{s-1} \frac{\mathbf{P}}{|\lambda'(1)|} + \mathbf{Q} + O(s-1), \quad \text{with } \mathbf{Q} = \frac{\Delta \mathbf{P}}{|\lambda'(1)|} + \left(\frac{\lambda''(1)}{2|\lambda'(1)|^2} - 1 \right) \mathbf{P} + (I - \mathbf{N})^{-1},$$

involves the so-called Porter Operator \mathbf{Q} , closely related to the Porter constant [see the book [13] for precisions on the Porter constant]. In particular, with (79, 81), for any operator $\mathbf{H} \in \mathcal{L}(\mathcal{C}^1(I))$, one has

$$(82) \quad (I - \mathbf{G}_s)^{-1} \circ \mathbf{H}[\varphi] \sim \frac{1}{s-1} \cdot \frac{1}{|\lambda'(1)|} \cdot \varphi \cdot I[\mathbf{H}], \quad \text{with } I[\mathbf{H}] := \int_I \mathbf{H}[\varphi](t) dt.$$

This proves:

Proposition 6. *Any bracket of order k (a square bracket $[A_1, A_2, \dots, A_k]$ or an angle bracket $\langle A_1, A_2, \dots, A_k \rangle$) [see Definition 3] has a pôle of order $k + 1$ at $s = 1$, and it admits an expansion of the form*

$$\begin{aligned} [A_1, A_2, \dots, A_k](s) &= \sum_{p=0}^k \frac{a_{k-p}}{|\lambda'(1)|^{p+1}} \cdot \frac{1}{(s-1)^{p+1}} + O(1) \quad \text{with } a_0 = \mathbf{F}[\varphi](0) \cdot \prod_{i=1}^k I[A_i \mathbf{G}], \\ \langle A_1, A_2, \dots, A_k \rangle(s) &= \sum_{p=0}^k \frac{\hat{a}_{k-p}}{|\lambda'(1)|^{p+1}} \cdot \frac{1}{(s-1)^{p+1}} + O(1) \quad \text{with } \hat{a}_0 = \Delta \mathbf{F}[\varphi](0) \cdot \prod_{i=1}^k I[A_i \mathbf{G}], \end{aligned}$$

where $I[\cdot]$ is defined in (82) and φ is defined in (79).

Remark. Then, the dominant constants a_0, \hat{a}_0 depend on the subset $\{A_1, A_2, \dots, A_k\}$ and do not depend on the order of the sequence (A_1, A_2, \dots, A_k) . There are two important instances of this fact in the expressions of Proposition 5. There is a cancellation in the dominant term of $\Gamma_1(s)$, and $\Gamma_1(s)$ has a pôle of order at most 4. There is also a cancellation of the angle brackets in the dominant term of $\Gamma_2(s)$, whose dominant term finally involves only square brackets.

5.2. Various extractors. We then now wish to transfer these informations towards coefficients and obtain asymptotic expressions for these coefficients. We use, as a main tool, convenient “extractors” which express coefficients of series as a function of the series itself. There exist various “extractors”, which will be chosen according to the informations that are expected for coefficients. There are three main cases, which are summarised as follows:

Case 1. [Average case analysis] We wish to obtain estimates for all the moments of order k , [obtained from coefficients of univariate series $S_R^{[i]}(s)$], with only the dominant term. This is useful here for proving Theorem 4 (d) : mean for end-costs.

Case 2. [Analysis of the variance] We wish to obtain dominant and subdominant terms for the moments of order 1 and 2 [obtained from coefficients of univariate series $S_R^{[i]}(s)$]. This is useful for the variance of costs of intermediate growth, and study of Conjecture C.

Case 3. [Distributional analysis] We wish to obtain gaussian normal law. Since we use the Quasi-Powers Theorem [see Theorem B, Section 2.6], we need expansions for coefficients of bivariate generating functions $S_R(s, w)$ which must be uniform with respect to w . This is useful for proving Theorem 4 (a), (b), and studying Conjecture (G).

For Case 1, Tauberian Theorems are used as our main extractor. When we wish to obtain remainder terms (or uniform terms), we then adopt the Perron Formula, and use it with some success, provided that we have a precise knowledge of the series –univariate series in case 2, or bivariate series in case 3.

5.3. Study of case 1. Tauberian Theorems. As we said, Tauberian Theorems [7, 25] are used when we only wish the dominant term of the estimates for the plain moments, as this is the case for end costs.

Theorem D. [Tauberian Theorem]. [Delange] *Let $F(s)$ be a Dirichlet series with non negative coefficients such that $F(s)$ converges for $\Re(s) > \sigma > 0$. Assume that*

- (i) $F(s)$ is analytic on $\Re(s) = \sigma, s \neq \sigma$, and
- (ii) for some $\gamma \geq 0$, one has $F(s) = A(s)(s - \sigma)^{-\gamma-1} + C(s)$, where A, C are analytic at σ , with $A(\sigma) \neq 0$.

Then, as $K \rightarrow \infty$,

$$\sum_{n \leq K} a_n = \frac{A(\sigma)}{\sigma \Gamma(\gamma + 1)} K^\sigma \log^\gamma K [1 + \epsilon(K)], \quad \epsilon(K) \rightarrow 0.$$

This Theorem is easy to deal with. The generating function $S_E^{[k]}(s)$ of Section 4.13 gives access to the moments of the end-cost E . The only property which has to be checked is the aperiodicity:

Aperiodicity. *The quasi-inverse $(I - \mathbf{G}_s)^{-1}$ is analytic on $\{\Re s = 1, s \neq 1\}$,*

whose proof is for instance in [2]. Then Tauberian Theorem can be applied and proves that $\mathbb{E}[E^k]$ is of order $O(1)$.

5.4. Study of cases 2 and 3. The Perron Formula and the US Properties. We follow the same lines as described in the work [2]. We consider Dirichlet series, univariate or bivariate, and we wish to obtain estimates for the partial sums of their coefficients. More precisely, we let

$$F(s) := \sum_{n \geq 1} \frac{a_n}{n^{2s}} \quad \text{or} \quad F(s, w) := \sum_{n \geq 1} \frac{a_n(w)}{n^{2s}}$$

and we study

$$(83) \quad \Phi(p) = \sum_{n \leq p} a_p \quad \text{or} \quad \Phi_w(p) = \sum_{n \leq p} a_p(w).$$

For a Dirichlet series $F(s) = \sum_{n \geq 1} a_n n^{-2s}$, the Perron Formula of order two (see [10]) relates partial sums of the coefficients of \bar{F} to the integral of F on a vertical line $\Re s = D > 0$ inside the convergence domain of F ,

$$(84) \quad \Psi(T) := \sum_{N \leq T} \sum_{n \leq N} a_n = \frac{1}{2i\pi} \int_{D-i\infty}^{D+i\infty} F(s) \frac{T^{2s+1}}{s(2s+1)} ds.$$

Of course, when the Dirichlet series is of the form $F(s, w) = \sum_{n \geq 1} a_n(w) n^{-2s}$, the Perron formula relates $F(s, w)$ and the analog $\Psi_w(T)$ of $\Psi(T)$ [when a_n is replaced by $a_n(w)$].

There are now two main steps: first apply (with some success) the Perron Formula, then return to the main object of interest, which is not the functions Ψ of (84), but the functions Φ of (83). The second step is easier than the first step: The functions Ψ can be viewed as smoothed versions of functions Φ , and it is sufficient to use the same arguments as in Baladi–Vallée [2], corrected by Cesaratto [4]. We now concentrate on the first step, where we use the Perron Formula.

Univariate case. It is next natural to modify the integration contour $\Re s = D$ into a contour which contains a unique pole of $F(s)$, and it is thus useful to know that the following Property US [Uniform Estimates on Strips] holds for F near $s = 1$.

Property $US(s)$. For any small ξ , there is $\alpha > 0$ for which the following is true:

- (i) $F(s)$ admits a unique pole in the strip $|\Re s - 1| \leq \alpha$.
- (ii) On the left vertical line $\Re s = 1 - \alpha$, the Dirichlet series $F(s)$ is $O(\max(1, |\Im s|^\xi))$, with a small ξ .

Bivariate case. We need uniform estimates when w is near 0, and it is natural to consider the following Property, which is a uniform perturbation of the previous one.

Property $US(s, w)$. For any small ξ , there is $\alpha > 0$ and a neighbourhood \mathcal{W} of $w = 0$ for which the following is true:

- (i) $s \mapsto F(s, w)$ admits a unique pole $\sigma(w)$ in the strip $|\Re s - 1| \leq \alpha$.
- (ii) On the left vertical line $\Re s = 1 - \alpha$, the Dirichlet series $F(s)$ is $O(\max(1, |\Im s|^\xi))$, with a small ξ , and a O -term uniform with respect to w .

Baladi and Vallée [2] have generalised ideas due to Dolgopyat [9] and prove that the US Properties hold for Dirichlet series relative to the quasi-inverses: Property $US(s)$ holds for the plain quasi-inverse $(I - \mathbf{G}_s)^{-1}$, and Property $US(s, w)$ holds for the quasi-inverse of the weighted operator $\mathbf{G}_{s, w, [c]}$ used for studying costs C of moderate growth [see Section 4.6]. For proving that Property US holds, the strip is split into two regions: a region near the real axis, where s is close to the pole

$s = 1$ [or its perturbation $\sigma(w)$ defined by relation $\lambda(\sigma(w), w) = 1$], and the region far from the real axis, where the powers of $\mathbf{G}_{s,w}$ are proven to satisfy

$$(85) \quad \exists M, \quad \exists \gamma < 1, \quad \forall n, \forall w \in \mathcal{W}, \quad \|\mathbf{G}_{s,w}^n\|_{1,t} \leq M \cdot \gamma^n |t|^\xi$$

[here, $t := \Im s$ and the norm $\|\cdot\|_{1,t}$ is defined by $\|f\|_{1,t} = \|f\|_0 + (1/t)\|f\|_1$].

In the sequel, we will extend this methodology in order to study

- the moments of a cost of intermediate growth, for proving Theorem 4(c),
- the moments of the cost $A, \bar{A}, A - \bar{A}$, for dealing with Conjecture (C),
- the moment generating function of cost $\hat{L}^{[\delta]}$, for proving Theorem 3,
- the moment generating function of cost $\bar{N}^{(v)}$, for dealing with conjecture (G).

We begin with the variance studies, which are related to costs expressed with square brackets.

5.5. Asymptotic estimates for coefficients of brackets. We are now ready to prove that, on Ω_n , the expectation of a cost whose generating function is a bracket admits an asymptotic expansion polynomial with respect to n .

Proposition 7. *Consider any cost R for which the relative Dirichlet series $S_R(s)$ involves a square bracket under the form $S_R(s) = \zeta(2s)[A_1, A_2, \dots, A_k](s)$. Then, the expectation $\mathbb{E}[R_n]$ admits an asymptotic expansion which is polynomial with respect to n , of the form*

$$\mathbb{E}[R_n] = \left[\frac{1}{k!} \left(\frac{2 \log 2}{|\lambda'(1)|} \right)^k \prod_{i=1}^k I[A_i \mathbf{G}] \right] n^k \cdot \left[1 + O\left(\frac{1}{n}\right) \right]$$

Proof. We use Property $US(s)$ for the quasi-inverse, namely (85) and we obtain for the square bracket $[A_1, A_2, \dots, A_k]$ in the region far from the real axis,

$$|[A_1, A_2, \dots, A_k]| \leq \left(\frac{1}{1-\gamma} \right)^{k+1} \cdot M^k \cdot |\Im s|^{(k+1)\xi} \cdot \prod_{i=1}^k \|A_i \mathbf{G}_s\|_{1,t}.$$

so that $[A_1, A_2, \dots, A_k]$ satisfies the Property US in this region. This is clearly the same for $\zeta(2s)$, and then for the product $\zeta(2s)[A_1, A_2, \dots, A_k](s)$.

For the region near the real axis, we use that the square bracket is meromorphic at $s = 1$, and $\zeta(2s)$ holomorphic at $s = 1$. We fix α sufficiently small and we consider the strip \mathcal{S} delimited by the vertical lines $|\Re(s) - 1| < \alpha$. With $US(s)$, this strip contains 1 as a unique pole of $\zeta(2s)[A_1, A_2, \dots, A_k]$ (of order $k + 1$). Consider now the rectangle \mathcal{R} delimited by \mathcal{S} and the two horizontal lines $|\Im(s)| = U$. With the Cauchy Theorem,

$$\frac{1}{2i\pi} \int_{\mathcal{R}} \zeta(2s)[A_1, A_2, \dots, A_k](s) \frac{T^{2s+1}}{s(2s+1)} ds = \frac{T^3}{3} \left(\sum_{p=0}^k \frac{a_{k-p}}{|\lambda'(1)|^{p+1}} \frac{2^p}{p!} \log^p T \right).$$

We now let U tend to ∞ . With Property $US(s)$, the left integral is $O(T^{3-2\alpha})$ and the right integral is exactly the integral of the Perron Formula.

Suppose that near $s = 1$, some generating function $\tilde{S}(s)$ relative to some cost R is expressed with square brackets. This entails the following estimates for the partial sums $\Psi_R(T)$ with $T = 2^n$

$$\Psi_R(2^n) = \frac{2^{3n}}{3} \left(\sum_{p=0}^k \frac{a_{k-p}}{|\lambda'(1)|^{p+1}} \frac{(2 \log 2)^p}{p!} n^p \right) + O(2^{n(3-2\alpha)}).$$

A first step for studying the expectation $\mathbb{E}_n[R]$ (on the set $\tilde{\Omega}_n$ of coprime inputs) considers the ratio between $\Psi_R(2^n)$ and $\Psi_0(2^n)$, where Ψ_0 is relative to the zero cost, which can be associated to the empty square bracket [see 63 for instance]. Then the dominant term of $\Psi_R(2^n)/\Psi_0(2^n)$ is

$$\left[\frac{1}{k!} \left(\frac{2 \log 2}{|\lambda'(1)|} \right)^k \prod_{i=1}^k I[A_i \mathbf{G}] \right] n^k$$

This dominant term is exactly the same if one considers the plain generating function $S(s)$ (no longer their tilde version). In this case, the dominant terms in $\Psi_0(2^n)$ and $\Psi_0(2^n)$ are just multiplied by $\zeta(2)$ so that the dominant term of the ratio does not change.

Then, with the same principles as in Baladi-Vallée [2] and Cesaratto [4], we obtain, after some steps of smoothing and de-smoothing, for some $\beta > 0$, the convenient expression for $\mathbb{E}[R_n]$. ■

5.6. Variance of costs of moderate growth. With relations (72), Proposition 7 entails the following estimates for $\mathbb{E}[C_n], \mathbb{E}[C_n^2]$,

$$\mathbb{E}[C_n] = I[W\mathbf{G}] \cdot \left(\frac{2 \log 2}{|\lambda'(1)|} \right) n + O(1) \quad \mathbb{E}[C_n^2] = 2 \frac{1}{2} \cdot I[W\mathbf{G}]^2 \cdot \left(\frac{2 \log 2}{|\lambda'(1)|} \right)^2 n^2 + O(n).$$

The dominant term (of order n^2) is the same in $\mathbb{E}[C_n]^2$ and in $\mathbb{E}[C_n^2]$, which proves an estimate for $\mathbb{V}[C_n]$ of the form $\mathbb{V}[C_n] = O(n)$. This proves the “difficult” assertion of Theorem 4 (c).

5.7. Moment of order 2 of $A - \bar{A}$ and Conjecture (C). Propositions 4 and 7 entail the following estimates for $\mathbb{E}[A_n], \mathbb{E}[A_n^2]$,

$$\begin{aligned} \mathbb{E}[A_n] &= \frac{1}{2 \log 2} I[\Delta\mathbf{G}] \cdot I[W\mathbf{G}] \cdot \left(\frac{2^2}{2!} \cdot \frac{(\log 2)^2}{|\lambda'(1)|^2} \right) n^2 + O(n) \\ \mathbb{E}[A_n^2] &= \frac{3}{2 \log^2 2} I[\Delta\mathbf{G}]^2 \cdot I[W\mathbf{G}]^2 \cdot \left(\frac{2^4}{4!} \cdot \frac{(\log 2)^4}{|\lambda'(1)|^4} \right) n^4 + O(n^3). \end{aligned}$$

We remark that the dominant term (of order n^4) is the same in $\mathbb{E}[A_n]^2$ and in $\mathbb{E}[A_n^2]$, which proves an estimate for $\mathbb{V}[A_n]$ of the form $\mathbb{V}[A_n] = \rho_0(\ell) \cdot n^3 + O(n^2)$. We recall the conjecture (C), about bit costs A and \bar{A} ,

$$\mathbb{E}[(A_n - \bar{A}_n)^2] - \frac{1}{3} \mathbb{V}[A_n + \bar{A}_n] = O(n^2).$$

For proving conjecture (C), we need proving that $\rho_0(\ell) = (1/3)\rho(\ell)$, where $\rho(\ell)$ is the constants which occurs in the dominant term of the variance in Theorem 1(I). We show the following:

Proposition 8. *Denote by \mathbf{Q} the Porter operator defined in (81). Then, Conjecture (C) holds if, for any $X, Y \in \{\Delta, W\}$, one has:*

$$I[X\mathbf{G} \circ \mathbf{Q} \circ Y\mathbf{G}] = \int_I (X\mathbf{G})[Y\varphi](t) dt - I[X\mathbf{G}] \int_I [Y\varphi](t) dt$$

Proof. With Proposition 6, and the remark after it, both series Γ_1 and Γ_2 of Proposition 5 have a pole of order at most four at $s = 1$ and can be written as

$$\Gamma_i(s) = \frac{1}{2 \log 2} \cdot \frac{1}{|\lambda'(1)|^4} \frac{\gamma_i}{\log^2 2} \frac{1}{(s-1)^4} + O\left(\frac{1}{(s-1)^3}\right).$$

Explicit form of constants γ_i . Using Iverson’s notation⁶, the dominant coefficient γ_2 equals

$$2\gamma_2 = \sum_{\substack{X, Y \in \{\Delta, W\} \\ X' \neq X, Y' \neq Y}} (-1)^{[X=Y]} \cdot I[X'\mathbf{G}] \cdot I[Y'\mathbf{G}] \cdot I[XY\mathbf{G}].$$

The dominant coefficient γ_1 is expressed with the subdominant terms in the expression of $\Gamma_1(s)$. At $s = 1$, the expansions of the three operators $(I - \mathbf{G}_s)^{-1}, \Delta\mathbf{G}_s, W\mathbf{G}_s$ respectively involve the Porter operator \mathbf{Q} , already defined in (81), together with the operators $\Delta^2\mathbf{G}, \Delta W\mathbf{G}$, which intervene in the expansion of $\Delta\mathbf{G}_s$ and $W\mathbf{G}_s$ at $s = 1$,

$$\Delta\mathbf{G}_s = \Delta\mathbf{G} + (s-1)\Delta^2\mathbf{G} + O((s-1)^2) \quad W\mathbf{G}_s = W\mathbf{G} + (s-1)\Delta W\mathbf{G} + O((s-1)^2).$$

The subdominant constant of the series Γ_1 is obtained when replacing, in each of the four terms of Γ , one of the nine places⁷ (and only one) by its subdominant constant. However, all the terms obtained by replacing $\Delta\mathbf{G}_s$ or $W\mathbf{G}_s$ by their subdominant terms disappear. This is the same for terms which contain the operator \mathbf{Q} at the beginning or at the end. Then, the subdominant constant γ_1 of Γ_1 is expressed via integrals of the form $I[\mathbf{H}]$ defined in (82) as a sum of four main terms, namely,

$$\gamma_1 = \sum_{\substack{X, Y \in \{\Delta, W\} \\ X' \neq X, Y' \neq Y}} (-1)^{[X=Y]} \cdot I[X'\mathbf{G}] \cdot I[Y'\mathbf{G}] \cdot I[X\mathbf{G} \circ \mathbf{Q} \circ Y\mathbf{G}].$$

⁶Iverson’s notation is defined as follows: $\llbracket X = Y \rrbracket = 1$ if $X = Y$ and 0 elsewhere.

⁷There are nine places in a square bracket of order 4: the four “written” places and the five “implicit” places, where the \mathbf{Q} is omitted.

Finally, the coefficient $\gamma := \gamma_1 + \gamma_2$ satisfies

$$(86) \quad 2\gamma = \sum_{\substack{X, Y \in \{\Delta, W\} \\ X' \neq X, Y' \neq Y}} (-1)^{[X=Y]} \cdot I[X'\mathbf{G}] \cdot I[Y'\mathbf{G}] \cdot (I[XY\mathbf{G}] + 2I[X\mathbf{G} \circ \mathbf{Q} \circ Y\mathbf{G}]).$$

Then, Proposition 7 entails

$$\mathbb{E}_n[(A - \bar{A})^2] = \frac{2 \log 2}{3|\lambda'(1)|^3} \cdot (2\gamma) \cdot n^3 + O(n^2).$$

Explicit form of constant $\rho(\ell)$. For Conjecture (C), we aim comparing the constant 2γ to the constant $\tilde{\rho}(\ell)$ which appears in the variance of the extended binary cost, via the relation

$$\mathbb{V}[A_n + \bar{A}_n] = \frac{2 \log 2}{|\lambda'(1)|^3} \cdot \tilde{\rho}(\ell) \cdot n^3 + O(n^2).$$

An alternative expression for $\tilde{\rho}(\ell)$ is obtained in Relation (15) of Theorem A

$$(87) \quad \tilde{\rho}(\ell) = \lambda_s'^2(1, 0) \cdot \lambda_{w^2}''(1, 0) - 2\lambda_w'(1, 0) \cdot \lambda_s'(1, 0) \cdot \lambda_{sw}''(1, 0) + \lambda_w^2(1, 0) \cdot \lambda_{s^2}''(1, 0).$$

We consider the weighted operator relative to the binary length cost ℓ , and we omit the reference to cost ℓ . We denote it by $\mathbf{G}_{s,w}$, its dominant eigenvalue by $\lambda(s, w)$, and its dominant eigenfunction by $\varphi(s, w)$. With taking derivatives of the relation $\mathbf{G}_{s,w}[\varphi_{s,w}] = \lambda_{s,w}\varphi_{s,w}$, with respect to s at $s = 1$ [Operation Δ] and with respect to w at $w = 0$ [operation W], we obtain the following relations: with first derivatives,

$$(88) \quad X\lambda = I[X\mathbf{G}],$$

and with second derivatives,

$$(89) \quad XY\lambda = I[XY\mathbf{G}] + \int_I (X\mathbf{G})[Y\varphi](t)dt + \int_I (Y\mathbf{G})[X\varphi](t)dt - I[X\mathbf{G}] \int_I [Y\varphi](t)dt - I[Y\mathbf{G}] \int_I [X\varphi](t)dt.$$

Finally, replacing in (87) the first and second derivatives by the expressions provided in (88) or (89) proves that the constant $\tilde{\rho}(\ell)$ has exactly the same structure as γ , and comparing with (86) proves Proposition 8. ■

We have now proven all the results about the moments of the bit-complexities A, \bar{A} , the additive costs, the end-costs. In particular, the proof of Theorem 1 (I), Theorem 2 (I) and Theorem 4 (I) is now complete. We now deal with the gaussian law of $L^{[\delta]}$ [or equivalently $\widehat{L}^{[\delta]}$, Theorem 3] and Conjecture (G).

5.8. Gaussian law for $L^{[\delta]}$. We follow the general lines described in Section 5.4. The generating function $S^{[\delta]}(s, w)$ relative to the cost $2 \cdot \widehat{L}^{[\delta]}$ involves the pseudo quasi-inverse $\mathbb{G}_{s,w}$ defined in (69). Hence, we first exhibit the poles of $\mathbb{G}_{s,w}$ and proves that $S^{[\delta]}(s, w)$ satisfies the $US(s, w)$ property. Then, extracting with the Perron formula and applying the smoothing/de-smoothing step of Baladi-Vallée, we obtain the moment generating function of $2 \cdot \widehat{L}^{[\delta]}$. We will see that it satisfies the Quasi-power Theorem hypotheses and entails that $2 \cdot \widehat{L}^{[\delta]}$ admits a gaussian limit law [which is sufficient].

For the region far from the real axis, it is easy to obtain the estimate $US(s, w)$: using the relation (85), we obtain for the pseudo-quasi-inverse $\mathbb{G}_{s,w}$ defined in (69),

$$\|\mathbb{G}_{s,w}\|_{1,t} \leq M \cdot \left(\sum_p \gamma^p \right) |\Im s|^{2\xi},$$

so that $F(s, w) = \mathbb{G}_{s,w}[1](0)$ satisfies $US(s, w)$ on a region “far from” the real axis.

Near the real axis, the study is more intricate for the pseudo-quasi-inverse operator $\mathbb{G}_{s,w}$ than for the plain quasi-inverse. It is clear that $\mathbb{G}_{s,w}$ has a singularity at $(s, w) = (1, 0)$. In order to obtain $US(s, w)$, it is then necessary to describe the behaviour of $\mathbb{G}_{s,w}$ when (s, w) is near $(1, 0)$.

If (s, w) belongs to a (fixed) neighbourhood \mathcal{V}_1 of $(1, 0)$, the two values s and $s - w$ belong to the previous neighbourhood \mathcal{V} of $s = 1$. Then, the two operators $\mathbf{G}_s, \mathbf{G}_{s-w}$ are quasi-compact, the dominant eigenvalue $\lambda(s), \lambda(s - w)$ of the operators $\mathbf{G}_s, \mathbf{G}_{s-w}$ are well-defined, and the spectral decomposition (77) of \mathbf{G}_t applies to $t = s, t = s - w$ and extends to the operator $\mathbb{G}_{s,w}$ which decomposes into a sum of four terms, a “dominant” term and three “remainder” terms.

Remainder terms. Each of the three remainder terms is obtained by replacing in the operator $\mathbb{G}_{s,w}$, and for at least one value of $t = s$ or $t = s - w$, the iterates \mathbf{G}_t^k by the corresponding powers of the operator \mathbf{G}_t , the other terms being (possibly) replaced by the corresponding term of the dominant operator $\lambda(t) \cdot \mathbf{P}_t$ or \mathbf{N}_t . One obtains three operators: one operator which contains only operators of type \mathbf{N} , and two operators with exactly one occurrence of type \mathbf{P} .

Denote by $\nu(t)$ the spectral radius of the operator \mathbf{N}_t , and by $R := \log \nu$. There exists a neighbourhood such that $\nu(s)$ and $\nu(s - w)$ are strictly less than some $a < 1$. Then, the series with only operators of type \mathbf{N} is absolutely convergent. Consider now the other two series, whose norms can be easily compared to a geometric sum, whose logarithm of the general term is

$$(90) \quad \delta R(s) + (1 - \delta)\Re\Lambda(s - w), \quad \delta\Re\Lambda(s) + (1 - \delta)R(s - w).$$

We now prove that these terms are strictly negative on a neighbourhood of $(s, w) = (1, 0)$ of the form $|s - 1| + |w| < \rho$. First, there exists a complex neighbourhood \mathcal{V} of $\tau = 1$ for which

$$R(\tau) < (1/2)R(1) < 0, \quad |\Lambda'(\tau)| \leq 2B,$$

with B defined in (80). Then one has

$$\max(|\Lambda(s)|, |\Lambda(s - w)|) \leq (|s - 1| + |w|) 2B\rho,$$

and, finally, if $\beta := \inf(\delta, 1 - \delta)$, and if $\rho \leq \beta \cdot |R(1)|/(8B)$, both terms in (90) are less than $\beta R(1)/8 < 0$. Finally, for (s, w) near $(1, 0)$, the norm of the remainder operator is bounded by $(1 - \exp[\beta R(1)/8])^{-1}$

The dominant term. The dominant term is obtained when replacing each occurrence of \mathbf{G}_t by the term $\lambda(t)\mathbf{P}_t$, and is of the form $F(s, w) \cdot [\mathbf{P}_{s-w} \circ \mathbf{P}_s[1](0)]$, with

$$F(s, w) = \sum_{p=0}^{+\infty} \lambda(s)^{\lfloor \delta p \rfloor} \cdot \lambda(s - w)^{p - \lfloor \delta p \rfloor}.$$

The properties of $F(s, w)$ will heavily depend on the nature of δ [rational versus irrational]. If δ is rational, the function $F(s, w)$ is a rational fraction with respect to two variables $\lambda(s - w)$ and $\lambda(s)$. More precisely, if δ is of the form c/D , with $d = D - c$, one has

$$F(s, w) = \left(\sum_{j=0}^{D-1} \lambda(s - w)^{j - \lfloor \delta j \rfloor} \cdot \lambda(s)^{\lfloor \delta j \rfloor} \right) \left(\sum_{k \geq 0} (\lambda^d(s - w) \lambda^c(s))^k \right).$$

Then, if we let $\psi(s, w) := \lambda(s - w)^{1 - \delta} \lambda(s)^\delta$, $F(s, w)$ can be written as

$$F(s, w) = \frac{P(s, w)}{1 - \psi(s, w)^D} \quad \text{with} \quad P(s, w) := \sum_{j=0}^{D-1} \lambda(s - w)^{j - \lfloor \delta j \rfloor} \lambda(s)^{\lfloor \delta j \rfloor}.$$

It is then essential to study the function $\psi(s, w)$. The denominator $s \rightarrow 1 - \psi(s, w)^D$ admits as zeroes all the values of s for which

$$\psi(s, w) = \exp[2iL\pi/D] \quad \text{with} \quad 0 \leq L < D.$$

This means that the function Ψ defined as $\Psi := \log \psi$ satisfies

$$\Psi(s, w) := (1 - \delta)\Lambda(s - w) + \delta\Lambda(s) = \frac{2iL\pi}{D}, \quad \text{with} \quad L \in \mathbb{Z}.$$

For $w = 0$, one has $\Psi(s, w) = \Lambda(s) = 2iL\pi/D$. Then, for w close to 0, the poles of $F(s, w)$ are near to the curve $\mathcal{R} := \{s; \Re\Lambda(s) = 0\}$. We now describe this curve \mathcal{R} : the expansion of $\Lambda(s)$ near $s = 1$, involves the first derivatives A and B defined in (80) under the form

$$(91) \quad \Lambda(s) = -B(s - 1) + A \cdot (s - 1)^2 + O(|s - 1|^3).$$

This entails that for s close enough to 1, with $s = \rho + it$,

$$\Re\Lambda(s) \sim -B(\rho - 1) - At^2, \quad \Im\Lambda(s) \sim -Bt.$$

Then, the curve \mathcal{R} is close to the curve of equation $B(\rho - 1) + At^2 = 0$ and is contained in the right plane $\Re s \leq 1$.

Consider two parts of this curve \mathcal{R} . The first part,

$$\mathcal{A} := \{s; \Re\Lambda(s) = 0, \quad |\Im\Lambda(s)| > \frac{3\pi}{2D}\}$$

is strictly contained inside the right plane $\{\Re s < 1 - 4\Delta\}$ for some $\Delta > 0$. By a small perturbation, there exists a neighbourhood \mathcal{W}_A of $w = 0$ for which the domain

$$(92) \quad \mathcal{A}_w := \{s; \quad |\Re\Psi(s, w)| \leq \frac{C}{D^2}, \quad |\Im\Psi(s, w)| > \frac{3\pi}{2D}\}$$

is strictly contained inside the right plane $\{\Re s < 1 - 3\Delta\}$, for any $w \in \mathcal{W}_A$. The second part of the curve is the portion of the curve

$$\mathcal{B} := \{s; \Re\Lambda(s) = 0, \quad |\Im\Lambda(s)| < \frac{\pi}{2D}\},$$

which is contained in the strip $|\Re s - 1| < d$ for some d . By a small perturbation, there exists a neighbourhood \mathcal{W}_B of $w = 0$ for which the domain

$$(93) \quad \mathcal{B}_w := \{s; \quad |\Re\Psi(s, w)| \leq \frac{C}{D^2}, \quad |\Im\Psi(s, w)| < \frac{\pi}{2D}\}$$

is strictly contained in the strip $|\Re s - 1| < 2d$, for any $w \in \mathcal{W}_B$.

Property $US(s, w)$ for $F(s, w)$. The expansion in (91) entails that $3\Delta > 2d$. We choose $\alpha \in]2d, 3\Delta[$ and we prove that the property $US(s, w)$ holds in the strip $|\Re s - 1| < \alpha$ for $w \in \mathcal{W}_A \cap \mathcal{W}_B$.

First, from (92), the only possible pôle of $F(s, w)$ in the strip $|\Re s - 1| < 3\Delta$ is the pôle $s = \sigma_0(w)$. Since the strip $|\Re s - 1| < \alpha$ is contained in $|\Re s - 1| < 3\Delta$, the only possible pôle of $F(s, w)$ in the strip $|\Re s - 1| < \alpha$ is the pôle $s = \sigma_0(w)$. We prove now that $s = \sigma_0(w)$ is actually a pôle for $F(s, w)$. We now omit the index 0 in σ_0 . The numerator $P(\sigma(w), w)$ satisfies at $w = 0$ the relation $P(\sigma(w), w) = P(1, 0) = D$. Then, there exists a neighbourhood of $w = 0$ for which $P(\sigma(w), w)$ is not zero. Moreover, at $w = 0$, the derivative $\Psi'(\rho(w), w)$ equals $\Psi'(1, 0) = \Lambda'(1) \neq 0$. Then, for w close enough to 0, the derivative $\Psi'(\rho(w), w)$ is non zero.

Second, with (92) and (93), there are only two possibilities on the line $\Re s = 1 - \alpha$, namely,

$$|\Re\Psi(s, w)| > \frac{C}{D^2} \quad \text{or} \quad \frac{\pi}{2D} \leq |\Im\Psi(s, w)| \leq \frac{3\pi}{2D}.$$

This entails that the denominator $1 - \psi(s, w)^D$ of $F(s, w)$ admits a lower bound, either

$$|\psi(s, w)^D - 1| \geq \exp[C/D] - 1 \geq C/D \quad \text{or} \quad |\psi(s, w)^D - 1| \geq 1.$$

On the other hand, since the numerator $P(s, w)$ satisfies

$$|P(s, w)| \leq \sum_{j=0}^{D-1} |\lambda(s-w)|^{j-\lfloor \delta j \rfloor} \cdot |\lambda(s)|^{\lfloor \delta j \rfloor},$$

it is (uniformly) bounded. Finally, on the line $\Re s = 1 - \alpha$, the dominant term admits a uniform bound with respect to w .

End of the proof of Theorem 3. We end the proof with the same principles as described in 5.4. We then obtain a uniform estimate for the moment generating function of $\hat{L}^{[\delta]}$

$$\mathbb{E}[\exp(2w\hat{L}_n^{[\delta]})] = \exp[nA(w) + B(w)] \cdot [1 + O(2^{-n\gamma})].$$

Here $A(w) = -\sigma_0(w) + \sigma_0(0)$ is defined by the implicit equation $\psi(\sigma_0(w), w) = 1$. The expression of $\sigma_0(w)$ is then given by

$$\delta\Lambda(\sigma_0(w)) + (1 - \delta)\Lambda(\sigma_0(w) - w) = 0.$$

With two derivations, the dominant coefficients of the mean and the variance are obtained. With the Quasi-Powers Theorem, the speed of convergence is $O(n^{-1/2})$.

We obtain an asymptotic gaussian law for the parameter $\hat{L}^{[\delta]}$ which is the logarithm of the remainder at the fraction δ of the execution. The algorithmic parameter of interest is the size of the remainder. As we already said it in Section 4.7 with (66), the relation between $L^{[\delta]}$ and $\hat{L}^{[\delta]}$, together with Proposition 1 entails Theorem 3.

Remark. In the case when δ is not rational, the property $US(s, w)$ does not hold for $F(s, w)$. See remarks for the polynomial case at the end of 3.6.

5.9. About the conjecture (G). The cost of interest is the cost $\bar{N}^{(v)}$ defined in (59), whose bivariate generating function is $\bar{S}_{(v)}(s, w) = \mathbb{S}_{(v)}(s, w)[1](0)$, where the operator $\mathbb{S}_{(v)}(s, w)$ satisfies

$$\mathbb{S}_{(v)}(s, w) = \sum_{p \geq 1} \mathbf{F}_{s-pw} \circ \mathbf{G}_{s-(p-1)w} \circ \dots \circ \mathbf{G}_{s-w}.$$

There exists a functional equation satisfied by $\mathbb{S}_{(v)}(s, w)$,

$$\mathbb{S}_{(v)}(s, w) = \mathbb{S}_{(v)}(s-w, w) \circ \mathbf{G}_{s-w}.$$

Comparing to the polynomial case shows that we loose many properties in the integer case. Since operators do not commute, it is no longer possible to obtain an exact expression as in (35). We perhaps may obtain informations on $S(s, w)$ when s is near 1, directly with the functional equation. However, even if we succeed in this first task, we do not see how to prove that the Property $US(s, w)$ holds for $S(s, w)$.

6. A COMMON FRAMEWORK FOR POLYNOMIALS AND INTEGERS.

Our analyses are now complete. Even these analyses were led in a sequential form –polynomials, then integers–, there is clearly a close connection between them, and we have tried to insist on these similarities by using “parallel” notations. This section aims to now describe our analyses in parallel, then provides a common framework, which will also explains the differences and the difficulties of the integer study.

6.1. Similarities. The similarities are obvious, since this is the *same* algorithm! The bijection (5) is the same⁸, and the decompositions of Proposition 2 (P) and Proposition 2 (I) quite similar. There is a clear analogy between the generating function $G(z)$, and its bivariate extensions, on the one hand, and the operator \mathbf{G}_s , and its bivariate extension on the other hand.

The reader must compare

- For additive costs of moderate growth: Relations (29) of Section 3.3 and (65) of Section 4.6.
- For the size of remainders at a fraction of the execution: Relations (37) of Section 3.6 and (68) of Section 4.7
- For the cost N , the same functional equation in (36) of Section 3.5 and in (71) of Section 4.8.

However, even if these objects are similar, they are not the same. In the integer case, we need a dynamical system and a transfer operator, which are of no use in the polynomial case. . . Of no use, is it true?

6.2. The polynomial dynamical system. We recall that the gcd algorithm on $\mathbf{F}_q[X]$ is based on the Euclidean division: on a pair (u, v) of polynomials with $\deg v > \deg u$,

$$v = m \cdot u + r, \quad \text{with } r = 0 \text{ or } \deg r < \deg u.$$

As we did it in Sections 4.1 and 4.5 in case (I), it is possible to define a continuous extension of this division. This construction is due to Artin. The analogue of the ring \mathbb{Z} is the ring $\mathbf{F}_q[Z]$ of polynomials, and the field $\mathbf{F}_q(Z)$ (the field of rational fractions) plays the same rôle as the field \mathbb{Q} of rational numbers. We work on the completion of $\mathbf{F}_q[Z]$ with respect to the (ultrametric) absolute value $\|\cdot\|$ defined as $\|u\| := q^{-\deg u}$: this is the field of Laurent formal power series $\mathbf{F}_q((1/Z))$ where each element f has a Hensel expansion

$$(94) \quad f = \sum_{n \geq n_0} f_n (1/Z)^n, \quad \text{with } f_n \in \mathbf{F}_q \text{ and } n_0 \in \mathbb{Z}.$$

This expansion is parallel to the binary expansion of a real [replace Z by 2]. From the Hensel expansion (94), it is possible to define the function integer part, denoted by $\lfloor \cdot \rfloor$, and the function fractional part, denoted with $\{ \cdot \}$, with

$$\lfloor f \rfloor := \sum_{n=n_0}^0 f_n (1/Z)^n \quad \{f\} := \sum_{n \geq 1} f_n (1/Z)^n.$$

⁸Forget the particularities of the last step in case (I)!

The analog of the unit interval $[0, 1]$ is the unit open ball \mathcal{X}_q of $\mathbf{F}_q((1/Z))$, which is also the set of elements with zero integer part. The shift $T : \mathcal{X}_q \rightarrow \mathcal{X}_q$ is defined by

$$T(x) = \frac{1}{x} - \left\lfloor \frac{1}{x} \right\rfloor = \left\{ \frac{1}{x} \right\}, \quad \text{for } x \neq 0, \quad T(0) = 0.$$

The set \mathcal{G} of possible quotients is

$$\mathcal{G} := \{m \in \mathbf{F}_q[Z]; \ ||m|| \geq 1\} = \{m \in \mathbf{F}_q[Z]; \ \deg m > 0\},$$

and the set of the inverse branches of T is just the set

$$\mathcal{H} := \{h_{[m]} : x \mapsto \frac{1}{m+x}; \ m \in \mathcal{G}\}.$$

This dynamical systems is precisely described for instance in [3].

This dynamical system possesses very particular properties. The density transformer, and its extension the transfer operator, are defined as usual as

$$\mathbf{G}_s[f](x) = \sum_{m \in \mathcal{G}} \frac{1}{\|m+x\|^{2s}} \cdot f\left(\frac{1}{m+x}\right),$$

and acts on $\mathcal{C}^1(\mathcal{X}_q)$. Thanks to the ultrametric topology on \mathcal{X}_q , the absolute value $\|m+x\|$ is constant on \mathcal{X}_q and equals to $\|m\|$. Then, the operator \mathbf{G}_s is equal to

$$\mathbf{G}_s[f](x) = \sum_{m \in \mathcal{G}} \frac{1}{\|m\|^{2s}} \cdot f\left(\frac{1}{m+x}\right).$$

When applied to the uniform density $f_0 = 1$, the transfer operator \mathbf{G}_s transforms it into a constant function

$$\mathbf{G}_s[1] = \sum_{m \in \mathcal{G}} \frac{1}{\|m\|^{2s}} = \sum_{m \in \mathcal{D}} \frac{1}{q^{2s \deg m}}.$$

This means that the complex number $\mathbf{G}_s[1]$ is the eigenvalue relative to the eigenfunction equal to 1. On a convenient functional space, this is the dominant eigenvalue. This number $\mathbf{G}_s[1]$ is also a Dirichlet series, but this is also a power series with respect to $z = q^{-2s}$. With this change of variables, it coincides with the (usual) generating function $G(z)$ of the set \mathcal{G} , which gathers all the non constant polynomials of $\mathbf{F}_q(Z)$,

$$\mathbf{G}_s[1] = G(z) = \sum_{m \in \mathcal{G}} z^{\deg m} = (q-1) \sum_{n \geq 1} q^n z^n = \frac{q(q-1)z}{1-qz} = \frac{(q-1)}{q^{2s-1}-1}.$$

This allows a better understanding of the relation between the operator \mathbf{G}_s and the generating function $G(z)$. But, it is not yet clear why it is possible to replace the polynomial transfer operator by its dominant eigenvalue. This is due to the fact that the branches of the polynomial dynamical system are affine, namely, the (ultrametric) norm of their derivatives is constant.

For a dynamical system with affine branches, the transfer operator admits 1 as an eigenfunction, for any value of parameter s . This will be also the case for any weighted transfer operator. Then, Section 3 is completely useless. We could have chosen to perform only one analysis, common to case (P) and (I). Section 4 provides all the results of Section 3: we forget the \circ of composition, the last function 1, and the last point 0. This allows to transform a non commutative framework into a commutative one. Then, we perform the change of variables $z := q^{-2s}$. We obtain in this way all the expressions of the generating functions of Section 3 with this syntactic transformation.

6.3. Analytical differences. Then, there is a common framework, given by the underlying dynamical system, and it would be possible to eliminate the algebraic part of Section 3, with a rewriting of Section 4. However, the analytic part of Section 3 is not a rewriting of Section 5: The analytical studies are very different, in the sense that the analytical study in case (P) is much more easier. The change of variables $z := q^{-2s}$ transforms (unbounded) vertical strips into compact crowns. For instance, the property equivalent to the *US* Property is very often much more easier to check in the power series. This explains why the Riemann Hypothesis is proven in $\mathbb{F}_q[X]$ (and not yet for numbers...)

Finally, the explanation of the difference is simple: there are no carries for polynomials, then the degree (quite close to the size) is an additive morphism with respect to the multiplication. This gives rise to an ultrametric topology, where it is possible to work with power series.

The existence of carries for integer leads to the usual topology, and it is no longer possible to use power series. Dirichlet series are then used, but, at the same time, the branches of the dynamical systems are no longer affine for the usual topology. This leads to a dynamical system with memory, for which the transfer operator cannot be reduced to its dominant eigenvalue.
