HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

11 **Abstract**

12 The fate of benthic bacterial biomass in benthic food webs is a topic of major importance
13 but poorly described. This paper describes an alternative method for evaluation of bacterial
14 grazing rate by meiofauna and macrofauna using bacteria pre-enriched with stable isotopes.
15 Natural bacteria from the sediment of an intertidal mudflat were cultured in a liquid medium
16 enriched with $^{15}\text{NH}_4\text{Cl}$. Cultured bacteria contained 2.9 % of ^{15}N and were enriched
17 sufficiently to be used as tracers during grazing experiments. Cultured-bacteria presented a
18 biovolume ($0.21 \mu\text{m}^3$) and a percentage of actively respiring bacteria (10 %) similar to those
19 found in natural communities. The number of Operational Taxon Units found in cultures
20 fluctuated between 56 and 75 % of that found in natural sediment. Despite this change in
21 community composition, the bacterial consortium used for grazing experiments exhibited
22 characteristics of size, activity and diversity more representative of the natural community
23 than usually noticed in many other grazing studies. The bacterial ingestion rates of three
24 different grazers were in the range of literature values resulting from other methods: 1149
25 $\text{ngC ind}^{-1} \text{h}^{-1}$ for the mud snail *Hydrobia ulvae*, $0.027 \text{ ngC ind}^{-1} \text{h}^{-1}$ for the nematode
26 community, and $0.067 \text{ ngC ind}^{-1} \text{h}^{-1}$ for the foraminifera *Ammonia tepida*. The alternative
27 method described in this paper overcomes some past limitations and it presents interesting
28 advantages such as short time incubation and *in situ* potential utilisation.

30 Bacteria, grazing, sediment, stable isotope, tracer

31 **Introduction**

32 Development of improved methods for measuring bacterial abundance and production
33 have radically changed the perception of the role of bacteria in pelagic marine ecosystems.

34 Bacteria are known to play a major role in organic matter degradation and regeneration of
35 nutrients. Moreover the “microbial loop” model (e.g. Azam et al. 1983) considers bacteria as
36 a “link” more than a “sink”, increasing the ratio of primary production available for higher
37 trophic levels. Therefore, bacteria appear to play a major role in pelagic foods web models
38 (e.g. Vézina and Savenkoff 1999).

39 Bacterial abundance in marine soft sediments is relatively constant, around 10^9 cells.ml⁻¹
40 porewater (Schmidt et al. 1998), being a thousand times more abundant than in pelagic
41 systems. Moreover, high rates of production have been measured in aquatic sediments (e.g.
42 van Duyl and Kop 1990). These findings have driven a debate on the fate of bacteria in
43 benthic food webs. Due to technical limitations, studies dealing with benthic bacterivory are
44 not as developed as pelagic ones (Kemp 1990).

45 Pelagic bacteria are mainly grazed by protozoa (e.g. Sherr and Sherr 1994) and a similar
46 pattern was expected in benthic systems (van Duyl and Kop 1990; Bak et al. 1991; Hondeveld
47 et al. 1994). Nevertheless, numerous authors consider the bacterial grazing by benthic ciliates
48 and flagellates as insignificant (Alongi 1986; Kemp 1988; Epstein and Shiaris 1992; Epstein
49 1997). Depending on the studies, meiofauna grazing is considered either as (i) high enough to
50 structure microbial communities (Montagna 1984b), (ii) using 3 % of bacterial production
51 (van Oevelen et al. 2006a), or (iii) negligible (Epstein and Shiaris 1992). Data on macrofaunal
52 grazing rates are not less variable than on meiofaunal ones. In a synthesis, Kemp (1990)
53 asserted that bacteria density is not high enough to play a major role in macrobenthos diet.
54 These contrasting conclusions probably reflect the use of different methods. In conclusion, it
55 appears that drawing a general view of the role played by microfauna, meiofauna and
56 macrofauna in bacterial grazing is presently difficult (Kemp 1990).

57 Most of the benthic studies on trophic process employ tracers. Labels can be added directly
58 to sediment. In such a situation, bacteria incorporate labels and are simultaneously grazed by

59 predators (Montagna 1995; van Oevelen et al. 2006a; van Oevelen et al. 2006b). This
60 technique minimizes disturbance of the spatial distribution and metabolism of grazers and
61 bacteria (Carman et al. 1989). Nevertheless, only a small part of the bacterial assemblages
62 takes up detectable quantities of labels (Carman 1990b). Moreover, the main drawback to this
63 method is that a large part (up to 83 % in Montagna & Bauer (1988)) of the total labels uptake
64 may be attributable to processes other than grazing. Grazers may become labelled by
65 absorption and adsorption of dissolved organic matter (DOM) (Montagna 1984a) or by uptake
66 of labels by non-prey microorganisms associated with grazers (e. g. epicuticular or gut
67 microorganisms) (Carman 1990a).

68 To reduce this bias, microbial prey can be prelabelled with fluorescent products, or
69 isotopes either stable or radioactive. Fluorescent Labelled Bacteria (FLB) with monodispersed
70 FLB or whole-sediment staining methods are used mainly to assess grazing activity of small
71 predators like flagellates and ciliates (Novitsky 1990; Epstein and Shiaris 1992; Hondeveld et
72 al. 1992; Starink et al. 1994; Hamels et al. 2001). Meiofauna studies using FLB are seldom
73 because FLB detection is difficult and time consuming in large sized grazers. Consequently,
74 only a small number of specimens can be examined preventing detection of inter individual
75 variations in grazing rate. Therefore, grazers like nematodes are able to discharge various
76 digestive enzyme to realise extracorporeal hydrolyse of food (Riemann and Helmke 2002). In
77 such a case, pre-digested FLB ingested are impossible to detect in grazers. Nevertheless
78 bacterivory levels by foraminifera (Langezaal et al. 2005) and nematodes (Epstein 1997) were
79 assessed using FLB.

80 Bacterivory assessment by the way of adding radioactive or stable isotope to sediment was
81 performed on meiofauna and macrofauna (e. g. Montagna 1984b; Sundback et al. 1996; van
82 Oevelen et al. 2006a; van Oevelen et al. 2006b).

83 Bacterivory assessment using prelabelled bacteria was performed with radioactive isotopes
84 (Rieper 1978; Carman and Thistle 1985). To our knowledge, the use of stable isotopes on
85 prelabelled bacteria has never been performed until present. Compared to radioactive
86 isotopes, bacteria enriched with stable isotopes are more convenient to use, since they can be
87 used *in situ* without negative environmental effects and legal restrictions. This method will
88 help investigators who are limited by radioactive material prohibition.

89 The aim of this paper is to describe a method using ^{15}N stable isotope to prelabel bacteria
90 in the view to assess bacterivory of large size benthic organisms (meiofauna and macrofauna).
91 Experiments were performed mainly to assess the validity of this method, taking in
92 consideration size, diversity, and activity of the prelabelled bacteria in order to be close to
93 natural population parameters. The method was applied to 3 grazers from an intertidal mudflat
94 in order to appreciate its potential generalization: one mollusc *Hydrobia ulvae*, a nematode
95 community and the foraminifera *Ammonia tepida*.

96 **Material and methods**

97 *Bacterial culture*

98 Superficial sediment (1 cm) was collected from the Brouage intertidal mudflat located in
99 the eastern part of Marennes-Oléron Bay (45°55N, 1°06W) on the Atlantic Coast of France.
100 One ml of this sediment was added to 20 ml of bacterial liquid culture medium and kept in the
101 dark at 13°C during 24 hours. The liquid bacterial culture medium was composed of: peptone
102 3 g.l⁻¹ (BioRad), yeast extract 1 g.l⁻¹ (BioRad), $^{15}\text{NH}_4\text{Cl}$ 1 g.l⁻¹ (99 % ^{15}N -enriched NH_4Cl
103 CortecNet); sodium glycerophosphate 0.025 g.l⁻¹ and sequestren Fe 6 g.l⁻¹. It was completed
104 with 0.2 μm filtered distilled water (500 ml) and 0.2 μm filtered sea water (500 ml) at pH 7.4.
105 The first culture was subcultured during 24 hours under the same incubation conditions in the
106 view to reach approximately 2×10^9 cells.ml⁻¹. Bacteria were rinsed (i.e. separated from

107 culture medium) by the means of 3 centrifugations (3500 g, 10 min, 20°C) in 0.2 µm filtered
108 sea water, then frozen in liquid nitrogen and kept frozen (-80°C) until grazing experiments.

109 The bacteria $\delta^{15}\text{N}$ was measured on an Eurovector Elemental Analyser coupled with an
110 Isotope Mass Ratio Spectrometer (Isoprime, Micromass). Nitrogen isotope composition is
111 expressed in the delta notation ($\delta^{15}\text{N}$) relative to air N_2 : $\delta^{15}\text{N} = [({}^{15}\text{N}/{}^{14}\text{N})_{\text{sample}} /$
112 $({}^{15}\text{N}/{}^{14}\text{N})_{\text{reference}} - 1] \times 1000$. Rinsing efficiencies were tested using bacteria cultured in the
113 medium previously described with non-enriched NH_4Cl . These bacteria were killed by
114 formalin (2 %), placed in the ^{15}N -enriched culture medium previously described, harvested by
115 the means of 3 centrifugations (3500 g, 10 min, 20°C) before isotope ratio measurement.

116 *Cultured bacteria size*

117 Size of bacteria from original sediment and cultures were measured. For sediment samples,
118 particle-associated bacteria were detached by pyrophosphate (0.01M) and sonication. Bacteria
119 were stained using 4,6-diamidino-2-phenylindole dihydrochloride (DAPI) (2500 µg.l⁻¹) and
120 filtered onto 0.2 µm Nucleopore black filters (Porter and Feig 1980).

121 Length (L) and width (2r) of each bacteria was determined by a computer-assisted image
122 analysis (AxioVision Release 4.3) with an epifluorescence microscope (AxioSkop 2 mot plus
123 – Zeiss) equipped with a charge-coupled device camera (AxioCam MRc5 – Zeiss). Bacterial
124 biovolumes (V) were calculated for cultured bacteria (N = 1981) and natural bacteria (N =
125 1806) as follows: $V = \pi r^2 \cdot (L - 2/3 r)$ (Fuhrman 1981).

126 *Cultured bacteria activity*

127 Frozen aliquots of cultured bacteria were thawed and immediately incubated with 5-cyano-
128 2,3-ditoyl tetrazolium chloride (CTC) (final concentration of 5 mM). After 2, 3 and 5 hours of
129 incubation, experiments were stopped with formalin (2%) and stored at 4°C. Bacterial
130 samples were processed as described above for the DAPI staining in order to simultaneously
131 count total cells (UV excitation) and active cells (green excitation) on same slide.

132 *Cultured bacteria diversity*

133 The bacterial diversity of original sediment and culture aliquots was assessed. The DNA
134 was extracted using an Ultraclean Soil DNA Kit (MO BIO, Ozyme) for sediment samples and
135 a QIAamp DNA Mini Kit (Qiagen) for cultures. Bacterial 16S rRNA gene fragments of about
136 520 bp (the V6-V8 regions of 16r DNA (Gelsomino et al. 1999)) were amplified by PCR
137 using primers 968fGC (5'-AACGCGAAGAACCTTAC-3'[with GC clamp 5']) and 1401r
138 (5'-CGGTGTGTACAAGGCC-3').

139 PCR products (300 ng) were loaded onto polyacrilamide gel (8% w/v, 7M urea) in TAE 1
140 X buffer. Electrophoresis was processed under a constant voltage of 68 V, during 17 h, with a
141 thermal gradient from 66 to 69.7°C increasing at the rate of 0.2°C h⁻¹ (Dcode™ System:
142 Biorad). The gel was stained with 0.5 µg.ml⁻¹ Gelstar (BMA) in 1.25× TAE buffer during 30
143 min and checked through a UV transilluminator system (Versa Doc (Bio-Rad)) equipped with
144 a camera. Temperature Gradient Gel Electrophoresis (TGGE) banding patterns were
145 automatically calculated by the Bionumerix software (Applied Biomaths, Koutrai, Belgium)
146 using the Dice coefficient (DC), without band weighing by both the complete linkage and
147 unweighted pair group method with arithmetic mean (UPGMA) algorithms (threshold of 1%).

148 *Grazing experiments*

149 The first centimetre of sediment was collected from a square meter patch during ebb tide
150 from the Brouage intertidal mudflat (France) on March 13, 2006. It was sieved on 500 µm,
151 200 µm and 50 µm in order to concentrate respectively *H. ulvae*, *A. tepida* and nematodes.
152 Choice of these organisms was driven by their high natural abundance in the study area. Each
153 type of grazer was placed in individual microcosms. Seventeen handpicked specimens of *H.*
154 *ulvae* were placed in polypropylene Petri dishes (diameter 9 cm). For the foraminifera and
155 nematode experiments, 1 ml of the fraction remaining on the 200 µm and on the 50 µm mesh
156 sieves respectively were placed in 100 ml Pyrex beakers. Each experiment was carried out in

157 triplicate, along with triplicate controls. Control samples were frozen (-80°C) during 12 hours
 158 in order to kill grazers before thawing.

159 Sediment that passed through the 50 µm mesh was mixed with ¹⁵N enriched bacteria.
 160 Abundance of sediment and cultured bacteria were counted using the methods previously
 161 described. This slurry containing 1.05×10^9 bacteria ml⁻¹ and ¹⁵N enriched bacteria were
 162 twice as abundant as natural ones. Seventeen ml of this slurry were placed in *H. ulvae*
 163 microcosms and 4 ml were placed in nematode and foraminifera microcosms. Grazing
 164 incubations were run in the dark at 20°C. Incubations were stopped by freezing the
 165 microcosms at -80°C.

166 *H. ulvae* were separated by hand from their shell and all specimens of each microcosm
 167 were pooled and homogenised using a Potter-Eveljhem. Nematodes were extracted from
 168 sediment using ludox (Heip et al. 1985). Approximately 700 nematodes were randomly
 169 handpicked from each sample. Foraminifera were stained with rose Bengal in order to identify
 170 living specimens. As Rose Bengal is an organic compound, it could affect isotopic
 171 composition but control experiments were also stained in order to take this bias into account.
 172 For each sample, 150 specimens of *A. tepida* were picked individually and cleaned of any
 173 adhering particles.

174 $\delta^{15}\text{N}$ of grazers was determined using the technique described above. Incorporation of ¹⁵N
 175 is defined as excess (above background) ¹⁵N and is expressed in terms of specific uptake (*I*)
 176 (gN ind⁻¹). *I* was calculated as the product of excess ¹⁵N (*E*) and biomass of N per grazer. *E* is
 177 the difference between the fraction ¹⁵N in the background ($F_{\text{background}}$) and in the sample
 178 (F_{sample}): $E = F_{\text{sample}} - F_{\text{background}}$, where $F = {}^{15}\text{N} / ({}^{15}\text{N} + {}^{14}\text{N}) = R / (R + 2)$ and *R* = the
 179 nitrogen isotope ratio. For the $F_{\text{background}}$, we used control values measured with killed grazers
 180 (frozen). *R* was derived from the measured $\delta^{15}\text{N}$ values as: $R = ((\delta^{15}\text{N}/1000)+1) \times R_{\text{airN}_2}$ with
 181 $R_{\text{airN}_2} = 7.35293 \times 10^{-3}$ (Mariotti 1982). The uptake of bacteria (gC ind⁻¹ h⁻¹) was calculated as

182 Uptake = $(I \times (\% C_{\text{enriched bacteria}} / \% N_{\text{enriched bacteria}})) / (F_{\text{enriched bacteria}} \times \text{incubation time})$. This
183 uptake was multiplied by the ratio between the abundance of total and enriched bacteria,
184 determined from DAPI counts. Uptake ($\text{gC}_{\text{bacteria}}/\text{h}/\text{gC}_{\text{grazer}}$) were obtained by dividing uptake
185 of bacteria ($\text{gC}/\text{ind}/\text{h}$) by grazer mean weight (gC/ind).

186 **Results**

187 *Characteristics of enriched bacteria*

188 Bacteria cultured in a liquid medium with a 18 mM $^{15}\text{NH}_4\text{Cl}$ subsequently centrifuged to
189 remove unincorporated label were found to contain $2.88 \pm 0.03 \% ^{15}\text{N}$. Bacteria killed by
190 formaldehyde before being placed in the same culture medium and centrifuged, contained
191 $0.028 \% ^{15}\text{N}$. Cultured bacteria were enriched enough to allow their detection in the three
192 studied grazers (Tab. 1). Bacterial abundance was not affected by the liquid nitrogen freezing
193 process.

194 Cell volume of cultured bacteria ($0.21 \mu\text{m}^3 \pm 0.26$) was not significantly (bilateral
195 unpairwise student test; $p = 0.07$) different from cell volume of natural bacteria ($0.23 \mu\text{m}^3 \pm$
196 0.62).

197 The ratio between active and non active bacteria increased significantly with time in
198 cultured bacteria (Analyse of variance, $p < 0.01$) and evolved from 9.9 to 12.9 % during the
199 first five hours after thawing.

200 The number of Operational Taxon Units (OTU) found in cultures fluctuated between 56
201 and 75 % of that found in natural sediment (Fig. 2). The resulting dendrogram of TGGE
202 patterns for cultured and natural sediment samples displayed two clusters. These clusters, of
203 similar community composition, were defined by 49 % pattern similarity. Subculturing does
204 not seem to affect community composition to a great extent (75 % of similarity) and did not
205 change bacterial diversity. Freezing process induced a decline of 25 % in the diversity of
206 bacteria and slightly affected the bacterial community composition (84 % of similarity).

207 *Bacterial ingestion rates*

208 After grazing experiments with pre-labelled bacteria, frozen grazers (control) were
209 systematically less ^{15}N enriched than living ones for the three grazers types under study (Tab.
210 1). ^{15}N concentration increased linearly in grazers according to incubation time (Fig. 3). This
211 linearity pointed that ingestion rates were constant during incubation period studied: 2 hours
212 for *H. ulvae* and 5 hours for the nematode community and *A. tepida*. Raw data used for
213 ingestion rates calculations are presented in Tab. 1. The mud snail *H. ulvae* grazed 1149 (\pm
214 0.285) $\text{ngC ind}^{-1} \text{h}^{-1}$, each nematode in the community grazed 0.027 (\pm 0.005) $\text{ngC ind}^{-1} \text{h}^{-1}$
215 and the foraminifera *A. tepida* grazed 0.067 (\pm 0.013) $\text{ngC ind}^{-1} \text{h}^{-1}$.

216 **Discussion**

217 *Discussion on methodology*

218 ◆ Success of enrichment

219 Rinsing efficiency was tested by placing non enriched killed bacteria in enriched medium
220 and by separating them from this medium by centrifugations. Those bacteria were poorly
221 enriched in ^{15}N , showing that the bacterial rinsing centrifugation process was efficient. Thus,
222 ^{15}N enrichment of bacteria was due to a bacterial assimilation and not to culture medium
223 remaining between bacterial cells. This high bacterial rinsing efficiency is essential, since
224 some grazers are able to consume directly DOM (Montagna and Bauer 1988) from the culture
225 medium.

226 There is one disadvantage in using ^{15}N instead of ^{13}C enriched bacteria. As grazers contain
227 more C than N, more biomass is required for isotopic measurements. However, the use of ^{15}N
228 avoids the decalcification step required by ^{13}C and bias associated with this decalcification
229 (Jacob et al. 2005). Moreover, grazing experiences are based on the assumption that isotopic
230 composition of bacteria remains constant during the incubation period. The isotopic

231 composition of ^{13}C enriched bacteria will vary quickly due principally to respiration loss and
232 to a lower degree to production of DOM (Ogawa et al. 2001; Kawasaki and Benner 2006).
233 The use of ^{15}N permits to limit this respiration loss bias so isotopic composition of bacteria
234 remains more stable during incubation.

235 ◆ Size of cultured bacteria

236 Discrimination of prey by grazers on the basis of size can influence the estimate of total
237 bacterivory. Bacterial selection according to size has been well documented in planktonic
238 protozoa (Pérez-Uz 1996; Hahn and Höfle 1999). Most protists graze preferentially on
239 medium-sized bacterial cells, grazing being less efficient with smaller and larger cells (review
240 in Hahn and Höfle 2001). The soil nematode, *Caenorhabditis elegans* feeds on bacteria
241 suspended in liquid and smaller bacteria are better food sources than larger ones for this
242 species (Avery and Shtonda 2003). Since, in our study, cultured and natural bacteria presented
243 a similar average size, it can be inferred that there is only a small bias if any due to cell size
244 selection by grazers.

245 ◆ Activity of cultured bacteria

246 Few data are available on CTC activities of natural benthic bacteria for comparison with
247 our results. In superficial sediments from intertidal mudflats, 4 to 20% of benthic bacteria
248 were found to be active (van Duyl et al. 1999). Proctor and Souza (2001) found 9 to 10 %
249 active cells in river sediments and 25 % in intertidal sediments in the Gulf of Mexico.
250 Halgund *et al.* (2002) detected 46 % active bacteria in lake sediments.

251 Enriched bacteria with activity levels different from those of the natural community may
252 induce a bias if grazers select bacteria according to prey activity. Nematodes can discriminate
253 bacteria exhibiting different physiological or nutritional states (Grewal and Wright 1992).
254 *Pellioiditis marina* do not assimilate heat-killed bacteria even though it feeds on live cells at

255 high rates (Moens 1999). In contrast, *Diplolaimelloides meyli* is more attracted by killed than
256 by live bacteria (Moens et al. 1999a). The foraminifera *Ammonia beccarii* collects dead and
257 living stained bacteria without discrimination (Langezaal et al. 2005).

258 Many existing methods to quantify bacterivory use bacterial communities with activity
259 levels different from those of the natural communities. For instance, labels directly added to
260 the sediment are only incorporated by the active fraction of the bacterial community: 100 %
261 of labelled bacteria are active. In contrast, prelabelled bacteria such as standard FLB are
262 generally dead (heat-killed): 0 % of labelled bacteria are active. With the method described in
263 our study, 10 % of labelled bacteria are active after thawing of frozen cultures (Fig. 1). This
264 activity is included in range found in natural environments (van Duyl et al. 1999; Proctor and
265 Souza 2001; Haglund et al. 2002). With the present method, grazers have the opportunity to
266 pick up active or inactive bacteria according to their preference like in the natural
267 environment.

268 ◆ Diversity in the cultured bacteria

269 Subculturing of bacteria produces a final culture free of sediment. Freezing allows storage
270 of aliquots that may be enriched under standardised conditions at any time. The freezing step
271 induces small variations in the diversity of the bacterial community that must be nevertheless
272 kept in mind when using this method.

273 Grazers may be highly selective of prey species. To our knowledge, selection of bacteria
274 has never been observed for macrofauna but demonstrated for nematodes (Moens et al.
275 1999a) and foraminifera (Lee et al. 1966; Bernhard and Bowser 1992; Langezaal et al. 2005).

276 Nematodes used to be considered as generalist feeders, but they were recently shown to be
277 selective feeders exhibiting various preferences for algal and microbial prey. Their
278 reproduction rates differ according to the ingested strain of bacteria (Venette and Ferris 1998;
279 Blanc et al. 2006). Moens *et al.* (1999a) show that monhysterid nematodes are able to select

280 bacterial strain. Selection can be due to the bacterial size: filamentous bacteria escape uptake
281 by nematodes with small buccal cavities (Blanc et al. 2006). Moens *et al.* (1999a) consider
282 that the chemotaxic responses of nematodes to their bacterial prey may be due more to
283 chemical cues produced by the bacteria than to bacterial cell-wall structure that determine
284 their palatability. Nematodes are also able to significantly modify the composition of a
285 bacterial community by their species-specific bacterial food preferences (De Mesel et al.
286 2004).

287 The foraminifera *A. beccarii* distinguishes food and non-food particles during collection
288 (Langezaal et al. 2005). Two allogromiidae species (Foraminifera) have been shown to be non
289 selective grazers, actively harvesting bacterial biofilm from 3 different inocula (Bernhard and
290 Bowser 1992). Lee *et al.* (1966) found that most species of bacteria do not serve as food for
291 foraminifera whereas selected species of bacteria are consumed in large quantity.

292 Each bacterial species presents characteristics such as cell surface, nutritional quality or
293 chemical cues which may influence bacterial grazer behaviour. These differences have not
294 been evaluated between cultured versus natural bacteria in the present study. However,
295 estimation of total community composition and diversity gives us an approximate idea of
296 these differences. This molecular approach has the advantage to target dominant community
297 members. The cultured community presents 49 % of similarity with the natural bacterial
298 community. Although cultivation of natural bacteria induces a shift in community
299 composition (Fig. 2), this bacterial consortium seems more representative of the natural
300 community than that of many other grazing studies. The majority of experiments that use FLB
301 are done with monospecific bacteria or with a really limited number of bacterial species. Even
302 if natural and cultured community are not strictly identical, the probability for grazers to find
303 and ingest their preferred bacterial species is higher in the supplied bacterial consortium than
304 with monospecific bacteria.

305 ◆ Characteristics of grazing experiment

306 All various methods developed and applied to measure bacterivory in natural communities
307 possess methodological shortcomings that make interpretation of the resulting data
308 problematic. The method presented in this study, using ^{15}N pre-enriched bacteria also presents
309 bias. Sieving the sediment changes the bacterial availability for predators, bacteria being not
310 attached to particle as in natural situation. The best way to minimize this artefact is to add the
311 label directly to sediment in order to label bacteria while they are being grazed. This method
312 is problematic as a high fraction of label found in grazers is due to processes other than
313 grazing as underlined before. This requires control of incubations with a prokaryote activity
314 inhibitor and the effectiveness of this inhibitor has to be tested for each grazer. The pre-
315 enriched bacteria technique does not require the use of such inhibitors and only necessitate
316 one control to determine adsorption of enriched bacteria on grazers.

317 Nematodes (Gerlach 1978), foraminifera from the genera *Ammonia* (Chandler 1989) and
318 *H. ulvae* secrete mucus. During experiments with pre-enriched bacteria, controls must be
319 performed to determine abundance of enriched bacteria stuck in the mucus secreted by
320 grazers. Stuck bacteria modify the isotopic composition of grazers and controls are required to
321 evaluate this bias due to non-grazing processes. In this study, freeze-killed grazer controls
322 were used to determine this adsorption assuming that mucus post-freezing and mucus never
323 frozen absorb bacteria at the same rate.

324 During grazing experiments, prey egestion from grazers may occur when chemical
325 preservatives are used and this leads to underestimating grazing rates. Nematodes can egest a
326 significant part of their gut contents when killed with formaldehyde (Moens et al. 1999b). In
327 this study, grazers were frozen at -80°C to reduce this bias.

328 Prior to grazing experiments, enriched bacteria were frozen in liquid nitrogen to prevent
329 spontaneous and enzymatic degradation and maintain their viability. Bacteria are commonly

330 cryopreserved during long-term storage in liquid nitrogen. Some agents like glycerol and
331 methanol can be used to enhance cryopreservation, but in the case of grazing experiments,
332 they can be toxic to grazers. Low-temperature storage enables standardised cultures, helping
333 to ensure reproducible results in a series of experiments. This storage is really useful when
334 monitoring over long periods is considered.

335 The method used allows short incubations that limit bias due to recycling. Bacterial
336 ingestion is detectable after 2 hours of incubation for 3 grazers (Fig. 3). During incubation,
337 labelled bacteria may be first ingested by grazers that are themselves preyed by studied
338 grazers. In such a situation, it is impossible to determine the part of label present in studied
339 grazers that is provided respectively by bacteria and first grazers. Even if a short incubation
340 time does not prevent this type of bias, it reduces it substantially.

341 *Demonstration of applicability*

342 Data from literature to compare with our values are scarce. First, these predator species
343 have not been systematically studied. Secondly, herbivory is more commonly studied than
344 bacterivory. Thirdly, the manner in which to report grazing rates depends on the aim of the
345 study. Studies dealing with carbon flow generally report values on a biomass basis (e.g. ngC.
346 ind⁻¹ h⁻¹). When the aim of the study is the impact of grazers on microbial community,
347 grazing rates are generally reported as rate constants (e.g. h⁻¹) (Montagna 1995).

348 While meiofaunal grazers are adapted to pick out specific microbial particles, macrofaunal
349 deposit feeders process large volumes of sediment. Mud snails of the genus *Hydrobia*
350 assimilate epipelagic diatoms and attached bacteria (Newell 1965; Kofoed 1975; Lopez and
351 Levinton 1978; Jensen and Siegismund 1980) contained in the ingested sediment. To our
352 knowledge bacterial ingestion rates have never been determined but data is available
353 concerning algal ingestion rates. The bacterial ingestion rate found in our study is in the same

354 range as algal ingestion rates found by Forbes and Lopez (1989), Blanchard *et al.* (2000) and
355 Haubois *et al.*, (2005) (Tab. 2).

356 In literature, grazing rates of nematodes are strongly variable with a range of fluctuations
357 of more than two orders of magnitude (Tab. 2). Thus, comparison of our data with literature is
358 difficult. Those discrepancies may arise from a lot of reasons such as the use of different
359 techniques or the experimental conditions. When grazing experiments are performed in
360 monoxenical conditions, nematodes are in an environment constituted by water (or agar) and
361 bacteria. Nematodes would probably present higher grazing rates in such conditions than
362 during grazing experiments where bacterial food is mixed with minerals and refractory
363 organic matter and therefore is less available. However, when our results are compared to
364 values resulting from experiments using nematodes from mudflat grazing on labelled bacteria
365 mixed with sediment, it appeared that they are in the range of grazing rates found by Epstein
366 & Shiaris (1992) but more than ten times lower than those found by Montagna (1984b).

367 Algal ingestion rates by *A. tepida* are higher (Moodley *et al.* 2000) than bacterial ingestion
368 rates found in our study (Tab. 2). Langezaal *et al.* (2005) used FLB in simplified microcosms
369 with one specimen of *A. beccarii* in a reduced volume of water. Their bacterial grazing rate is
370 lower than ours. This may be linked to the bacterial concentration used in microcosms (1.4
371 $10^3 \text{ cell ml}^{-1}$), which is considerably lower than benthic bacterial abundance in the natural
372 environment (c.a. $10^9 \text{ cell ml}^{-1}$) and in the present study.

373 **Conclusion**

374 The fate of benthic bacterial biomass is a topic of major importance in microbial ecology
375 and in food web studies. All various methods developed and applied to measure bacterivory
376 in natural communities possess artefacts and difficulties that make interpretation of the
377 resulting data problematic. Our experimental approach is not an exception and also presents
378 shortcomings. These bias are due principally to sediment manipulation. Labelled bacteria are

379 not available to bacterivores in the same manner as bacteria in unmanipulated sediment.

380 However, grazing experiments with ^{15}N pre-enriched bacteria also present several
381 advantages: (i) they can be performed *in situ* without environmental consequences, (ii) they
382 do not require long incubations, so bias due to recycling is minimized, (iii) they require quite
383 simple control tests with freezing of enriched prey, (iv) they can be performed at different
384 times under standardised conditions, (v) they can be extended to other types of sediment or
385 soil and (vi) they can be used in double-labelling experiments with ^{13}C enriched algae, in
386 order to simultaneously measure bacterial and algal ingestion rates.

387

387 **Acknowledgements**

388 Thanks to Amélie Sallon for her help in sample preparation and to Gaël Guillou for
389 isotopic analyses. We thank Alain Vézina for his helpful review of the manuscript. The
