Abstract

Layered Neural Networks, which are a class of models based on neu-5 ral computation, are applied to the measurement of uranium enrichment. The usual methods consider a limited number of γ -ray and X-7 ray peaks, and require previously calibrated instrumentation for each sample. But since, in practice, the source-detector ensemble geometry 9 conditions are critically different, a mean of improving the above con-10 ventional methods is to reduce the region of interest; this is possible 11 by focusing on the $K_{\alpha}X$ region where the three elementary components 12 are present. The measurement of these components in mixtures leads to 13 the desired ratio. Real data are used to study the performance of neu-14 ral networks and training is done with a Maximum Likelihood Method. 15 We show that the encoding of data by Neural Networks is a promising 16 method to measure uranium ^{235}U and ^{238}U quantities in infinitely thick 17 samples. 18

¹⁹ 1 Introduction

4

In the past few years, the topic of neural computing has generated widespread interest and popularity. The popularity of this technique is due in part to the analogy between Artificial Neural Networks (ANNs) and biological neural networks. Many applications have been investigated using ANNs. We

⁰Corresponding author: e-mail vvigne@soleil.serma.cea.fr.

demonstrate here how they can be used, with photons spectra, in the particular case of uranium enrichment measurements, to determine the $\frac{^{235}U}{U_{total}}$ isotope ratio. Indeed, with modern detectors and high technology, spectral data are collected with even finer sampling and with even large precision, what imposes a perpetual need for efficient interpretation methods.

Traditional non-destructive methods for uranium enrichment use several X-29 and γ -ray peaks, mainly in the 60 to 200 keV region. Most of these methods, 30 which were developed more than 20 years ago, are based on measurements 31 of the full energy peak at 185,7 keV ([10],[5],[9],[8]). They require a prior 32 calibration of the system and the measurement conditions to be constant. 33 Other methods have been developed using several γ -ray peaks [3],[2]. In fact, 34 these latter methods require a self-calibration with a limited number of peaks, 35 making them difficult to implement. 36

³⁷ Calibration procedures and matrix effects can be avoided by first, focusing ³⁸ the spectra analysis on a limited region, called $K_{\alpha}X$ region, containing the ³⁹ main uranium components, second, by using so-called infinitely thick samples. ⁴⁰ These samples are such that any further thickness increase does not affect the ⁴¹ γ emission.

The processing of the $K_{\alpha}X$ region requires taking into account 3 elemental images corresponding to ^{235}U , ^{238}U and X-ray fluorescence. This approach requires that all the parameters for constituting each elemental image are well-known and is based on the use of external data characterising the photon spectral emission together with the detector characteristics and geometry.

It is precisely in this context that a Neural Network appears to be a useful 47 tool. In fact, the training by ANNs can be considered as a search procedure for 48 an "optimum" regression function among a set of acceptable functions using a 49 set of training examples. From the statictical point of view, ANNs belong to 50 the evaluation techniques for non-parametric models, still called *tabula rasa*. 51 ANNs, like most statistical methods, are able to process vast amounts of data 52 and to make predictions that are sometimes surprisingly accurate. This does 53 not make them intelligent in the usual sense of the word. ANNs learn in 54 much the same way that many statistical algorithms do estimation. But in 55 contrast to usual automatic spectra analysis methods, ANNs use full-parallel 56 computing, are simple to implement, not very sensitive to outliers and contain 57 nonlinearities. 58

In the following, we describe the identification method based on neural networks to quantify uranium quantities. Section II covers the experimental procedure and the neural networks technique is explained in section III. Finally, Section IV gives the outlook and conclusion.

⁶³ 2 Experimental Aspect

⁶⁴ 2.1 Preliminaries

In the case of uranium spectra, the efficiency response is difficult to establish due to insufficient number of peaks that can be used. This can be overcome by reducing the region of interest of the spectrum so that the variation in the detector efficiency is limited. This is possible by considering only the relatively complex $K_{\alpha}X$ region, which extends from 83 to 103 keV, where many peaks are superimposed (Fig. 1).

Figure 1: Principal useful X- and γ -rays in the spectral analysis of the $K_{\alpha}X$ region.

This region contains enough information to allow the determination of 235 U and 238 U and is sufficiently small for considering the efficiency as constant. It is however very complex to analyze, due to several interfering X- and γ -rays. These can be grouped as follows :

• ²³⁵U and daughters : 84.21 keV (γ^{231} Th), 89.95 keV (γ^{231} Th, $ThK_{\alpha_2}X$), 92.28 keV ($PaK_{\alpha_2}X$), 93.35 keV ($ThK_{\alpha_1}X$), 95.86 keV ($PaK_{\alpha_1}X$)

• ²³⁸U and daughters : 83.30 keV (γ^{234} Th), 92.28 keV ($PaK_{\alpha_2}X$), 92.38 keV (γ^{234} Th), 92.79 keV (γ^{234} Th), 94.65 keV ($UK_{\alpha_2}X$), 95.86 keV ($PaK_{\alpha_1}X$), 98.43 keV ($UK_{\alpha_1}X$), 99.85 keV (γ^{234} Pa)

80

• Uranium X-ray fluorescence : 94.65 keV $(K_{\alpha_2}X)$, 98.43 keV $(K_{\alpha_1}X)$.

In the standard approach, the processing of the considered region takes into account the 3 elemental images, the first corresponding to 235 U and his daughters, the second to 238 U and its daughters and the third to the uranium X-ray fluoresence spectrum. These images are then represented by mathematical expressions taking into account the shapes of the X-ray (Voigt profile) and γ -ray ⁸⁶ (Gaussian) peaks, their energies, and intensities. The determination is then
⁸⁷ carried out conventionally with a least squares method, like the MGA-U code
⁸⁸ [1]. The final enrichment is obtained by correcting for the presence of ²³⁴U
⁸⁹ with the 120.9 keV peak.

⁹⁰ 2.2 Experimental protocol

Six uranium oxide standards with different enrichments, from 0.7 to 9.6%, and infinite thickness were counted several times by γ -ray spectrometry to test the neural procedure. These were bare cylindrical pellets, with certified enrichments and their main characteristics are presented in Table 1.

$egin{array}{c} { m Diameter(cm)} imes { m Height(cm)} \end{array}$	$rac{U}{O}$ ratio ($g.g^{-1}\%$)	$egin{array}{llllllllllllllllllllllllllllllllllll$	${235 U \over 235 U + 238 U}$ ratio $(g.g^{-1}\%)$
$1,\!30 \times 2,\!00$	88,00	$0,7112 \pm 0,004$	0,7112
$1,30 \times 1,90$	88,00	$1,416 \pm 0,001$	1,416
$0,80 \times 1,10$	88,00	$2,785 \pm 0,004$	2,786
$0,80 \times 1,02$	87,96	$5,\!111 \pm 0,\!015$	$5,\!112$
$0,80 \times 1,00$	87,98	$6,\!222 \pm \! 0,\!018$	6,225
$0,92 \times 1,35$	87,90	$9,548 \pm 0,04$	9,558

Table 1: Characteristics of UO_2 standards

The Ge(HP) planar detector used in the measurement system had the 95 following specification : surface, 2.00 cm^2 ; thickness, 1.00 cm; FWHM, 190 96 eV at 6 keV and 480 eV at 122 keV. All the measurements were made under 97 the same conditions, i.e. with 0.05 keV per channel and a distance between 98 source and detector-window of 1.1 cm. Ten 20000-s. spectra for each standard 99 pellet were analysed by our procedure. The ^{234}U concentration is relatively 100 low, although a $\frac{^{234}U}{^{235}U}$ mass ratio varying from 0,5 to 1,1%, depending on the 101 pellet, was determined by γ -ray spectrometry by using both the 53.2 and the 102 120.9 keV peaks for ^{234}U and the 185.7 keV peak for ^{235}U . 103

In short, 65 sets of experimental data from real-life experiments were prepared using the concentrations given in Table 1, and are illustrated in Fig. 2.

¹⁰⁷ **3** Layered Neural Network and Training method

¹⁰⁸ 3.1 Using Neural Networks

The purpose of this section, rather than the presentation of the neural network theory, is to present the place of the connectionnist approach in γ -spectrometry

Figure 2: 3D-Representation of the UO_2 spectra set.

problems. Neural Networks are non-linear black-box model structures, to be 111 used with conventional parameter estimation methods. Most details and basic 112 concepts are clearly described in a paper to be published [12]. ANN consists 113 of a large number of neurons, i.e. simple linear or nonlinear computing el-114 ements, interconnected in complex ways and often organized into layers [6]. 115 The collective or parallel behaviour of the network is determined by the way 116 in which the nodes are connected and the relative type and strengh (excitory 117 or inhibitory) of the interactions among them [7]. 118

The objective of ANNs is to construct a suitable model which, when applied to a ^{235}U enrichment spectrum, produces an output, y, which approximates the exact uranium enrichment ratio. The principal idea of the connectionist approach is to substitute a neural model and the learning procedure of the network for classical fitting algorithms, which make use of complex mathematical algorithms, generally based on the separation of a given curve, associated to each individual peak, plus a background.

An exemple of multi-layer network is given in Fig. 3.a. The notation 126 convention is such that the square represents a computational unit into which 127 the input variables x_j 's are fed and multiplied by the respective weights ω_j 's. 128 The fundamental processing element of an ANN is a node (Fig. 3.b). Nodes are 129 analogous to neurons in biological systems. Each node has a series of weighted 130 inputs, ω_i , which may be either an external signal or the output from other 131 nodes. The sum of the weighted inputs is transformed with a linear or a 132 non-linear transformation function (often the logistic function $f(x) = \frac{1}{1+e^{-x}}$). 133 In the statistical context, this standard Neural Network called Multi-Layered 134 Perceptron (*MLP*), is analogous to the Multivariate Nonlinear Regression. 135

Figure 3: (a) MLP 3-5-1 with nonlinear threshold and (b) schematic representation of a node in an ANN.

Transmission of information between units of two neighboring layers is performed through oriented links. These links are level-headed by connection weights. The essential of the construction is as follows :

input layer : this layer contains input units. Each unit receives input variables, selected through a free parameters reduction procedure.

hidden layer : this layer acts as an array of feature detectors picking up features without regard to position. The information coming to the input units is coded on the hidden layer into an internal representation Thus, the input-layer units contribute to the input of each second-layer unit. It is fully-connected to the output.

146 147 • output layer : it applies a sigmoïd activation function to the weighted sum of the hidden outputs.

The role of the hidden layer is fundamental. A network without hidden units will be unable to perform the necessary multi-input multi-output mappings, in particular with non-linear problems. Input pattern can always be encoded, if there are enough hidden units, in a form so that the appropriate output pattern can be generated from the corresponding input pattern.

The training data are denoted by $\chi = (\mathbf{x}, \mathbf{y}^{\mathbf{d}})_{t=1}^{N}$ where N is the number of observations and \mathbf{x} is the feature vector corresponding to the t^{th} observation. The expected response $\mathbf{y}^{\mathbf{d}} = (y_1, y_2, \dots, y_M)$ is related to the inputs $\mathbf{x} = (x_1, x_2, \dots, x_N)$ according to

$$\mathbf{y} = \phi(\mathbf{x}, \omega),\tag{1}$$

¹⁵⁷ where ω are the *connection weights*.

The approximation results are non-constructive, and in practice the weights have to be chosen to minimize some fitting criterion, e.g. least squares

$$J(\omega) = \frac{1}{2} \sum_{p}^{N} (\mathbf{y}_{p}^{\mathbf{d}} - \phi(\mathbf{x}_{p}, \omega))^{2}, \qquad (2)$$

with respect to all the parameters, where $\mathbf{y}_p^{\mathbf{d}}$ is the target for the *p*th example pattern. The minimization has to be done by some numerical search procedure. This is called *nonlinear optimization*. The parameter estimate is defined as the minimizing argument :

$$\hat{\omega} = \operatorname{argmin}_{\omega} J(\omega) \tag{3}$$

Most efficient search routines are based on local iteration along a "downhill" direction from the current point. We then have an iterative scheme of the following kind :

$$\hat{\omega}^{(i+1)} \leftarrow \hat{\omega}^{(i)} - \eta \times \frac{\partial J}{\partial \omega^{(i)}} \tag{4}$$

where $\hat{\omega}^{(i)}$ is the parameter estimate after iteration number $i, \eta (> 0)$ is the step size and $\frac{\partial J}{\partial \omega^{(i)}}$ an estimate of the gradient of $J(\omega^i)$. The practical difference between this device and the statistical version lies in the way the training data are used to dictate the values for ω . It turns out that there are 2 main aspects to the processing : (1) specifying the architecture of a suitable network, (2) training the network to perform well with reference to a training set.

¹⁷³ 3.2 Application of the ANN

To check that this method was general and reliable, we have applied it to 65 sets of experimental data from real-life experiment : five ^{235}U -pure idealized spectra, and ten of each precited standard (see Table 1). Each spectrum contains 4096 points. The computations of the spectra are compared on two regression models: the **MLP MODEL** (Fig. 3), where the inputs are spectral data, and the **MIXTURES OF EXPERTS MODEL** (Fig. 4) [4] where the inputs are the enrichment values.

The specifications for the networks created for the calibration of the simulated data are listed in Table 2. They were found to be optimal according to the rigourous methodology described in [12], for low prediction bias. The choice of the right architecture is mainly intuitive and implies arbitrary decisions. But an attempt to apply ANN directly fails due to dimensionability. In acccordance with this, the dimension of the input vector has been reduced dramatically by Principle Components Analysis (PCA), leading to the adequate

Figure 4: Mixtures of Experts model.

reduction of weights emerging from the first layer of the ANN.

parameter	MLP 6-3-1	MLP 3-5-1	Mixtures of Experts
Type of input	spectral data	spectral data	enrichment value
input nodes	6	3	1
hidden node	3	5	1050
output node	1	1	210
learning rule	BP	BP	Maximum Likelihood
input layer transfer function	linear	linear	linear
hidden layer transfer function	sigmoïdal	sigmoïdal	sigmoïdal
output layer transfer function	linear	linear	exponential

 Table 2: ANNs specifications and parameters

The MLP MODEL, depicted in Fig. 3, consists of an input layer of 6 or 3 189 units leading up through one layer of hidden units to an output layer of a single 190 unit that corresponds to the desired enrichment. This network represents a 191 poor parametrized model, but the training dataset $(\mathbf{x}; \mathbf{y}^{(d)})_{t=1}^{65}$ was small. The 192 network is initialized with random weights and trained. For each pattern, the 193 bias, Eq. 2, is evaluated. This quantity decreases rapidly (Fig. 5) in the 194 beginning, and the training is stopped when the network reaches a minimum 195 error on the training set, because this is an efficient way to avoid overfitting. 196 After 32 000 successful training passes, the bias rate range from -0.05 to 0.04%197 for the 6-3-1 net (from -0.031 to 0.061% for the 3-5-1 net). 198

In the case of mixtures of experts (MEX), each item is associated with a vector of measurable features, and a target $\mathbf{y}^{\mathbf{d}}$ which represents the enrichment. The network receives the input \mathbf{x} and creates the output vector \mathbf{y} as

Figure 5: Sum of squares of bias on the training set for MLP architectures

a predicted value of the unknown y^d . This model consists of 210 indepen-202 dant fully-connected networks (Fig. 4): One expert is put for one channel of 203 the $K_{\alpha}X$ region, each expert being an observer, trying to find a "signal" due 204 to radioactive decay in a large amount of noise, the variance of each count 205 being proportional to the level and thus depending on the enrichment of a 206 particular sample and on the background level of the particular observation. 207 A cooperation-competition procedure driven by a supervisor between the ex-208 pert's outputs leads to the choice of the most appropriate concentration. 209

Let $\mathbf{y_1}, \mathbf{y_2}, \ldots$ denote the output vectors of the experts, and g_1, g_2, \ldots the supervisor output units, then the output of the entire architecture, \mathbf{y} , is $\mathbf{y} = \sum_{i=1}^{210} g_i \mathbf{y_i}$. The supervisor decides whether expert *i* is currently applicable or not. The winning expert is the network with the smallest bias $(\mathbf{y^d} - \mathbf{y_i})$.

²¹⁵ 4 Discussion of the Results using ANN

As the initial base included only 65 examples, we wanted to keep a maximum of examples for the training base. Redundances in the data-set enrichments present one main advantage : as we measure more than one response for each case, information from all the measured responses can be combined to provide more precise parameter estimation and to determine a more realistic model.

In all simulations, the measure of the system's performance is the Mean Square Error. The bias rates obtained by using MEX are benchmarked against the results obtained by using MLPs in Table 3 and on Fig. 5 and Fig. 7. The Fig. 5 shows the learning curves (i.e. the learning performances) for the two MLP networks using a random training procedure. The horizontal axis gives the number of epochs ; the vertical axis gives the Mean Square Errors value (MSE). Clearly, the 6-3-1 network learned significantly faster than the 3-51. This difference can be explained by the information gain of the 6-inputs
network vs the 3-inputs network.

Declared enrich- ment	MLP 3-5-1	MLP 6-3-1	MEXs
0.711%	0.691 - 0.723	0.700 - 0.720	0.702 - 0.710
1.416%	1.394 - 1.426	1.406 - 1.435	1.406 - 1.416
2.785%	2.732 - 2.822	2.762 - 2.799	2.784 - 2.790
5.111%	5.066 - 5.148	5.089 - 5.132	5.112 - 5.136
6.122%	6.105 - 6.162	6.117 - 6.133	6.088 - 6.112
9.548%	9.531 - 9.570	9.541 - 9.550	9.542 - 9.552

Table 3: Ranges of calculated Enrichments with MLP and MEX

The Fig. 6 concerns the Multi-Expert model. The plotted points are pre-230 dicted enrichment value (one for each of the 210 experts) when a $5.111\% - {}^{235}U$ 231 spectrum is presented to the MEX model. The credit assignment procedure 232 on these 210 contributions is supervised to produce a final estimation. In the 233 right most column of Table 3, the final predicted values of the simulations with 234 MEX can be seen. Compared with the MLPs, this shows that MEX method is 235 really reliable; for example, the bias between the predicted and the calculated 236 2.785% enrichments range from 2.784 to 2.790%. As noted above, after 32 237 000 successful training passes, the larger bias happens for 5.111 and 6.122%238 enrichments. This relative lack of precision can be ascribed to the small size 239 of the training dataset. 240

Figure 6: Example of enrichment value (at 5,785 %) predicted by the Mixtures of Experts

Fig. 7 compares the results of the three models. The bias between the predicted and the desired enrichments is plotted for each of the 65 samples.

The darkest line is put for the MEX. The results suggest that the strong dispersion of the bias with MLP is significantly attenuated when MEX is applied. This judgement must be moderated for the 6.122-enrichment-ratio samples. A comparison of the absolute bias curves suggest that, among of the three systems studied, the Mixtures of Experts is capable of showing the most robust performance.

Figure 7: Absolute bias in the enrichment estimation

In fact, the modular approach presents three main advantages on the MLP 249 models: it is able to model behavior, it learns faster than a global model 250 and the representation is easier to interpret. The modular architecture takes 251 advantage of task decomposition, but the learner must decide which variables 252 to allocate to the networks. This method is, at the same time, very general 253 and very specific. It is very general in the sense that no hypothesis is made 254 on the aspect of the spectra : it does not depend on whether the spectra are 255 well resolved or not, whether they are very likely or not, whether you select 256 most significative areas of spectrum only (MLP models) or a global part of the 257 spectrum (MEX model). But, at the same time, the method is very specific 258 because the ANN must learn representative spectra of the family spectra to 259 identify. Furthermore, other tests proved to us that ANNs are resistant to 260 noise. Presently, we must put the blame on the excessively short size of the 261 training dataset. 262

263 5 Conclusion

The simulation studies on UO_2 real spectra have shown that Neural Networks can be very effective to predict ${}^{235}U$ enrichment. They appear to be useful when a fast response is needed with a reasonnable accuracy, when no hypoth-

esis is made on the aspect of the spectra or when no definite mathematical 267 model can be assigned *a priori*. The resistance to noise is certainly one of the 268 most powerful characteristics of this method. Final network with connections 269 and weighting functions could be easily implemented using commercial digi-270 tal processing hardware. The good results obtained show that this method 271 can be considered at the state of art to produce quantitative estimates of 272 the concentrations of isotopic components in mixtures with fixed experimental 273 conditions: they may be better than those obtained with standard methods 274 in similar cases. This method has also been already successfully used in an 275 X-ray fluorescence application [11]. 276

There is no single learning procedure which is appropriate for all tasks. It is of fundamental importance that special requirements of each task are analyzed and that appropriate training algorithms are developed for families of tasks. However, an efficient use of the networks requires as careful as possible analysis of the problem, an analysis that is often ignored by impatient users.

282 Acknowlegments

The authors are extremely grateful to the staff of SAR and LPRI, and in particular J.L. Boutaine, A.C. Simon and R. Junca for their support and useful discussions during this work. V. Vigneron wishes to thank C. Fuche from CREL for her support in this research.
