SUMMARY

Nested sampling is a simulation method for approximating marginal likelihoods proposed by Skilling (2006). We establish that nested sampling has an approximation error that vanishes at the standard Monte Carlo rate $O(N^{-1/2})$, where N is a tuning parameter proportional to the computational effort, and that this error is asymptotically Gaussian. We show that the asymptotic variance of the nested sampling approximation typically grows linearly with the dimension of the parameter. We discuss the applicability and efficiency of nested sampling in realistic problems, and we compare it with two current methods for computing marginal likelihood. We propose an extension that makes it possible to avoid resorting to MCMC to obtain the simulated points.

Some key words: MCMC, Monte Carlo approximation, mixture of distributions, importance sampling.

1. INTRODUCTION

Nested sampling was introduced by Skilling (2006) as a numerical approximation method for integrals of the kind

$$\mathfrak{Z} = \int L(y|\theta)\pi(\theta) \, d\theta,$$

when π is the prior distribution and $L(y|\theta)$ is the likelihood. Those integrals are called *evidence* in the above papers and they naturally occur as marginals in Bayesian testing and model choice (Jeffreys, 1939; Robert, 2001, Chapters 5 and 7), even though the pairwise nature of those inferential problems, meaning that \mathfrak{Z} is never computed *per se* but in relation with another marginal \mathfrak{Z}' , makes the approximation of the integral ratio (or Bayes factor)

$$\mathfrak{B}_{12} = \int L_1(y|\theta_1)\pi_1(\theta_1) \, d\theta_1 \bigg/ \int L_2(y|\theta_2)\pi_2(\theta_2) \, d\theta_2$$

amenable to specific approximations (see, e.g., Chen & Shao, 1997; Gelman & Meng, 1998).

One important aspect of nested sampling is that it resorts to simulating points θ_i from the prior π , constrained to θ_i having a larger likelihood value than some threshold l ; the exact principle of nested sampling is described in the next section. In a brief discussion (Chopin & Robert, 2007), we raised concerns about the universality and the formal properties of the method. With respect to the former concern, we pointed out that simulating efficiently from a constrained distribution

49 may not always be straightforward, even when the MCMC scheme suggested by Skilling (2006)
 50 is used. With respect to the latter one, the convergence properties of the method had not been
 51 fully established: Evans (2007) showed convergence in probability, but called for further work
 52 towards obtaining the rate of convergence and the nature of the limiting distribution.

53 The purpose of this paper is to investigate both points presented above. Our main contribution
 54 is to establish the convergence properties of the nested sampling estimates: the approximation
 55 error is dominated by a $O(N^{-1/2})$ stochastic term, which has a limiting Gaussian distribution,
 56 and where N is a tuning parameter proportional to the computational effort. We also investigate
 57 the impact of the dimension d of the problem on the performances of the algorithm. In a simple
 58 example, we show that the asymptotic variance of nested sampling estimates grows linearly with
 59 d ; this means that the computational cost is $O(d^3/e^2)$, where e is the selected error bound.

60 In a second part, we discuss the difficulty to sample from the constrained prior. Using MCMC,
 61 as suggested by Skilling (2006), could incur a curse of dimensionality, although this pitfall seems
 62 model-dependent in our simulations. Murray's PhD thesis (2007, University College London)
 63 also includes a numerical comparison of nested sampling with other methods for several models.

64 Since the ability to simulate from the constrained prior is crucial in the applicability of the
 65 algorithm, we further propose an extension of nested sampling, based on importance sampling,
 66 that introduces enough flexibility so as to perform the constrained simulation without resorting to
 67 MCMC. Finally, we examine two alternatives to nested sampling for computing evidence, both
 68 based on the output of MCMC algorithms. We do not aim at an exhaustive comparison with all
 69 existing methods (see, e.g., Chen et al., 2000, for a broader review), and restrict our attention
 70 to methods that share the property with nested sampling that the same algorithm provides ap-
 71 proximations of both the posterior distribution and the marginal likelihood, at no extra cost. We
 72 provide numerical comparisons between those methods.

74 2. NESTED SAMPLING: A DESCRIPTION

75 2.1. Principle

76 We describe briefly here the nested sampling algorithm, as provided in Skilling (2006). We
 77 use $L(\theta)$ as a short-hand for the likelihood $L(y|\theta)$, omitting the dependence on y .

78 Nested sampling is based on the following identity:

$$80 \mathfrak{Z} = \int_0^1 \varphi(x) dx, \quad (1)$$

81 where φ is the inverse of

$$82 \varphi^{-1} : l \rightarrow P^\pi(L(\theta) > l).$$

83 Thus, φ is the inverse of the survival function of the random variable $L(\theta)$, assuming $\theta \sim \pi$ and
 84 φ^{-1} is a decreasing function, which is the case when L is a continuous function and π has a
 85 connected support. (The representation $\mathfrak{Z} = \mathbb{E}^\pi[L(\theta)]$ holds with no restriction on either L or π .)
 86 Formally, this one-dimensional integral could be approximated by standard quadrature methods,

$$87 \widehat{\mathfrak{Z}} = \sum_{i=1}^j (x_{i-1} - x_i) \varphi_i \quad (2)$$

88 where $\varphi_i = \varphi(x_i)$, and $0 < x_j < \dots < x_1 < x_0 = 1$ is an arbitrary grid over $[0, 1]$. (This reduc-
 89 tion in the dimension due to a change of measure can be found in the earlier numerical literature,
 90

 95
 96

like Burrows, 1980.) Function φ is intractable in most cases however, so the φ_i 's are approximated by an iterative random mechanism:

- Iteration 1: draw independently N points $\theta_{1,i}$ from the prior π , determine $\theta_1 = \arg \min_{1 \leq i \leq N} L(\theta_{1,i})$, and set $\varphi_1 = L(\theta_1)$.
- Iteration 2: obtain the N ‘current’ values $\theta_{2,i}$, by reproducing the $\theta_{1,i}$'s, except for θ_1 that is replaced by a draw from the prior distribution π conditional upon $L(\theta) \geq \varphi_1$; then select θ_2 as $\theta_2 = \arg \min_{1 \leq i \leq N} L(\theta_{2,i})$, and set $\varphi_2 = L(\theta_2)$.
- Iterate the above step until a given stopping rule is satisfied, for instance observing very small changes in the approximation $\hat{\mathfrak{Z}}$ or reaching the maximal value of $L(\theta)$ when it is known.

In the above, the value $x_i^* = \varphi^{-1}(\varphi_i)$ that should be used in the quadrature approximation (2) is unknown. An interesting property of the generating process is however that the random variables defined by $t_i = \varphi^{-1}(\varphi_{i+1})/\varphi^{-1}(\varphi_i) = x_{i+1}^*/x_i^*$ are independent $\text{Beta}(N, 1)$ variates. Skilling (2006) takes advantage of this property by setting $x_i = \exp(-i/N)$, so that $\log x_i$ is the expectation of $\log \varphi^{-1}(\varphi_i)$. Alternatively to this deterministic scheme, Skilling (2006) proposes a *random scheme* where the x_i 's are random, by mimicking the law of the t_i 's, i.e. $x_{i+1} = x_i \cdot t_i$, where $t_i \sim \text{Beta}(N, 1)$. In both cases the relation $\varphi_i = \varphi(x_i)$ does not hold; instead, φ_i should be interpreted as a ‘noisy’ version of $\varphi(x_i)$.

We focus on the deterministic scheme in this paper. It seems reasonably easy to establish a central limit theorem and other results for the random scheme, but the random scheme always produces less precise estimates, as illustrated by the following example.

Example 1. Consider the artificial case of a posterior distribution equal to $\pi(\theta|y) = \exp\{-\theta\}$ for a specific value of y , derived from the model $\pi(\theta) = \delta \exp\{-\delta\theta\}$ and $L(\theta) = \exp\{-(1 - \delta)\theta\}/\delta$, so that $\mathfrak{Z} = 1$ for every $0 < \delta < 1$. Nested sampling can then be implemented with no MCMC approximation, each new θ in the running sample being simulated from an exponential $\mathcal{E}(\delta)$ distribution truncated to $(0, \theta_i)$, θ_i being the point with lowest likelihood excluded from the running sample. A small experiment summarised by Table 1 shows that the random scheme is systematically doing twice as worse than the deterministic scheme, both for the variance and for the mean square error (MSE) $\mathbb{E}[(\hat{\mathfrak{Z}} - \mathfrak{Z})^2]$ criteria. Both quantities decreases in $\mathcal{O}(1/N)$.

Table 1. *Comparison of the deterministic and random schemes in Example 1. First row: variance, second row: MSE, when using 10^3 replications, $\delta = .1, .5, .9$ (left, centre, right) and a stopping rule chosen as $\max(L_i) < 10^{-3}\mathfrak{Z}$.*

All values are multiplied by 10^{-4}

2.2. Variations and posterior simulation

Skilling (2006) points out that nested sampling provides simulations from the posterior distribution at no extra cost: “the existing sequence of points $\theta_1, \theta_2, \theta_3, \dots$ already gives a set of

posterior representatives, provided the i 'th is assigned the appropriate importance weight $\omega_i L_i$ ". (The weight ω_i is equal to the difference $(x_{i-1} - x_i)$ and L_i is equal to φ_i .) This can be justified as follows. Consider the computation of the posterior expectation of a given function f

$$\mu(f) = \int \pi(\theta)L(\theta)f(\theta) d\theta \Big/ \int \pi(\theta)L(\theta) d\theta.$$

One can then use a single run of nested sampling to obtain estimates of both the numerator and the denominator (the latter being the evidence \mathfrak{Z} , estimated by (2)). The estimator

$$\sum_{i=1}^j (x_{i-1} - x_i)\varphi_i f(\theta_i) \tag{3}$$

of the numerator is a noisy version of

$$\sum_{i=1}^j (x_{i-1} - x_i)\varphi_i \tilde{f}(\varphi_i),$$

where $\tilde{f}(l) = \mathbb{E}^\pi[f(\theta)|L(\theta) = l]$, the (prior) expectation of $f(\theta)$ conditional on $L(\theta) = l$. This Riemann sum is, following the principle of nested sampling, an estimator of the evidence.

LEMMA 1. *Let $\tilde{f}(l) = \mathbb{E}^\pi[f(\theta)|L(\theta) = l]$ for $l > 0$, then, if \tilde{f} is absolutely continuous,*

$$\int_0^1 \varphi(x)\tilde{f}\{\varphi(x)\} dx = \int \pi(\theta)L(\theta)f(\theta) d\theta. \tag{4}$$

A proof is provided in Appendix 1. Clearly, the estimate of $\mu(f)$ obtained by dividing (3) by (2) is the estimate obtained by computing the weighted average mentioned above. We do not discuss further this aspect of nested sampling, but our convergence results can be easily extended to such estimates. In many cases, however, the distribution of the weights $\omega_i L_i$ may be quite skewed, since a certain proportion of points is simulated from the prior constrained by a low likelihood, and such approximations may thus suffer from a large variance.

2.3. Connection with slice sampling

In every situation where simulating independently from the constrained prior is feasible, a corresponding slice sampler (e.g., Robert & Casella, 2004, Chapter 8) can be implemented with at most the same computational cost (in the sense that increasing the bound l on the likelihood may induce a diminishing efficiency in computing). Thus, in settings where slice samplers are slow to converge (e.g. Roberts & Rosenthal, 1998), it is likely that nested sampling requires a large computational effort as well. Consider the following example, adapted from Roberts & Rosenthal (1999): $L(\theta) \propto \exp(-\|\theta\|)$, and $\pi(\theta) \propto \|\theta\|^{(1-d^2)/d} \mathbb{I}(\|\theta\| < 1)$, which is rotation invariant, hence $\mathfrak{Z} = \int_0^1 \exp(-\omega^{1/d}) d\omega$. Since the maximum of $\exp(-\omega^{1/d})$ is 1, if we set the stopping rule for the maximum observed likelihood to be at least .99, the number m of uniform simulations that is necessary to get under the limit $\beta_d = (-\log .99)^d \approx 10^{-2d}$ is given by $\mathbb{P}^\pi(\min(\theta_1, \dots, \theta_m) < \beta_d) \approx 0.95$, namely $m \approx 3 \cdot 10^{2d}$. Using a sequence of uniforms to reach the maximum of the likelihood is therefore delicate for $d > 3$ and the slice sampler of Roberts & Rosenthal (1999) performs more satisfactorily for such dimensions.

3. A CENTRAL LIMIT THEOREM FOR NESTED SAMPLING

We establish in the section the convergence rate and the limiting distribution of nested sampling estimates. To this effect, we decompose the approximation error as follows:

$$\begin{aligned} \sum_{i=1}^j (x_{i-1} - x_i) \varphi_i - \int_0^1 \varphi(x) \, dx &= - \int_0^\varepsilon \varphi(x) \, dx \\ &+ \left[\sum_{i=1}^j (x_{i-1} - x_i) \varphi(x_i) - \int_\varepsilon^1 \varphi(x) \, dx \right] + \sum_{i=1}^j (x_{i-1} - x_i) \{ \varphi_i - \varphi(x_i) \} \end{aligned}$$

where

1. The first term is a truncation error, resulting from the feature that the algorithm is run for a finite time. For simplicity's sake, we assume that the algorithm is stopped at iteration $j = \lceil (-\log \varepsilon)N \rceil$, so that $x_j = \exp(-j/N) \leq \varepsilon < x_{j-1}$. (More practical stopping rules will be discussed in §7.) Assuming φ , or equivalently L , bounded from above, the error $\int_0^\varepsilon \varphi(x) \, dx$ is exponentially small with respect to the computational effort.
2. The second term is a (deterministic) numerical integration error, which, provided φ' is bounded over $[\varepsilon, 1]$, is of order $O(N^{-1})$, since $x_{i-1} - x_i = O(N^{-1})$.
3. The third term is stochastic and is denoted

$$e_N = \sum_{i=1}^j (x_{i-1} - x_i) [\varphi(x_i^*) - \varphi(x_i)], .$$

where the x_i^* 's are such that $\varphi_i = L(\theta_i) = \varphi(x_i^*)$, i.e. $x_i^* = \varphi^{-1}(\varphi_i)$.

The asymptotic behaviour of e_N is characterised as follows.

THEOREM 1. *Provided that φ is twice continuously-differentiable over $[\varepsilon, 1]$, and that its first and second derivatives are bounded over $[\varepsilon, 1]$, $N^{1/2}e_N$ converges in distribution to a Gaussian distribution with mean zero and variance*

$$V = - \int_{s,t \in [\varepsilon,1]} s \varphi'(s) t \varphi'(t) \log(s \vee t) \, ds \, dt.$$

The stochastic error is of order $O_P(N^{-1/2})$ and it dominates both other error terms. The proof of this theorem relies on the functional central limit theorem and is detailed in Appendix 2.

As pointed out by one referee, it usually is more relevant in practice to consider the log-scale error, $\log \hat{\mathfrak{Z}} - \log \mathfrak{Z}$. A straightforward application of the delta-method shows that the log-error has the same asymptotic behaviour as above, but with asymptotic variance V/\mathfrak{Z}^2 .

4. PROPERTIES OF THE NESTED SAMPLING ALGORITHM

4.1. Simulating from a constrained prior

The main difficulty of nested sampling is to simulate θ from the prior distribution π subject to the constraint $L(\theta) > L(\theta_i)$; exact simulation from this distribution is an intractable problem in many realistic set-ups. As noted in § 2.3, it is at least of the same complexity as a one-dimensional slice sampler, which produces an uniformly ergodic Markov chain when the likelihood L is bounded but may be slow to converge in other settings (Roberts & Rosenthal, 1999).

241 Skilling (2006) proposes to sample values of θ by iterating M MCMC steps, using the trun-
 242 cated prior as the invariant distribution, and a point chosen at random among the $N - 1$ survivors
 243 as the starting point. Since the starting value is already distributed from the invariant distribu-
 244 tion, a finite number M of iterations produces an outcome that is marginally distributed from the
 245 correct distribution. This however introduces correlations between simulated points. Our central
 246 limit theorem applies no longer and it is unclear whether a nested sampling estimate based on
 247 MCMC converges as $N \rightarrow +\infty$, for a fixed M , or if it should merely be interpreted as an ap-
 248 proximation of an ideal nested sampling output based on independent samples. A reason why
 249 such a theoretical result seems difficult to establish is that each iteration involves both a different
 250 MCMC kernel and a different invariant distribution.

251 In addition, there are settings when implementing an MCMC move that leaves the truncated
 252 prior invariant is not straightforward. In those cases, one may instead implement an MCMC move
 253 (e.g., random walk Metropolis-Hastings) with respect to the unconstrained prior, and subsample
 254 only values that satisfy the constraint $L(\theta) > L(\theta_i)$, but this scheme gets increasingly inefficient
 255 as the constraint moves closer to the highest values of L . Obviously, more advanced sampling
 256 schemes can be devised that overcome this difficulty, as for instance the use of a diminishing
 257 variance factor in the random walk, with the drawback that this adaptive scheme requires more
 258 programming effort, when compared with the basic nested sampling algorithm.

259 In §5, we propose an extension of nested sampling based on importance sampling. In some
 260 settings, this may facilitate the design of efficient MCMC steps, or even allow for sampling
 261 independently from the (instrumental) constrained prior.

262 4.2. Impact of dimensionality

263 Although nested sampling is based on the unidimensional integral (1), this section shows that
 264 its theoretical performance typically depends on the dimension d of the problem in that the
 265 required number of iterations (for a fixed truncation error) and the asymptotic variance both grow
 266 linearly with d . A corollary of this result is that, under the assumption that the cost of a single
 267 iteration is $O(d)$, the computational cost of nested sampling is $O(d^3/e^2)$, where e denotes a given
 268 error level, as also stated in Murray's PhD thesis, using a more heuristic argument. This result
 269 applies to the *exact* nested algorithm. Resorting to MCMC usually entails some additional curse
 270 of dimensionality, although simulation studies in §7 indicate that the severity of this problem is
 271 strongly model-dependent.

272 *Example 2.* Consider the case where, for $k = 1, \dots, d$, $\theta^{(k)} \sim \mathcal{N}(0, \sigma_0^2)$, and $y^{(k)} | \theta^{(k)} \sim$
 273 $\mathcal{N}(\theta^{(k)}, \sigma_1^2)$, independently in both cases. Set $y^{(k)} = 0$ and $\sigma_0^2 = \sigma_1^2 = 1/4\pi$, so that $\mathfrak{J} = 1$
 274 for all d 's. Exact simulation from the constrained prior can be performed as follows: sim-
 275 ulate $r^2 \leq -\sqrt{2} \log l$ from a truncated $\chi^2(d)$ distribution and $u_1, \dots, u_d \sim \mathcal{N}(0, 1)$, then set
 276 $\theta^{(k)} = r u_k / \sqrt{u_1^2 + \dots + u_d^2}$.

277 Since $\mathfrak{J} = 1$, we assume that the truncation point ε_d is chosen so that $\varphi(0)\varepsilon_d = \tau \ll 1$, $\tau =$
 278 10^{-6} say, where $\varphi(0) = 2^{d/2}$ is the maximum likelihood value. Therefore, $\varepsilon_d = \tau 2^{-d/2}$ and the
 279 number of iterations required to produce a given truncation error, i.e. $j = \lceil (-\log \epsilon)N \rceil$, grows
 280 linearly in d . To assess the dependence of the asymptotic variance with respect to d , we state the
 281 following lemma, established in Appendix 3:

282 **LEMMA 2.** *In the setting of Example 2, if V_d is the asymptotic variance of the nested sampling*
 283 *estimator with truncation point ε_d , there exist constants c_1, c_2 such that $V_d/d \leq c_1$ for all $d \geq 1$,*
 284 *and $\liminf_{d \rightarrow +\infty} V_d/d \geq c_2$.*

289 This lemma is easily generalised to setups where the prior is such that the components are
 290 independent and identically distributed, and the likelihood factorises as $L(\theta) = \prod_{k=1}^d L(\theta^{(k)})$.
 291 We conjecture that V_d/d converges to a finite value in all these situations and that, for more
 292 general models, the variance grows linearly with the ‘actual’ dimensionality of the problem, as
 293 measured for instance in Spiegelhalter et al. (2002).
 294

295 5. NESTED IMPORTANCE SAMPLING

296 We introduce an extension of nested sampling based on importance sampling. Let $\tilde{\pi}(\theta)$ an
 297 instrumental prior with the support of π included in the support of $\tilde{\pi}$, and let $\tilde{L}(\theta)$ an instrumental
 298 likelihood, namely a positive measurable function. We define an importance weight function
 299 $w(\theta)$ such that $\tilde{\pi}(\theta)\tilde{L}(\theta)w(\theta) = \pi(\theta)L(\theta)$. We can approximate \mathfrak{Z} by nested sampling for the
 300 pair $(\tilde{\pi}, \tilde{L})$, that is, by simulating iteratively from $\tilde{\pi}$ constrained to $\tilde{L}(\theta) > l$, and by computing
 301 the generalised nested sampling estimator
 302
 303

$$304 \sum_{i=1}^j (x_{i-1} - x_i) \varphi_i w(\theta_i). \quad (5)$$

305
 306
 307 The advantage of this extension is that one can choose $(\tilde{\pi}, \tilde{L})$ so that simulating from $\tilde{\pi}$ under the
 308 constraint $\tilde{L}(\theta) > l$ is easier than simulating from π under the constraint $L(\theta) > l$. For instance,
 309 one may choose an instrumental prior $\tilde{\pi}$ such that MCMC steps wr.t. the instrumental constrained
 310 prior are easier to implement than wr.t. the actual constrained prior, as illustrated in §7.2. In a
 311 similar vein, nested importance sampling facilitates contemplating several priors at once, as one
 312 may compute the evidence for each prior by producing the same nested sequence (based on the
 313 same pair $(\tilde{\pi}, \tilde{L})$) and by simply modifying the weight function.
 314

315 Ultimately, one may choose $(\tilde{\pi}, \tilde{L})$ so that the constrained simulation is performed exactly.
 316 For instance, if $\tilde{\pi}$ is a Gaussian $\mathcal{N}_d(\hat{\theta}, \hat{\Sigma})$ distribution with arbitrary hyper-parameters, take

$$317 \tilde{L}(\theta) = \lambda \left((\theta - \hat{\theta})^T \hat{\Sigma}^{-1} (\theta - \hat{\theta}) \right),$$

318 where λ is an arbitrary decreasing function. Then
 319

$$320 \varphi_i w(\theta_i) = \tilde{L}(\theta_i) w(\theta_i) = \pi(\theta_i) L(\theta_i) / \tilde{\pi}(\theta_i).$$

321
 322 In this case, the x_i 's in (2) are error-free: at iteration i , θ_i is sampled uniformly over the ellipsoid
 323 that contains exactly $\exp(-i/N)$ prior mass as $\theta_i = q_i C v / \|v\|_2^{1/2}$, where C is the Cholesky
 324 lower triangle of $\hat{\Sigma}$, $v \sim N_d(0, I_d)$, and q_i is the $\exp(-i/N)$ quantile of a $\chi^2(d)$ distribution.
 325

326 The nested ellipsoid strategy seems useful in two scenarios. First, assume both the posterior
 327 mode and the Hessian at the mode are available numerically and tune $\hat{\theta}$ and $\hat{\Sigma}$. In this case,
 328 this strategy should outperform standard importance sampling based on the optimal Gaussian
 329 proposal, because the nested ellipsoid strategy uses a $O(N^{-1})$ quadrature rule on the radial axis,
 330 along which the weight function varies the most; see §7.4 for an illustration. Second, assume
 331 only the posterior mode is available, so one may set $\hat{\theta}$ to the posterior mode, and set $\hat{\Sigma} = \tau I_d$,
 332 where τ is an arbitrary, large value. §7.4 indicates that the nested ellipsoid strategy may still
 333 perform reasonably in such a scenario. Models such that the Hessian at the mode is tedious to
 334 compute include in particular Gaussian state space models with missing observations (Brockwell
 335 & Davis, 1996), Markov modulated Poisson processes (Rydén, 1994), or, more generally, models
 336 where the EM algorithm (see, e.g. MacLachlan & Krishnan, 1997) is the easiest way to compute

337 the posterior mode (although one may use Louis' 1982 method for computing the information
338 matrix from the EM output).

339
340

6. ALTERNATIVE ALGORITHMS

341
342

6.1. Approximating \mathfrak{Z} from a posterior sample

343
344

As shown in §2.2, the output of nested sampling can be “recycled” so as to provide approxi-
mations of posterior quantities. From the opposite perspective, we can recycle the output of an
MCMC algorithm so as to estimate the evidence, with no or little additional programming effort.
Several solutions are available in the literature, including Gelfand & Dey (1994), Meng & Wong
(1996), and Chen & Shao (1997). We describe below those solutions used in the subsequent
comparison with nested sampling, but first we stress that we do not pretend at an exhaustive
coverage of those techniques (see Chen et al., 2000 or Han & Carlin, 2001 for deeper coverage)
nor at using the most efficient approach (see, e.g., Meng & Schilling, 2002). In her evaluation of
Chib's (1995) method, Frühwirth-Schnatter (2004) used the solutions we present below.

352
353

6.2. Approximating \mathfrak{Z} by a formal reversible jump

354
355

We first recover Gelfand and Dey's (1994) solution of reverse importance sampling by an
integrated reversible jump, as a natural approach to compute a marginal likelihood is to use a
reversible jump MCMC algorithm (Green, 1995). However, this may seem wasteful as it involves
simulating from several models, while only one is of interest. But we can in theory contemplate
a single model \mathfrak{M} and still implement reversible jump in the following way. Consider a formal
alternative model \mathfrak{M}' , for instance a fixed distribution like the $\mathcal{N}(0, 1)$ distribution, with prior
weight $1/2$ and build a proposal from \mathfrak{M} to \mathfrak{M}' that moves to \mathfrak{M}' with probability (Green,
1995) $\rho_{\mathfrak{M} \rightarrow \mathfrak{M}'} = \{1/2g(\theta)\} / \{1/2\pi(\theta)L(\theta)\} \wedge 1$ and from \mathfrak{M}' to \mathfrak{M} with probability $\rho_{\mathfrak{M}' \rightarrow \mathfrak{M}} =$
 $\{1/2\pi(\theta)L(\theta)\} / \{1/2g(\theta)\} \wedge 1$, $g(\theta)$ being an arbitrary proposal on θ . Were we to actually run
this reversible jump MCMC algorithm, the frequency of visits to \mathfrak{M} would then converge to \mathfrak{Z} .

359
360

However, the reversible sampler is not needed since, if we run a standard MCMC algorithm
on θ and compute the probability of moving to \mathfrak{M}' , the expectation of the ratio $g(\theta)/\pi(\theta)L(\theta)$
(under stationarity) is equal to the inverse of \mathfrak{Z} :

366
367

$$\mathbb{E} [g(\theta)/\pi(\theta)L(\theta)] = \int \frac{g(\theta)}{\pi(\theta)L(\theta)} \frac{\pi(\theta)L(\theta)}{\mathfrak{Z}} d\theta = 1/\mathfrak{Z},$$

368
369

no matter what $g(\theta)$ is, in the spirit of both Gelfand & Dey (1994) and Bartolucci et al. (2006).

371
372

Obviously, the choice of $g(\theta)$ impacts on the precision of the approximated \mathfrak{Z} . When using a
kernel approximation to $\pi(\theta|y)$ based on earlier MCMC simulations and considering the variance
of the resulting estimator, the constraint is opposite to the one found in importance sampling,
namely that $g(\theta)$ must have lighter (not fatter) tails than $\pi(\theta)L(\theta)$ for the approximation

375
376

$$\widehat{\mathfrak{Z}}_1 = 1 / \frac{1}{T} \sum_{t=1}^T g(\theta^{(t)}) / \pi(\theta^{(t)})L(\theta^{(t)})$$

377
378

to have a finite variance. This means that light tails or finite support kernels (like an Epanechnikov
kernel) are to be preferred to fatter tails kernels (like the t kernel).

380
381

In the comparison in §7.3, we compare $\widehat{\mathfrak{Z}}_1$ with a standard importance sampling approximation

382
383

$$\widehat{\mathfrak{Z}}_2 = \frac{1}{T} \sum_{t=1}^T \pi(\theta^{(t)})L(\theta^{(t)}) / g(\theta^{(t)}), \quad \theta^{(t)} \sim g(\theta),$$

384

where g can also be a non-parametric approximation of $\pi(\theta|y)$, this time with heavier tails than $\pi(\theta)L(\theta)$. Frühwirth-Schnatter (2004) uses the same importance function g in both $\widehat{\mathfrak{Z}}_1$ and $\widehat{\mathfrak{Z}}_2$, and obtain similar results that $\widehat{\mathfrak{Z}}_2$ performs better than $\widehat{\mathfrak{Z}}_1$.

6.3. Approximating \mathfrak{Z} using a mixture representation

Another approach in the approximation of \mathfrak{Z} is to design a specific mixture for simulation purposes, with density proportional to $\omega_1\pi(\theta)L(\theta) + g(\theta)$ ($\omega_1 > 0$), where $g(\theta)$ is an arbitrary (fully specified) density. Simulating from this mixture offers the same complexity as simulating from the posterior, the MCMC code used to simulate from $\pi(\theta|y)$ can be easily extended by introducing an auxiliary variable δ that indicates whether or not the current simulation is from $\pi(\theta|y)$ or from $g(\theta)$. The t -th iteration of this extension is as follows, where $\text{MCMC}(\theta, \theta')$ denotes an arbitrary MCMC kernel associated with the posterior $\pi(\theta|y) \propto \pi(\theta)L(\theta)$:

1. Take $\delta^{(t)} = 1$ (and $\delta^{(t)} = 2$ otherwise) with probability

$$\omega_1\pi(\theta^{(t-1)})L(\theta^{(t-1)}) / \left\{ \omega_1\pi(\theta^{(t-1)})L(\theta^{(t-1)}) + g(\theta^{(t-1)}) \right\} ;$$

2. If $\delta^{(t)} = 1$, generate $\theta^{(t)} \sim \text{MCMC}(\theta^{(t-1)}, \theta^{(t)})$, else generate $\theta^{(t)} \sim g(\theta)$ independently from the previous value $\theta^{(t-1)}$.

This algorithm is a Gibbs sampler: Step 1 simulates $\delta^{(t)}$ conditional on $\theta^{(t-1)}$, while Step 2 simulates $\theta^{(t)}$ conditional on $\delta^{(t)}$. While the average of the $\delta^{(t)}$'s converges to $\omega_1\mathfrak{Z}/\{\omega_1\mathfrak{Z} + 1\}$, a natural Rao-Blackwellisation is to take the average of the expectations of the $\delta^{(t)}$'s,

$$\hat{\xi} = \frac{1}{T} \sum_{t=1}^T \omega_1\pi(\theta^{(t)})L(\theta^{(t)}) / \left\{ \omega_1\pi(\theta^{(t)})L(\theta^{(t)}) + g(\theta^{(t)}) \right\} ,$$

since its variance should be smaller. A third estimate is then deduced from this approximation by solving $\omega_1\hat{\mathfrak{Z}}_3/\{\omega_1\hat{\mathfrak{Z}}_3 + 1\} = \hat{\xi}$.

The use of mixtures in importance sampling in order to improve the stability of the estimators dates back at least to Hesterberg (1998) but, as it occurs, this particular mixture estimator happens to be almost identical to the bridge sampling estimator of Meng & Wong (1996). In fact,

$$\hat{\mathfrak{Z}}_3 = \frac{1}{\omega_1} \sum_{t=1}^T \frac{\omega_1\pi(\theta^{(t)})L(\theta^{(t)})}{\omega_1\pi(\theta^{(t)})L(\theta^{(t)}) + g(\theta^{(t)})} \bigg/ \sum_{t=1}^T \frac{g(\theta^{(t)})}{\omega_1\pi(\theta^{(t)})L(\theta^{(t)}) + g(\theta^{(t)})}$$

is the Monte Carlo approximation to the ratio $\mathbb{E}_\varphi[\alpha(\theta)\pi(\theta)L(y|\theta)]/\mathbb{E}_{\pi(\cdot|y)}[\alpha(\theta)g(\theta)]$ when using the optimal function $\alpha(\theta) = 1/\omega_1\pi(\theta)L(\theta) + g(\theta)$. The only difference with Meng & Wong (1996) is that, since $\theta^{(t)}$'s are simulated from the mixture, they can be recycled for both sums.

6.4. Error approximations

Usual confidence intervals can be produced on the averages $1/\widehat{\mathfrak{Z}}_1$, $\widehat{\mathfrak{Z}}_2$ and $\omega_1\widehat{\mathfrak{Z}}_3/\{\omega_1\widehat{\mathfrak{Z}}_3 + 1\}$, from which confidence intervals on the $\widehat{\mathfrak{Z}}_i$'s and error estimates are easily deduced.

7. NUMERICAL EXPERIMENTS

7.1. A decentred Gaussian example

We modify the Gaussian toy example presented in §4.2: $\theta = (\theta^{(1)}, \dots, \theta^{(d)})$, where the $\theta^{(k)}$'s are i.i.d. $\mathcal{N}(0, 1)$ and $y_k|\theta^{(k)} \sim \mathcal{N}(\theta^{(k)}, 1)$ independently, but setting all the y_k 's to 3. To simulate

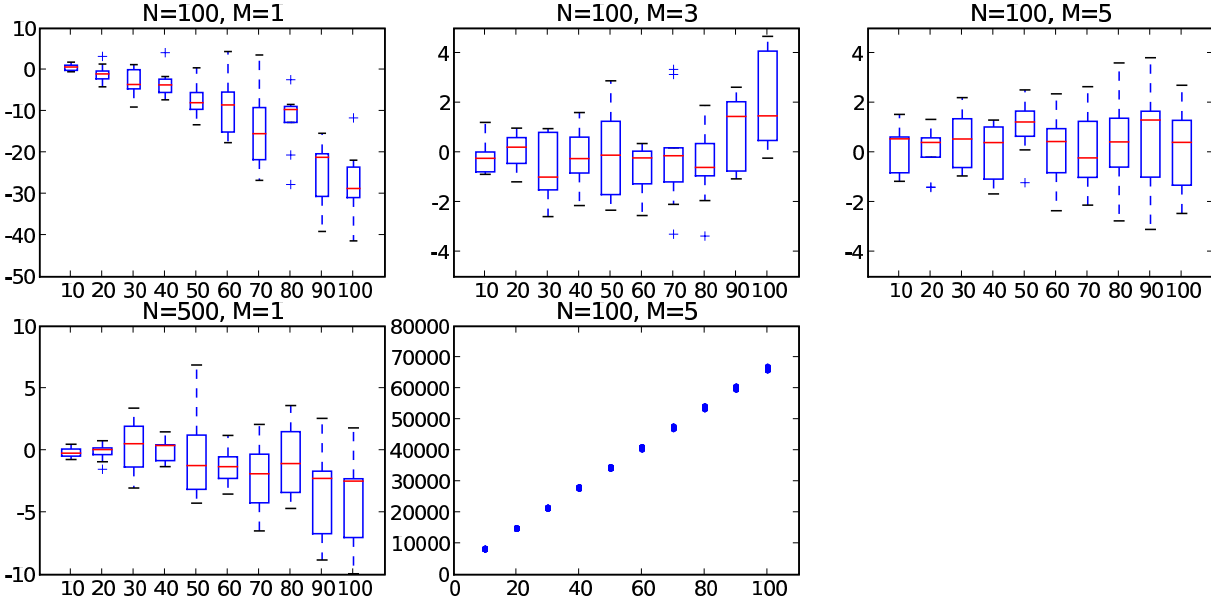

Fig. 1. Decentred Gaussian example: Box-plots of the log-relative error $\log \hat{\mathfrak{Z}} - \log \mathfrak{Z}$ versus dimension d for several values of (N, M) , and total number of iterations vs dimension for $(N, M) = (100, 5)$

from the prior truncated to $L(\theta) > L(\theta_0)$, we perform M Gibbs iterations with respect to this truncated distribution, with $M = 1, 3$ or 5 : the full conditional distribution of $\theta^{(k)}$, given $\theta^{(j)}$, $j \neq k$, is a $\mathcal{N}(0, 1)$ distribution that is truncated to the interval $[y^{(k)} - \delta, y^{(k)} + \delta]$ with

$$\delta^2 = \sum_j (y_j - \theta_0^{(j)})^2 - \sum_{j \neq k} (y_j - \theta^{(j)})^2$$

The nested sampling algorithm is run 20 times for $d = 10, 20, \dots, 100$, and several combinations of (N, M) : $(100, 1)$, $(100, 3)$, $(100, 5)$, and $(500, 1)$. The algorithm is stopped when a new contribution $(x_{i-1} - x_i)\varphi_i$ to (2) becomes smaller than 10^{-8} times the current estimate. Focussing first on $N = 100$, Figure 1 exposes the impact of the mixing properties of the MCMC step: for $M = 1$, the bias sharply increases with respect to the dimension, while, for $M = 3$, it remains small for most dimensions. Results for $M = 3$ and $M = 5$ are quite similar, except perhaps for $d = 100$. Using $M = 3$ Gibbs steps seems to be sufficient to produce a good approximation of an *ideal* nested sampling algorithm, where points would be simulated independently. Interestingly, if N increases to 500, while keeping $M = 1$, then larger errors occur for the same computational effort. Thus, a good strategy in this case is to increase first M until the distribution of the error stabilises, then to increase N to reduce the Monte Carlo error. As expected, the number of iterations linearly increases with the dimension.

While artificial, this example shows that nested sampling performs quite well even in large dimension problems, provided both prior and likelihood are close to Gaussianity.

7.2. A stochastic volatility example

We consider a simplified stochastic volatility model ($t = 1, \dots, T$):

$$h_0 = 0, \quad h_t = \rho h_{t-1} + \sigma \varepsilon_t, \quad \varepsilon_t \sim \mathcal{N}(0, 1), \quad y_t | h_t \sim \mathcal{N}\{0, \exp(h_t)\},$$

Fig. 2. Stochastic volatility example: box-plots of log-errors for different values of T (sample size), N and M

with a prior $\rho \sim \mathcal{U}([-1, 1])$, $\sigma^{-2} \sim \mathcal{G}(1/2, (0.05)^2/2)$ on the remaining components of the parameter $\theta = (\rho, \sigma, h_1, \dots, h_T)$. The data is simulated, using $\rho = 0.9$ and $\sigma = 0.05$. We implemented a MCMC strategy where realisations from the prior were generated using M steps of a fully conditional Gibbs sampler targeted at the constrained prior, the full conditionals being reasonably easy to simulate.

Figure 2 shows that, in contrast to the previous example, one gets better results with $(N, M) = (1000, 1)$ than with $(N, M) = (100, 10)$, although both scenarios cost the same. However, when we tried to increase N further to 10^5 , with $M = 1$, we obtained sensibly the same biases as for $(N, M) = (1000, 1)$ (results not shown). So this may be a case where nested sampling based on MCMC should be interpreted as a possibly good, but non necessarily convergent, approximation of the ideal nested sampling algorithm based on independent samples. On the other hand, stochastic volatility models are notoriously difficult to estimate, see e.g. Kim et al. (1998), in particular because Gibbs samplers tend to converge slowly; this difficulty may be the best explanation for this observed bias. For $T = 900$ a bias of order -4 may be small enough for model comparison purposes. (The actual log evidence is -1297.06 .)

Kim et al. (1998) propose a Beta prior as a more sensible choice for ρ . The full conditional distribution of ρ under the constraint is difficult to simulate, requiring an extra Hastings-Metropolis step. A convenient alternative is to use nested importance sampling, with $\tilde{\pi}(\theta)$ set to $\mathcal{U}[-1, 1]$, and $\tilde{L} = L$, the actual likelihood, in order to recycle the above algorithm, including the MCMC strategy, but with the weight function $w(\theta) = \pi(\theta)$ in the estimate of \mathfrak{J} .

7.3. A mixture example

Following Frühwirth-Schnatter (2004)'s study of several marginal likelihood estimates, a benchmark example is the posterior distribution on (μ, σ) associated with the normal mixture

$$y_1, \dots, y_n \sim p\mathcal{N}(0, 1) + (1 - p)\mathcal{N}(\mu, \sigma), \quad (6)$$

when p is known, for several compelling reasons:

1. Both the posterior distribution and the marginal likelihood are unavailable (unless n is small).
2. When σ converges to 0 and μ is equal to any of the x_i 's ($1 \leq i \leq n$), the likelihood diverges, as illustrated on Figure 3 by the tiny bursts in the vicinity of each observation when σ goes to 0. This represents a challenging problem for exploratory schemes such as nested sampling.

529 3. Efficient MCMC strategies have been developed and tested for mixture models since the early
 530 1990's (Diebolt & Robert, 1994; Richardson & Green, 1997; Celeux et al., 2000), but Bayes
 531 factors are notoriously difficult to approximate in this setting.

532 We designed a Monte Carlo experiment where we simulated n observations from a
 533 $\mathcal{N}(2, (3/2)^2)$ distribution, and then computed the estimates of \mathfrak{J} introduced above for the model
 534 (6). The prior distribution was a uniform both on $(-2, 6)$ for μ and on $(.001, 16)$ for $\log \sigma^2$. (The
 535 prior square is chosen arbitrarily to allow all possible values and still retain a compact parameter
 536 space. Furthermore, a flat prior allows for an easy implementation of nested sampling since the
 537 constrained simulation can be implemented via a random walk move.)

538 The two-dimensional nature of the parameter space allows for a numerical integration of $L(\theta)$,
 539 based on a Riemann approximation and a grid of 800×500 points in the $(-2, 6) \times (.001, 16)$
 540 square. This approach leads to a stable evaluation of \mathfrak{J} that can be taken as the reference against
 541 which we can test the various methods. (An additional evaluation based on a crude Monte Carlo
 542 integration using 10^6 terms produced essentially the same numerical values.) The MCMC algo-
 543 rithm implemented here is the standard completion of Diebolt & Robert (1994) and it does not
 544 suffer from the usual label switching deficiency (Jasra et al., 2005) because (6) is identifiable.
 545 As shown by the MCMC sample of size $N = 10^4$ displayed on the lhs of Fig. 3, the exploration
 546 of the modal region by the MCMC chain is satisfactory. This MCMC sample is used to compute
 547 the non-parametric approximations g that appear in the three alternatives of §6. For the reverse
 548 importance sampling estimate \mathfrak{J}_1 , g is a product of two Gaussian kernels with a bandwidth equal
 549 to half the default bandwidth of the R function density(), while, for both \mathfrak{J}_2 and \mathfrak{J}_3 , g is a product
 550 of two t kernels with a bandwidth equal to twice the default Gaussian bandwidth.

551 We ran the nested sampling algorithm, with $N = 10^3$, reproducing the implementation of
 552 Skilling (2006), namely using 10 steps of a random walk in $(\mu, \log \sigma)$ constrained by the like-
 553 lihood boundary. based on the contribution of the current value of (μ, σ) to the approximation
 554 of \mathfrak{J} . The overall number of points produced by nested sampling at stopping time is on aver-
 555 age close to 10^4 , which justifies using the same number of points for the MCMC algorithm. As
 556 shown on the rhs of Fig. 3, the nested sampling sequence visits the minor modes of the likeli-
 557 hood surface but it ends up in the same central mode as the MCMC sequence. All points visited
 558 by nested sampling are represented without reweighting, which explains for a larger density of
 559 points outside the central modal region.

560 The analysis of this Monte Carlo experiment in Figure 4 first shows that nested sampling
 561 gives approximately the same numerical value when compared with the three other approaches,
 562 exhibiting a slight upward bias, but that its variability is much higher. The most reliable approach,
 563 besides the numerical and raw Monte Carlo evaluations which cannot be used in general settings,
 564 is the importance sampling solution, followed very closely by the mixture approach of §6.3. The
 565 reverse importance sampling naturally shows a slight upward bias for the smaller values of n and
 566 a variability that is very close to both other alternatives, especially for larger values of n .

567 7.4. A probit example for nested importance sampling

568 To implement the nested importance sampling algorithm based on nested ellipsoids,
 569 we consider the arsenic dataset and a probit model studied in Chapter 5 of Gelman &
 570 Hill (2006). The observations are independent Bernoulli variables y_i such that $\Pr(y_i =$
 571 $1|x_i) = \Phi(x_i^T \theta)$, where x_i is a vector of d covariates, θ is a vector parameter of size
 572 d , and Φ denotes the standard normal distribution function. In this particular example,
 573 $d = 7$; more details on the data and the covariates are available on the book's web-page
 574 (<http://www.stat.columbia.edu/~gelman/arm/examples/arsenic>).
 575
 576

Fig. 3. Mixture example: (left) MCMC sample plotted on the log-likelihood surface in the (μ, σ) space for $n = 10$ observations from (6) (right) nested sampling sequence based on $N = 10^3$ starting points for the same dataset

Fig. 4. Mixture model: comparison of the variations of nested sampling (V1), reverse importance sampling (V2), importance sampling (V3) and mixture sampling (V4), relative to a numerical approximation of 3 (dotted line), based on 150 samples of size $n = 10, 50, 100$

The probit model we use is model 9a in the R program available at this address: the dependent variable indicates whether or not the surveyed individual changed the well she drinks from over the past three years, and the seven covariates are an intercept, distance to the nearest safe well (in 100 meters unit), education level, log of arsenic level, and cross-effects for these three variables. We assign $\mathcal{N}_d(0, 10^2 I_d)$ as our prior on θ , and denote θ_m the posterior mode, and Σ_m the inverse of minus twice the Hessian at the mode; both quantities are obtained numerically beforehand.

We run the nested ellipsoid algorithm 50 times, for $N = 2, 8, 32, 128$, and for two sets of hyper-parameters corresponding to the two scenarios described in §5. In the first scenario, we set $(\hat{\theta}, \hat{\Sigma}) = (\theta_m, 2\Sigma_m)$. The bottom row of Fig. 5 compares log-errors produced by our method (left), with those of importance sampling based on the optimal Gaussian proposal (with mean θ_m , variance Σ_m), and the same number of likelihood evaluations (as reported on the x-axis of the right plot). In the second scenario, we set $(\hat{\theta}, \hat{\Sigma}) = (\theta_m, 100 I_d)$. The top row compares log-errors produced by our method (left) with those of importance sampling, based again on the optimal proposal, and the same number of likelihood evaluations. The variance of importance

625 sampling estimates based on a Gaussian proposal with hyper-parameters $\hat{\theta}$ and $\hat{\Sigma} = 100I_d$ is
 626 higher by several order of magnitude, and is not reported in the plots.

627 As expected, the first strategy outperforms standard importance sampling, when both meth-
 628 ods are supplied with the same information (mode, Hessian), and the second strategy still does
 629 reasonably well compared to importance sampling based on the optimal Gaussian proposal, al-
 630 though only provided with the mode. For too small values of N , however, nested importance
 631 sampling is slightly biased.

632 As pointed out by one referee, results are sufficiently precise that one can afford to compute
 633 the evidence for the 2^7 possible models: the most likely model, with posterior probability 0.81,
 634 includes the intercept, the three variables mentioned above (distance, arsenic, education) and
 635 one cross-effect between distance and education level, and the second most likely model, with
 636 posterior probability 0.18, is the same model but without the cross-effect.

 errors of nested importance sampling estimates, for $N =$
 2, 8, 32, 128, compared with the log-error of importance
 sampling estimates (*right column*) based on the optimal
 Gaussian proposal, and the same number of likelihood
 evaluation (reported on the x axis of the right column
 plots). Bottom row corresponds to the first strategy (both
 mode and Hessian available), top row corresponds to the
 second strategy (only mode available).

664 8. CONCLUSION

664 We have shown that nested sampling is a valid Monte Carlo method, with convergence rate
 665 $O(N^{-1/2})$, which enjoys good performance in some applications, for example those where the
 666 posterior is approximately Gaussian, but which may also provide less satisfactory results in some
 667 difficult situations. Further work on the formal and practical assessment of nested sampling con-
 668 vergence would be welcomed. The convergence properties of MCMC-based nested sampling are
 669 unknown and technically challenging. Methodologically, efforts are required to design efficient
 670 MCMC moves with respect to the constrained prior. In that and other respects, nested importance
 671 sampling may be a useful extension. Ultimately, our comparison between nested sampling and
 672 alternatives should be extended to many more examples, to get a clearer idea of when nested

sampling should be the method of choice and when it should not. All the programs implemented for this paper are available from the authors.

ACKNOWLEDGEMENTS

The authors are grateful to R. Denny, A. Doucet, T. Loredo, O. Papaspiliopoulos, and G. Roberts, for helpful comments and discussions. Discussions with J. Skilling also helped in clarifying our understanding of the implementation of the method. The second author was supported by the 2005 project ANR-05-BLAN-0299 Adap'MC.

733 APPENDIX 1

734 *Proof of Lemma 1*

735 It is sufficient to prove this result for functions \tilde{f} that are real-valued, positive and increasing. First, the
 736 extension to vector-valued functions is trivial, so \tilde{f} is assumed to be real-valued from now on. Second,
 737 the class of functions that satisfy property (4) is clearly stable through addition. Since \tilde{f} is absolutely
 738 continuous, there exist functions f^+ and f^- , such that f^+ is increasing, f^- is decreasing, and $\tilde{f} = f^+ +$
 739 f^- , so we can restrict our attention to increasing functions. Third, absolute continuity implies bounded
 740 variation, so it is always possible to add an arbitrary constant to \tilde{f} to transform it into a positive function.

741 Let $\psi : l \rightarrow l\tilde{f}(l)$, which is a positive, increasing function and denote its inverse by ψ^{-1} . One has:

$$742 \mathbb{E}^\pi[\psi\{L(\theta)\}] = \int_0^{+\infty} P^\pi(\psi\{L(\theta)\} > l) dl = \int_0^{+\infty} \varphi^{-1}\{\psi^{-1}(l)\} dl = \int_0^1 \psi\{\varphi(x)\} dx,$$

743 which concludes the proof.

744 APPENDIX 2

745 *Proof of Theorem 1*

746 Let $t_i = x_{i+1}^*/x_i^*$, for $i = 0, 1, \dots$. As mentioned by Skilling (2006), the t_i 's are independent
 747 Beta($N, 1$) variates. Thus, $u_i = t_i^N$ defines a sequence of independent uniform $[0, 1]$ variates. A Taylor
 748 expansion of e_N gives:

$$749 e_N = \sum_{i=1}^{[cN]} (x_{i-1} - x_i) [\varphi(x_i^*) - \varphi(x_i)]$$

$$750 = \sum_{i=1}^{[cN]} (x_{i-1} - x_i) \left[\psi'(-\log x_i) (\log x_i - \log x_i^*) + O(\log x_i - \log x_i^*)^2 \right]$$

751 where $c = -\log \varepsilon$, and $\psi(y) = \varphi(e^{-y})$. Note that

$$752 S_i = N(\log x_i - \log x_i^*) = \sum_{k=0}^{i-1} (-1 - \log u_k)$$

769 is a sum of independent, standard variables, as $\mathbb{E}[\log u_i] = -1$ and $\text{var}[\log u_i] = 1$. Thus,
 770 $(\log x_i - \log x_i^*) = O_P(N^{-1/2})$, where the implicit constant in $O_P(N^{-1/2})$ does not depend on i , and

$$771 \quad N^{1/2}e_N = N^{-1/2} \sum_{i=1}^{\lceil cN \rceil} (e^{-(i-1)/N} - e^{-i/N}) S_i \left[\psi' \left(\frac{i}{N} \right) + O_P(N^{-1/2}) \right]$$

$$772 \quad = c^{1/2} \sum_{i=1}^{\lceil cN \rceil} \int_{(i-1)/N}^{i/N} e^{-t} \psi'(t) B_N \left(\frac{t}{c} \right) dt \left[1 + O_P(N^{-1/2}) \right]$$

773 since $\psi'(t) = \psi'(i/N) + O(N^{-1})$ for $t \in [(i-1)/N, i/N]$, where, again, the implicit constant in
 774 $O(N^{-1})$ can be the same for all i , as ψ'' is bounded, and provided $B_N(t)$ is defined as $B_N(t) =$
 775 $(cN)^{-1/2} S_{\lceil cNt \rceil}$ for $t \in [0, 1]$. According to Donsker's theorem (Kallenberg, 2002, p.275), B_N converges
 776 to a Brownian motion B on $[0, 1]$, in the sense that $f(B_N)$ converges in distribution to $f(B)$ for any
 777 measurable and a.s. continuous function f . Thus

$$778 \quad N^{1/2}e_N = c^{1/2} \int_0^{\lceil cN \rceil / N} e^{-t} \psi'(t) B_N \left(\frac{t}{c} \right) dt + O_P(N^{-1/2}) \xrightarrow{d} c^{1/2} \int_0^c e^{-t} \psi'(t) B \left(\frac{t}{c} \right) dt,$$

779 which has the same distribution as the following zero-mean Gaussian variate:

$$780 \quad \int_0^c e^{-t} \psi'(t) B(t) dt = \int_{\varepsilon}^1 s \varphi'(s) B(-\log s) ds.$$

781 APPENDIX 3

782 Proof of Lemma 2

783 For the sake of clarity, we make dependencies on d explicit in this section, e.g. φ_d for φ , ε_d for ε , etc.
 784 We will use repeatedly the facts that φ is nonincreasing and that φ' is nonnegative. One has:

$$785 \quad - \int_{s,t \in [\varepsilon_d, 1]} s \varphi'_d(s) t \varphi'_d(t) \log(s \vee t) dt \leq -\log \varepsilon_d \left(\int_{\varepsilon_d}^1 s \varphi'_d(s) ds \right)^2 \leq d \log(\sqrt{2}/\tau)$$

786 for $d \geq 1$, since $-\int_{\varepsilon_d}^1 s \varphi'_d(s) ds \leq -\int_0^1 s \varphi'_d(s) ds = 1$. This gives the first result.

787 Let $s_d = \varphi_d^{-1}(\alpha^d)$, for $0 < \alpha < 1$; s_d is the probability that

$$788 \quad (4\pi/d) \sum_{i=1}^d \theta_i^2 - 1 \leq -2 \log(\alpha/\sqrt{2}) - 1$$

789 assuming that the θ_i 's are i.i.d $\mathcal{N}(0, 1/4\pi)$ variates. The left-hand side is an empirical average of
 790 i.i.d. zero-mean variables. We take α so that the right-hand side is negative, i.e. $\alpha > \sqrt{2} \exp(-1/2)$.
 791 Using large deviations (Kallenberg, 2002, Chapter 27), one has $-\log(s_d)/d \rightarrow \gamma > 0$ as $d \rightarrow +\infty$, and

$$792 \quad \frac{1}{d} V_d = -\frac{1}{d} \int_{s,t \in [\varepsilon_d, 1]} s \varphi'_d(s) t \varphi'_d(t) \log(s \vee t) ds dt \geq \left(\frac{-\log s_d}{d} \right) \left(\int_{\varepsilon_d}^{s_d} s \varphi'_d(s) ds \right)^2$$

$$793 \quad \geq \left(\frac{-\log s_d}{d} \right) \left(\int_{\varepsilon_d}^{s_d} \varphi_d(s) ds + \varepsilon_d \varphi_d(\varepsilon_d) - s_d \varphi_d(s_d) \right)^2$$

$$794 \quad \geq \left(\frac{-\log s_d}{d} \right) \left(1 - \int_0^{\varepsilon_d} \varphi_d(s) ds - \int_{s_d}^1 \varphi_d(s) ds + \varepsilon_d \varphi_d(\varepsilon_d) - s_d \varphi_d(s_d) \right)^2.$$

795 As $d \rightarrow +\infty$, $-\log(s_d)/d \rightarrow \gamma$, $s_d \rightarrow 0$, $\varphi_d(s_d) = \alpha^d \rightarrow 0$, $\int_{s_d}^1 \varphi_d(s) ds \leq \varphi_d(s_d)(1 - s_d) \rightarrow 0$, and

$$796 \quad 0 \leq \int_0^{\varepsilon_d} \varphi_d(s) ds - \varepsilon_d \varphi_d(\varepsilon_d) \leq \varepsilon_d [\varphi_d(0) - \varphi_d(\varepsilon_d)] \leq \tau < 1,$$

817 by the definition of ε_d , and the squared factor is in the limit greater than or equal to $(1 - \tau)^2$.
