Abstract. The purpose of this study is to investigate horizontal transport processes in the winter stratosphere using data with a resolution relevant for chemistry and climate modeling. For this reason the Freie Universität Berlin Climate Middle Atmosphere Model (FUB-CMAM) with its model top at 83 km altitude, increased horizontal resolution T42 and the semi-Lagrangian transport scheme for advecting passive tracers is used.

A new approach of this paper is the classification of specific transport phenomena within the stratosphere into tropical-subtropical streamers (e.g. Offermann et al., 1999) and polar vortex extrusions hereafter called polar vortex streamers. To investigate the role played by these large-scale structures on the inter-annual and seasonal variability of transport processes in northern mid-latitudes, the global occurrence of such streamers was calculated based on a 10-year model climatology, concentrating on the existence of the Arctic polar vortex. For the identification and counting of streamers, the new method of zonal anomaly was chosen. The analysis of the months October-May yielded a maximum occurrence of tropical-subtropical streamers during Arctic winter and spring in the middle and upper stratosphere. Synoptic maps revealed highest intensities in the subtropics over East Asia with a secondary maximum over the Atlantic in the northern hemisphere. Furthermore, tropical-subtropical streamers exhibited a higher occurrence than polar vortex streamers, indicating that the subtropical barrier is more permeable than the polar vortex barrier (edge) in the model, which is in good correspondence with observations (e.g. Plumb, 2002; Neu et al., 2003). Interesting for the total ozone decrease in mid-latitudes is the consideration of the lower stratosphere for tropical-subtropical streamers and the stratosphere above ∼20 km altitude for polar vortex streamers, where strongest ozone depletion is observed at polar lat-

itudes (WMO, 2003). In the lower stratosphere the FUB-CMAM simulated a climatological maximum of 10% occurrence of tropical-subtropical streamers over East-Asia/West Pacific and the Atlantic during early- and mid-winter.

The results of this paper demonstrate that stratospheric streamers e.g. large-scale, tongue-like structures transporting tropical-subtropical and polar vortex air masses into mid-latitudes occur frequently during Arctic winter. They can therefore play a significant role on the strength and variability of the observed total ozone decrease at mid-latitudes and should not be neglected in future climate change studies.

1 Introduction

In recent years the role of mid-latitude ozone has increasingly captured public interest as a substantial decrease of total ozone is not only observed over the winter poles but also at mid-latitudes especially over the northern hemisphere (NH). Maximum ozone loss of up to −6% in winter and up to −12% in spring occurred over NH mid-latitudes during the early to mid 1990s (Fioletov et al., 2002; WMO, 2003). Besides the fundamental chemical processes involved, transport is an important factor in determining the global distribution of atmospheric trace gases, such as ozone.

The overall global transport of trace gases is mainly driven by the mean meridional circulation (MMC) caused by the breaking of planetary and gravity waves in the extratropical stratosphere/ mesosphere, the so-called "wave driving" or "extratropical pump" (Haynes et al., 1991; Plumb, 1996). A recent overview of the MMC, also called the Brewer-Dobson circulation (BDC) after its main observational discovers Brewer (1949) and Dobson (1956), is given by Plumb (2002).

A quasi isolation of the tropics was first postulated by Plumb (1996) with the concept of the "tropical pipe" model and was proven by the detection of the "tape recorder"

(kkrueger@awi-potsdam.de)

signature in the annual cycle of water vapor measurements in the tropical tropopause region (Mote et al., 1996). Both studies led to the conclusion that the subtropics act as a kind of transport barrier between the tropical and mid-latitudinal regions. Due to the breaking of planetary waves in mid-latitudes, a zone of well-mixed trace gases is built-up with weak gradients in concentrations, the so called "surf zone" (McIntyre and Palmer, 1983; 1984). On the poleward side of the surf zone, the polar vortex edge acts as a strongly confined transport barrier between the well-mixed surf zone and the air within the polar vortex. Rising evidence of a possible two way exchange through the subtropical barrier was found in observational and modeling studies, a recent overview of this now called "leaky pipe" model is given by e.g. Plumb (2002). A more comprehensive picture of specific transport processes at the edge and inside the polar vortex was also summarized by that author. More over, horizontal mixing processes through the transport barriers, either by smaller-scale (finger-like) structures (filaments/laminae) or by large-scale (tongue-like) structures (streamers), are thought to play a significant role and are subject of the present paper.

Observational evidence of narrow tongues of tropical air transported into mid-latitudes in the middle stratosphere was shown with low resolution satellite measurements (Leovy et al., 1985; Randel et al., 1993; Manney et al., 1993; Trepte et al., 1993). Rossby wave breaking events at the edge of the tropics and a shift of the polar vortex towards lower latitudes seem to be linked with tropical air extrusions into mid-latitudes (Chen et al., 1994; Waugh, 1996). On reaching higher latitudes, these tongues of tropical air are stretched into filaments which are wrapped around the edge of the polar night jet (Waugh, 1993). In the present study, the above described phenomena of large-scale, tongue-like features of tropical-subtropical air masses within the stratosphere are called "tropical-subtropical streamers" (Offermann et al., 1999). The term used in this study should not be mistaken with the terminology of "streamers" of a smaller-scale first introduced by Appenzeller and Davies (1992) and Appenzeller et al. (1996), describing stratospheric intrusions into the troposphere.

Large extrusions of polar vortex air into mid-latitudes in the middle stratosphere were first detected by McIntyre and Palmer (1983; 1984). The authors described the phenomena as big "blobs" of potential vorticity (PV), transporting high-latitude air masses equatorward. Due to the breaking of planetary waves at the edge of the polar vortex, these air masses are irreversibly mixed within the surf zone. Waugh et al. (1994b) investigated these large extrusions of polar vortex air with high resolution transport calculations and found that they were characteristic for the middle stratosphere, whose flow is dominated by the increase in amplitude of upward propagating planetary waves. Whereas the same calculations for the lower stratosphere suggested that air ejected from the

polar vortex forms thin filaments which are usually wrapped around the vortex edge. In the present work, large polar vortex extrusions in the form of blobs of PV or tail-like structures of passive tracers are termed "polar vortex streamers".

High temporal and spatial resolution of the CRyogenic Infrared Spectrometers and Telescopes for the Atmosphere (CRISTA) instrument on board the space shuttle, has shed more light into the detection of both large-scale and smaller-scale transport phenomena (Offermann et al., 1999; Riese et al., 1999). During the one week mission in November 1994, CRISTA measured broad, large-scale, tongue-like features of tropical and polar vortex air extrusions in the middle stratosphere. On the same platform independent measurements were carried out with the ATmospheric Trace Molecule Spectroscopy (ATMOS) instrument (Manney et al., 2000), supporting the findings of CRISTA. By comparing these measurements with satellite observations and fine scale trajectory calculations, tongue-like phenomena were detected in various trace gases, e.g. CH_4, O_3, NO_x, in the stratosphere in addition to filament like structures (Manney et al., 2000; Manney et al., 2001).

First evidence of thin, filament-like structures in ozonesonde profiles was given by Brewer and Milford (1960). Such structures are called laminae in vertical space (Dobson, 1973) and filaments in the horizontal plane. These phenomena were observed to have a small vertical extension from 200 m to 2.5 km and to vary between several hundred to a thousand kilometres in horizontal space (Dobson, 1973; Reid and Vaughan, 1991; Reid et al., 1993). Using regular ozonesonde ascents into the stratosphere since the 1960s, these authors found that such phenomena maximize between 12 and 18 km altitude range at high latitudes during the winter and spring seasons. They are thought to be mainly excited through differential advection in regions of strong horizontal and vertical wind gradients, e.g. in regions of strong jets (Appenzeller and Holton, 1997). The inter-annual, seasonal and long-term variability of laminae has been addressed by many observational studies (e.g. Reid and Vaughan, 1991; Reid et al., 1993; Appenzeller and Holton, 1997; Manney et al., 1998; Reid et al., 1998; Orsolini and Grant, 2000; Wahl, 2002). Strong gradients in the large-scale winds can lead to a layering of the laminae which results in a filament-like structure in the horizontal plane. High resolution transport studies, using contour advection techniques or similar methods, showed the effect of simulating ultra-thin filaments with the use of large-scale winds (e.g. Norton, 1994; Waugh and Plumb, 1994; Chen et al., 1994). Waugh et al. (1994a) and Plumb et al. (1994) demonstrated that these ultra-thin filaments of polar vortex extrusions and intrusions were realistic features, comparing them with in-situ aircraft measurements. These filaments were mainly observed at the edge of the polar vortex in the lower stratosphere, generated by Rossby wave breaking, where they irreversibly mix with the surrounding air masses (Waugh et al., 1994b). A regular occurrence of filaments of polar vortex extrusions is thought

to play a significant role in the observed total ozone loss in mid-latitudes (Norton and Chipperfield, 1995; Knudsen and Grooß, 2001; Marchand et al., 2003; Millard et al., 2003). These model studies concentrated on investigating smaller-scale, finger-like structures.

Large-scale, tongue-like features or stratospheric streamers were successfully simulated with comprehensive models (Mahlmann and Umscheid, 1987; Boville et al., 1991; Rood et al., 1992; Orsolini et al., 1995; Riese et al., 1999; Kouker et al., 1999; Steil et al., 2003). A first climatology of streamers was derived with the mechanistic model KArlsruher SImulation of the Middle Atmosphere (KASIMA) using analyzed winds for the winters 1990 to 1998 (Langbein et al., 2001). This "assimilated" streamer climatology was compared by Eyring et al. (2003) with simulations from the coupled chemistry-climate model ECHAM4.L39(DLR)/CHEM (E39/C). In general a good correspondence between the two was found, when applying the same streamer criterion. However, those authors investigated solely the transport of tropical air into higher latitudes, restricting their intercomparison to the lower stratosphere (21–25 km altitude).

The purpose of this model study is to investigate the possible role of air mass excursions by stratospheric streamers through both transport barriers – the subtropics and the polar vortex edge – during Arctic winter. In addition to previous studies, two types of streamers are investigated, tropical-subtropical streamers and polar vortex streamers, using a full climate middle atmosphere model including the whole branch of the BDC.

The paper is organized in the following way: a brief description of the model and the method to identify streamers is given in Sect. 2. The simulation of streamers is presented in a case study in Sect. 3. The inter-annual and seasonal distribution of streamers is investigated based on a 10-year model climatology in Sect. 4. The model results are discussed in Sect. 5. Finally, the results are summarized (Sect. 6).

2 Model description and method

2.1 Model

For the streamer study the Freie Universität Berlin Climate Middle Atmosphere Model (FUB-CMAM) with T42 horizontal resolution and a semi-Lagrangian transport scheme for advecting tracers is used. The FUB-CMAM is a general circulation model (GCM), run in the standard version with spectral horizontal resolution of T21 ($5.6° \times 5.6°$) and 34 layers in the vertical with a model top at $\sim$83 km (0.0068 hPa) altitude and a vertical grid spacing of 3.5 km in the middle atmosphere. A detailed description of the physical parameterizations is given by Pawson et al. (1998) and the new model configuration is described by Langematz (2000). For the purpose of this study, the horizontal resolution was increased to T42 ($2.8° \times 2.8°$), resulting in a grid mesh distance

of $\sim$300 km at the equator. Necessary changes in the model code are described in more detail in Krüger (2002). To guarantee numerical stability in the upper levels the model time step was reduced from 15 to 10 min integration.

2.1.1 Tracer advection

In order to study the transport of trace gases, the FUB-CMAM was coupled with a semi-Lagrangian transport (SLT) scheme with modified exponential splines (Böttcher, 1996; Braesicke and Langematz, 1998; Krüger, 2002). The SLT scheme was run with a transport time step of 4 hours and was thus less computer time consuming than Lagrangian schemes. The SLT scheme was used on the same horizontal grid of $2.8° \times 2.8°$ as the model physics and on a vertical grid of 2.4 km equidistant layers throughout the model atmosphere. To investigate especially horizontal transport processes in more detail an idealized passive, zonally stratified tracer was advected with zonally homogeneous concentrations. The concentration starts with zero at the South Pole and increases up to 180 arbitrary units (au) at the North Pole, with no changes in the vertical. This tracer has no sources and sinks in the model. Due to the limited computer time, the tracer was initialized on the first of October of each model year and advected until the end of May, covering the dynamical active period in the northern winter stratosphere.

2.1.2 Model integration

A T42 model run with seasonal variation in solar insolation and prescribed climatological sea surface temperatures (SSTs) has been carried out. After two years of initialization, the model was run for 10 years. Time series of the temperature for the grid box closest to the North Pole during Arctic winters and spring are shown in Fig. 1a for the middle stratosphere. A large year-to-year variability in winter is simulated solely due to the models' own internal mode of variability. No solar variability, quasi-biennial oscillation (QBO) or volcanic eruptions have been taken into account in the experiment. The simulated strength of variability is comparable to observed variations during the 1990s, shown here for the FUB observational data (Fig. 1b). For a description of the FUB analysis see e.g. Naujokat et al. (2002). Compared to the former T21 model simulations the inter-annual variability has increased. However, the cold pole bias, a familiar feature of GCMs (Pawson et al., 2000), is enhanced compared to observations, apparent in the low temperature of less than $-100°C$ at 10 hPa during mid and late winter in selected years. The inter-annual variability in the winter stratosphere is caused by ultra-long planetary waves propagating from the troposphere into the stratosphere where they tend to break and decelerate the stratospheric jet. A detailed analysis, comparing the T42- with former T21-model runs, revealed a stronger planetary wave activity but a constant wave mean flow interaction in the T42-simulation (Krüger, 2002).

2.2 Streamer criterion

2.2.1 The zonal anomaly method

To identify the location and the shape of streamers in the model, an objective criterion called the zonal anomaly method was developed. Using daily data, the difference in the concentration at each grid point and the zonal mean of the passive tracer is calculated to derive the zonal anomaly field. Analyzing the zonal anomaly, a threshold value is defined to identify and count a streamer event. According to the increasing tracer concentration from the South to the North Pole, a positive zonal deviation in the NH indicates high latitude air advected into lower latitudes, and a negative deviation marks low-latitude air advected into higher latitudes. In the SH the deviation changes sign for both transport cases. Different threshold values were tested for both transport phenomena independently, varying from ±15 au to ±25 au. Finally, anomalies of +20 au and more were chosen to identify polar vortex streamers and of −20 au and less to identify tropical-subtropical streamers in the NH. The occurrence of streamers per day at 12:00 UTC and per grid point is counted using this new algorithm. The purpose of this study is to count the total amount of time and location when streamers are present, not the total number of streamer developments. Therefore, the distributions are normalized, resulting in relative frequency of streamers (1.0≙100%, 0.0≙0% per time occurrence). The climatology will concentrate on the period October to May and on stratospheric levels. An altitude range from 15–40 km is chosen, sub-divided into 5 equal layers, each containing 2 vertical transport levels, from 16–20 km, 21–25 km, 26–30 km, 31–35 km and 36–40 km altitude.

Figure 2 illustrates the amplitudes of the Fourier analyzed zonal wave number-1 (ZW1) and -2 (ZW2) of geopotential height, calculated from daily data, then averaged for the October to May period. The characteristic features are simulated in the model with a growing amplitude of both wave numbers with increasing height, maximizing between 50 and 60 km altitude at high latitudes, and a smaller amplitude of ZW2 than of ZW1. According to the high variability present in the T42-simulation the amplitude of ZW1 is rather strong compared to observations (not shown). During the 10-year integration two "wave number-1" major mid-winter warmings are simulated with a break-down of the polar vortex and a reversal of the zonal mean zonal wind in 60° N (not shown) in the Arctic winters 02/03 and 10/11 (Fig. 1a).
3 Case study

In this case study the ability of the FUB-CMAM to simulate stratospheric streamers is presented. The objective criterion to identify and count streamers will be demonstrated in detail.

3.1 Synoptic situation

For this case study, a typical cold and undisturbed winter (year 11/12) was chosen (Fig. 1a). Figure 3 shows the synoptic situation for the early winter period, using geopotential height (at 10 hPa) and PV (at 850 K) fields for the middle stratosphere. On day 63 (3rd December), the centre of the cold vortex is directly situated over the North Pole. One day later an Aleutian high begins to form. In the following days the anticyclone strengthens, pushing the vortex centre towards lower latitudes and leading to an elongated polar vortex with a zonal wave number-2 pattern. Around day 71, a second anticyclone develops over Eurasia, indicating a strengthening of wave number-2. This dynamical situation can be categorized as a typical "cold wave 2" behaviour (Labitzke, 1977) with an eastward travelling wavenumber-2 characteristic (Krüger et al., 2005), and does usually not culminate in a break-down of the polar vortex, i.e. a major mid-winter warming.

Concerning transport processes in the stratosphere, PV on an isentropic level can be regarded to be a quasi-conserved quantity up to 5 days, behaving as a passive tracer. The PV field shows the development of tongues of tropical air over the Atlantic from days 67 to 78 and over East Asia from days 63 to 74. Extrusions of polar vortex air can be seen over the USA on days 69–70 and over the Atlantic on days 76–77, which seem to drop out of the polar vortex in the form of blobs, a couple of days later travel to the tropical belt as was described by McIntyre and Palmer (1983; 1984).

3.2 Simulation of streamers

For the same sequence, the passive tracer is shown in Fig. 4. One striking difference to the PV is, that the passive tracer shows a much more differential picture in its evolution. Finer transport structures are conserved in the passive tracer field during the presented period. As can be seen over the West Atlantic, air masses of tropical-subtropical origin are pulled out by the large-scale winds and are advected northeastward over the Atlantic towards Europe (day 67–70). This tongue of tropical air can be identified as an "Atlantic streamer" as defined by Offermann et al. (1999). After day 70 the streamer is advected further northeastward, close towards the edge of the polar vortex, here taken to be the region of maximum gradient in wind speed. There, the streamer is getting longer and thinner by differential advection as was also observed during the first CRISTA experiment. Finally, (after day 72) this "streamer-filament system" begins to roll-

up into a cat eye (McIntyre and Palmer 1983; 1984) over Eurasia, which typically indicates a Rossby wave breaking event associated with irreversible mixing. A simultaneous tropical-subtropical streamer event is visible over East Asia (day 63–74), called an "East Asian streamer" (Offermann et al., 1999), and is also rolling up into a cat eye over the Pacific. On days 63, 66, 70 and 78 the evolution of polar vortex streamers is visible, which seem to be connected with the development of tropical-subtropical streamers, as was also observed by CRISTA. A more detailed investigation of the processes which produce such transport phenomena was carried out with a correlation analysis of the passive tracer concentration at one grid point with relevant quantities e.g. zonal wind, meridional wind, ZW1, ZW2, PV and geopotential height (not shown). The highest anti-correlations for the "formation" of a tropical-subtropical streamer over the Atlantic on day 69 (see Fig. 4) were obtained by a change to and increase of southerly winds and the equatorward movement of the polar vortex. These negative correlations r were higher ($r < -0.8$) than taking the zonal wind or the zonal wave number-1 and -2 components ($r < -0.6$). Analyzing the "formation" of a polar vortex streamer is more complex. Calculating the correlation for the polar vortex extrusion over the Pacific on day 64 (see Fig. 4) revealed, that the increase of the southerly wind component and the formation of an Aleutian high ($r < -0.8$) were mainly responsible for this event. Another example over the West Atlantic on day 70 (see Fig. 4) showed that polar vortex streamers can also form in the vicinity of the polar vortex edge due to the strong wind gradient, which can lead to a slower advection and pulling out of high tracer gradients into mid-latitude regions. For the further development of both streamer types a strong wind shear and the differential advection of the high passive tracer gradients are necessary. The breaking or the final stadium of streamers leads to irreversible mixing of tracer contours with the surrounding air masses, which is visible for both streamers, e.g. in the cat eye structure over the Pacific on days 67–70 and 75–78 (see Fig. 4). Both type of streamers, namely tropical-subtropical and polar vortex, are found to have a width between 500 to 2000 km and a length of more than 10 000–20 000 km during the developmental stage. They span a whole latitudinal belt (e.g. the East Asian streamer at day 75). Their duration is between 1–3 weeks and they decay in 1–2 weeks in the model simulations. From this case study, it can be concluded that the main features of the simulated streamers are comparable to those observed during the space shuttle mission in November 1994 (Offermann et al., 1999; Manney et al., 2000; Manney et al., 2001).

3.3 Streamer criterion

Figure 5 shows the zonal anomaly field with the threshold criteria marked as contour lines for the same time sequence as for Fig. 4. A very good correspondence can be realized between the subjective counting by visible inspection of Fig. 4
Fig. 3. Synoptic development during December days 63 to 78 of year 11. Shown are contour lines (32 gpdam) for geopotential height at 10 hPa and shaded colours for PV at 850 K, from 20–90° N. 1 PVU ("Potential Vorticity Unit")=10^{-5} Km^{2}kg^{-1}s^{-1}; 5 PVU intervals.

and the objective method by using the zonal anomaly criterion to identify streamers (Fig. 6). For quiet a long period, the polar vortex was shifted off the pole towards lower latitudes, as can be seen in Fig. 3. This dynamical behaviour results in the regular development of tropical air extrusions shown

in Fig. 6. Two pathways are visible for tropical-subtropical streamers, one from the Caribbean Sea over the Atlantic reaching towards Europe/Asia and a second extending from Asia over the Pacific towards Alaska, reaching higher latitudes (up to 70° N) than the Atlantic streamer. Maximum
Fig. 4. Stratospheric streamers simulated in the FUB-CMAM for the same time sequence as in Fig. 3. Shown is the passive tracer [au] at 32 km altitude; 5 au intervals.

intensities of tropical-subtropical streamers, with more than 0.5 relative frequency which corresponds to 50% occurrence in time, are found over the Alëutian Islands. This result is not affected qualitatively when changing the threshold number by 25% ($\pm$5 au). During this case study, polar vortex streamers only occur for a quarter of the time of the tropical-subtropical streamers. High intensities with 0.15 relative frequency are found over the Atlantic region at mid to high latitudes. It is already visible in Fig. 4 that polar vortex streamers are weaker phenomena and are therefore detected less readily in this case study.
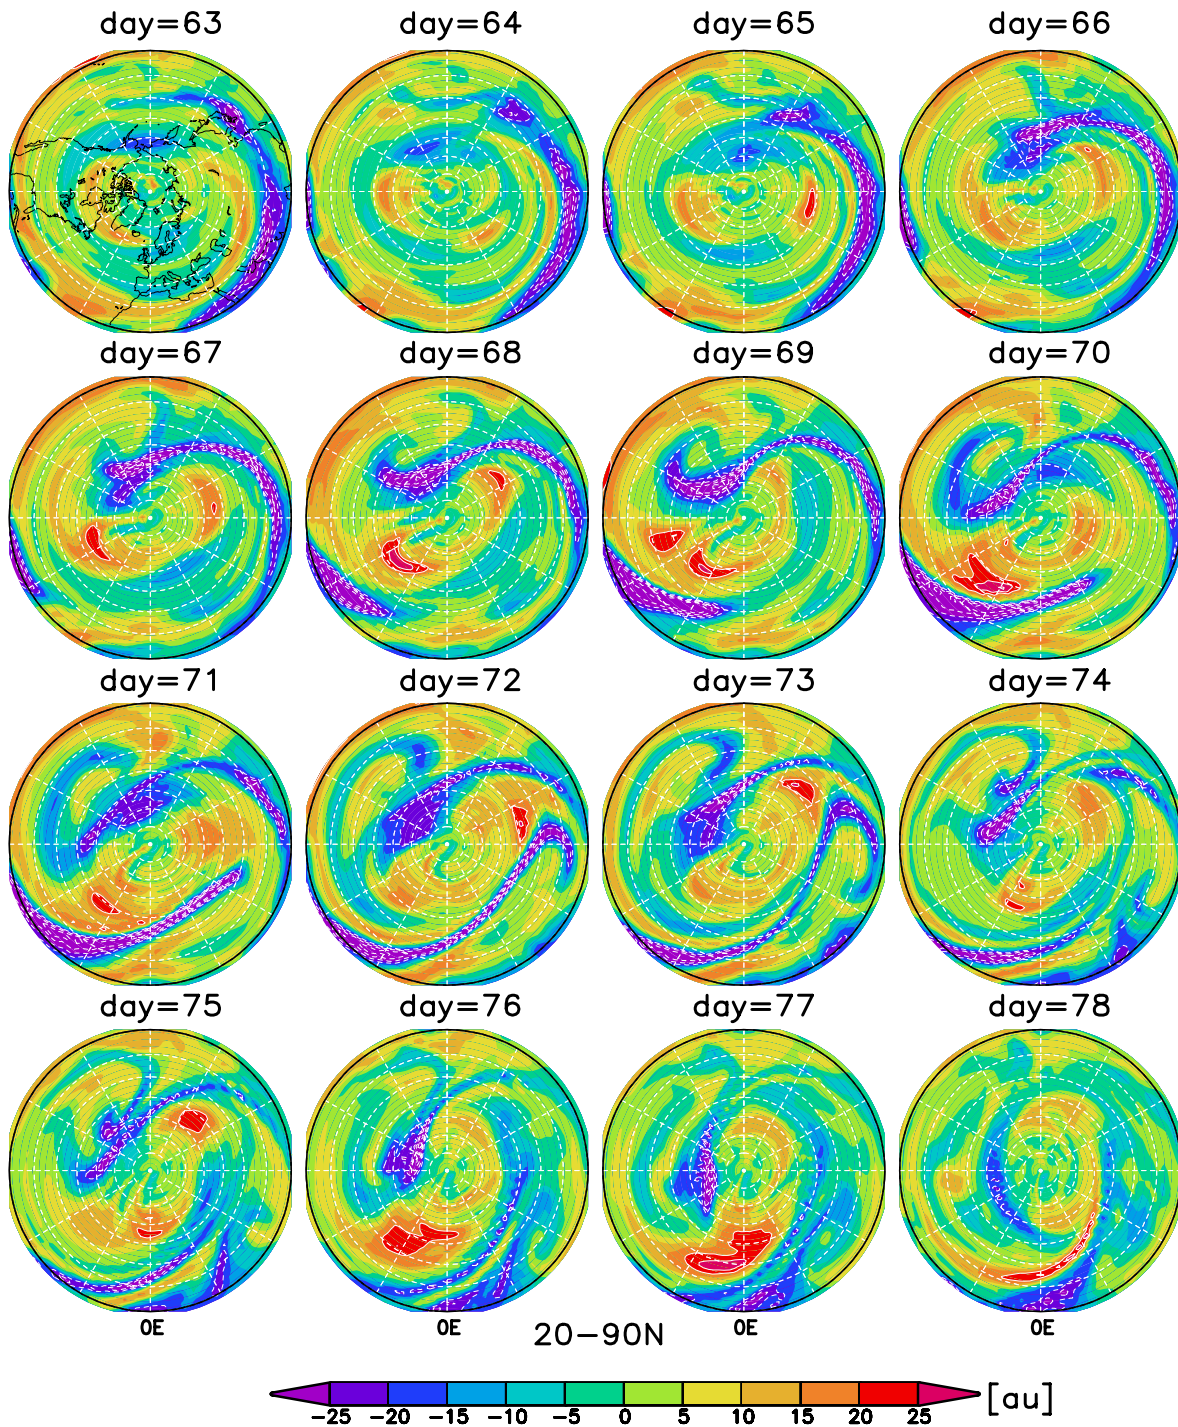

Fig. 5. Zonal anomaly of stratospheric streamers, as in Fig. 4. Shaded colours represent the anomaly fields and the contours mark the values of ±20, 25, 30, 35 thresholds.

Different criteria have been tested: the zonal anomaly (this study), the meridional gradient (Eyring et al., 2003) and the vertical gradient methods (e.g. Orsolini and Grant, 2000 and Langbein et al., 2001). For the design of this tracer experiment, use of the zonal anomaly method provided the most convincing results in detecting the horizontal shape of the streamers realistically without any shift in the meridional plane and location as was detected in the meridional gradient method by Eyring et al. (2003). The vertical gradient method (e.g. Orsolini and Grant, 2000 and Langbein et al., 2001) was
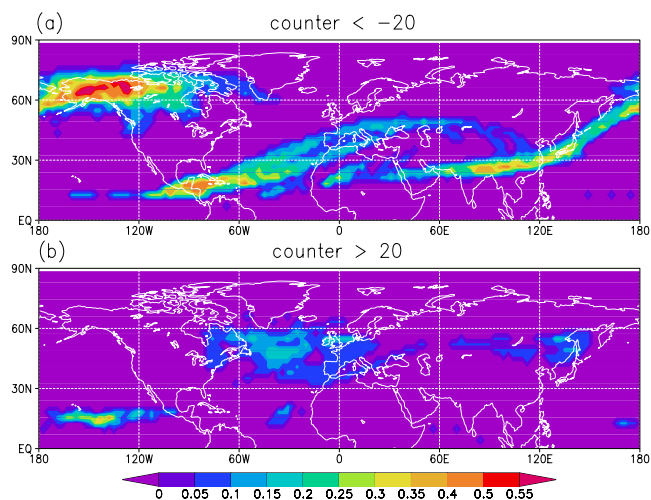

Fig. 6. Synoptic maps of relative frequency distributions of **(a)** tropical-subtropical streamers and **(b)** polar vortex streamers for the time sequence shown in Fig. 4.

not appropriate for our model experiments due to the limited vertical resolution. For a more detailed discussion of possible method deficiencies see Sect. 5.

4   Streamer climatology

In this section the zonal anomaly criterion will be used to investigate the occurrence of stratospheric streamers during 10 model years. The main emphasize will be placed on the inter-annual and seasonal variability of such phenomena in the northern winter stratosphere.

4.1   Inter-annual and seasonal variability

Figure 7 shows the inter-annual variability for (a) tropical-subtropical (counter <-20) and (b) polar vortex streamers (counter >20) in the NH for 10 years. The frequencies are averaged for the October to May period and over the 15–40 km altitude range. In every winter, a maximum occurs in the subtropics at 25° N with intensities varying from 3.5% to 6.0% per winter mean, which coincides with the formation region of tropical-subtropical streamers and is probably associated with the reversible distortion of tracer contour lines. In some of the winters the maximum in the subtropics can be tracked towards higher latitudes around 70–75° N (e.g. model years 4, 6, 8, 10 and 11), which are tropical-subtropical streamers advected towards higher latitudes and irreversibly mix to a large part within this region. The absolute maximum of these signals is reached in year 11 (corresponding to winter 11/12) at 70° N, which shows an anomalously high occurrence of tropical air masses at polar latitudes (see Sect. 3). In the same winter, an absolute maximum

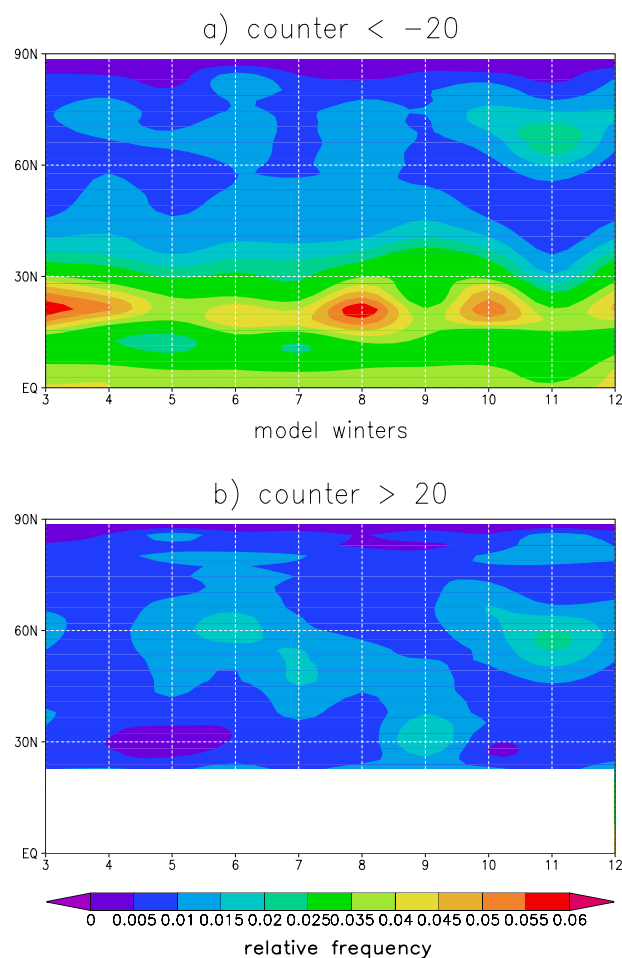

Fig. 7. Inter-annual variability of relative frequencies of tropical-subtropical streamers and (b) polar vortex streamers averaged over the October to May period and over 15–40 km altitude, zonal means from 0–90° N.

was also found for polar vortex streamer occurrences 10° southward (Fig. 7b). In general polar vortex streamers occur less frequently; maximum intensities from 1.5% to 2.0% are reached at 60° N during year 6 and 11. In model year 9, an extra-tropical air intrusion into the subtropics has taken place, indicating the existence of a leaky subtropical barrier in the FUB-CMAM. The seasonal evolution of tropical-subtropical streamers during northern winter is shown with zonal averages over the 15–40 km altitude range for each month in Fig. 8. In the subtropics, the region of streamer development, high frequencies are found from November to April maximizing in December and March. The advection of tropical-subtropical streamers towards higher latitudes seems to be preferred from October to February. Beginning in March, a minimum of streamer frequency is found at mid and high latitudes, indicating more quiescent dynamics due to the existence of easterly winds at polar latitudes. The frequency of polar vortex streamers (not shown) reveals a max-
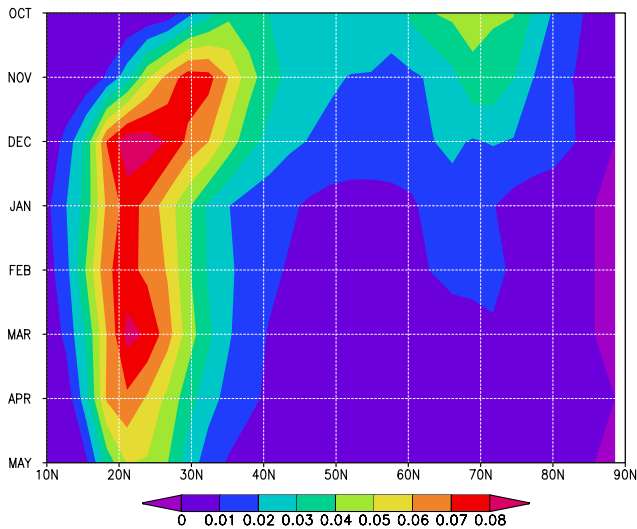

Fig. 8. Seasonal variability (October to May) of relative frequencies of tropical-subtropical streamers averaged over the 15–40 km altitude, zonal means from 10–90° N.

imum at 60° N and at 85° N only from October to February, whereby a higher occurrence of polar vortex streamers would be expected in spring due to the final break-down of the polar vortex, which occurs in the climatological model mean not before June. This discrepancy might be also influenced by a less readily detection of polar vortex streamers due to the weakening gradient of the passive tracer field at higher latitudes to the end of the simulation period caused by numerical diffusion of the SLT scheme (see section 5).

4.2 Vertical extension

For the vertical extension of streamers in the stratosphere, winter averages of zonal and area mean frequencies of tropical-subtropical streamers are shown in Fig. 9. The model climatology reveals maximum frequencies of 3% to 9% in the middle and upper stratosphere between 26 to 40 km altitude in the subtropics (Fig. 9a). A clear occurrence of streamers at higher altitudes in the stratosphere is demonstrated by this model study, indicating the role played by the ultra-long planetary waves on the development of stratospheric streamers, as ZW1 and ZW2 amplitudes grow with increasing altitude (Fig. 2). The area means approach enables us to follow the formation and existence stages of tropical-subtropical streamers (Fig. 9b–e). There are two main regions where streamers are excited in the model, mainly over Asia and a secondary region over the West Atlantic. This is visible in the strongest maximum over the 0–90° E sector, the excitation region of East Asian streamers, and in a smaller maximum over the 0–90° W sector illustrating a secondary excitation region of Atlantic streamers. After their excitation, tropical-subtropical streamers move progressive with the main flow and poleward. This can be seen by fol-

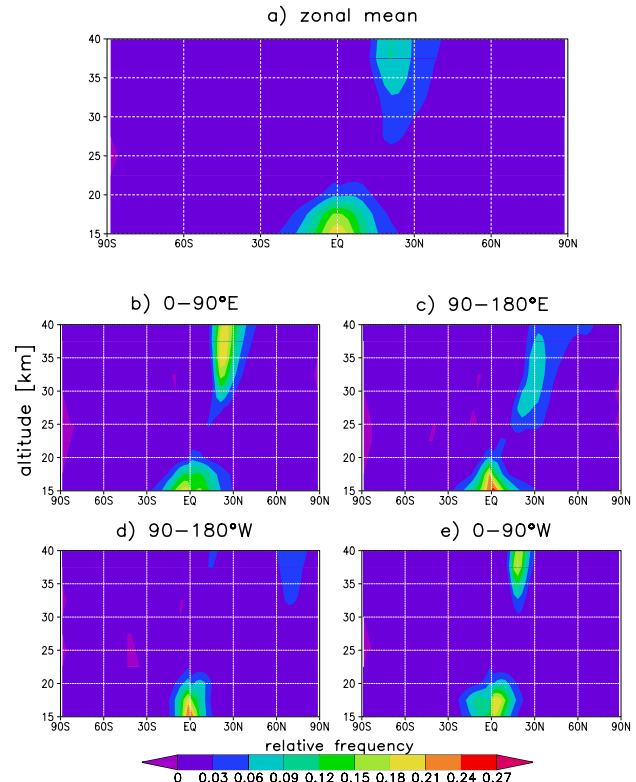

Fig. 9. Vertical distribution of relative frequencies for tropical-subtropical streamer averaged over the October to May period for **(a)** zonal mean, **(b)** 0–90° E, **(c)** 90–180° E, **(d)** 90–180° W and **(e)** 0–90° W.

lowing the first maximum into the 90–180° E and 90–180° W sectors and the secondary maximum into the 0–90° E sector, which then overlaps with the excitation region of the East Asian streamers.

4.3 Synoptic maps

Figure 10 shows the synoptic maps for tropical- subtropical streamers averaged over the October-November (ON), December to February (DJF) and March to May (MAM) periods during the 10 model-years. Maximum frequencies from 0.27 to 0.30 occur for tropical-subtropical streamers during winter and spring in the middle stratosphere (31–35 km mean). The band of high intensity extends from the Atlantic towards the Western Pacific for all three periods, containing also the secondary excitation region of the Atlantic streamers, as was visible in Fig. 4. During ON a large region of high intensities is analysed at polar latitudes, reaching from the Alëutian Islands towards Greenland. This maximum might be artificial as no high has been established in that season in the model. This behaviour may be associated with the time of the year (1st October) or/and the method of initializing the passive tracer (zonally homogeneous), as it takes several days before
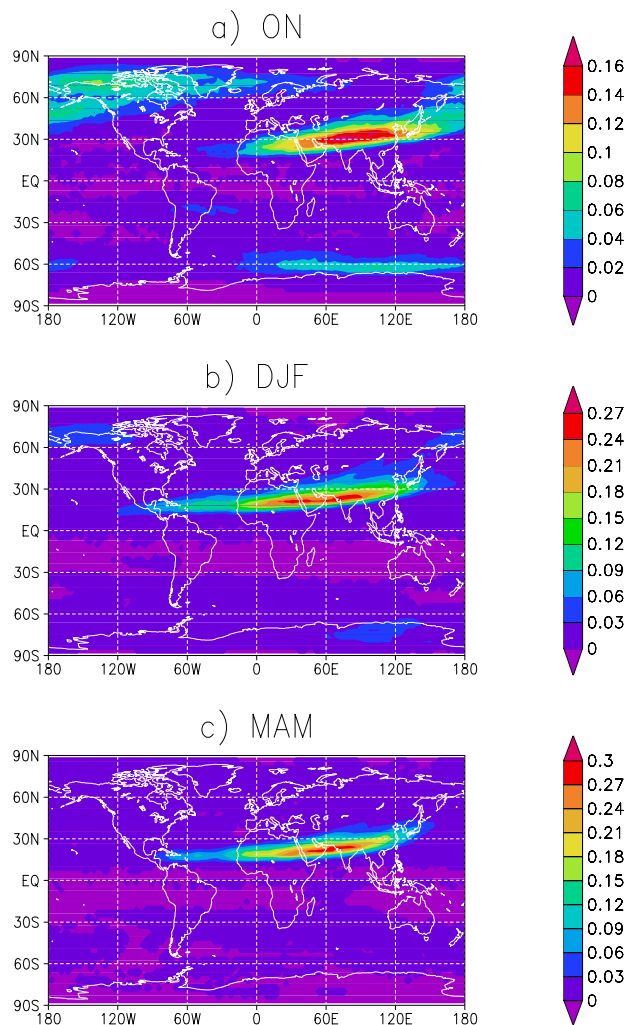

Fig. 10. Streamer climatology: synoptic maps of relative frequency distributions for tropical-subtropical streamer, averaged over 31–35 km altitude for **(a)** ON, **(b)** DJF and **(c)** MAM period; note the varying contour intervals.

Fig. 11. As in Fig. 10 but for 21–25 km altitude.

the contours of the passive tracer has adapted to the dynamical field.

Interesting for ozone loss at mid-latitudes is the consideration of the lower stratosphere, showing a direct influence of natural low-ozone air mass transport into mid-latitudes. Figure 11 displays tropical-subtropical streamer frequencies for the lower stratosphere averaged over 21–25 km altitude. In contrast to the middle stratosphere, maximum intensities occur during early- and mid-winter with only a third less appearance (11% during 10 years) compared with the middle stratosphere. In the lower stratosphere, excitation regions lie over the central Atlantic and over East Asia, tilting westward with increasing height as is visible when comparing Fig. 11 with Fig. 10, indicating the role of planetary waves in these processes. It is apparent that the Atlantic streamer becomes more important towards lower altitudes (21–25 km) whereas
the East Asian streamer is most pronounced in the middle stratosphere (31–35 km) during October/November, which is in good correspondence with CRISTA observations (Riese et al., 1999).

4.4 Comparison with observed tropical-subtropical streamer climatologies

The simulated strength of variability of e.g. the North Pole temperature in the stratosphere during Arctic winter is comparable to the observed inter-annual variability during the 1990s (see Fig. 1). Therefore, the streamer climatology of the T42-model is compared to assimilated streamers from the 1990s, derived with the mechanistic model KASIMA (Langbein et al., 2001). Only tropical-subtropical streamers can be compared as no polar vortex streamers have been taken into account by those authors. In the present study, the maximum of tropical-subtropical streamer activity lies in the NH,

whereas weak intensities are reached in the SH during October and November at mid and high latitudes (Figs. 10 and 11). The comparison concentrates on the lower stratosphere (21–25 km altitude) and on the latitude band between 20–70° N/S, for which results from the KASIMA climatology were available. To identify streamers, the authors employed the vertical gradient method based on the zonal mean field of the N_2O tracer. A streamer was counted, if the zonal mean at one layer reached more than 5% deviation from the vertical profile. In good agreement with this study, Langbein et al. (2001) analysed maximum intensities over the Pacific/East Asia and over the Atlantic in the subtropics reaching towards mid-latitudes during winter and spring.

It should be noted however that the main characteristics of the streamer climatology strongly depend on the chosen method and the respective streamer criterion. Eyring et al. (2003) analysed the same KASIMA data used by Langbein et al. (2001) with the meridional gradient method. Their results differ from Langbein et al. (2001) and other observational estimates (Offermann et al., 1999; Manney et al., 2000; Manney et al., 2001), as maximum streamer intensities were analysed further poleward over Central Europe and the Atlantic in mid-latitudes with a weak secondary maximum in the subtropics over East Asia during winter and spring. The results of the present study are more comparable with results derived from the vertical gradient method used by Langbein et al. (2001) than with those derived from the meridional gradient method (Eyring et al., 2003). More research has to be carried out, to determine the reasons for this is beyond the scope of this paper.

5 Discussion

The simulation of streamers in the FUB-CMAM is in very good agreement with most of the streamer observations to date (Offermann et al., 1999; Riese et al, 1999; Manney et al., 2000; Manney et al., 2001). It can be shown with this model study that stratospheric streamers (Offermann et al., 1999) occur preferentially at higher altitudes in the stratosphere in contrast to filaments/laminae, which were mainly observed in regions between 18–22 km height (e.g. Reid and Vaughan, 1991). Therefore, this streamer climatology cannot be compared with studies which restricted their analyses to filaments or laminae (e.g. Reid and Vaughan, 1991; Reid et al., 1993; Reid et al., 1998; Orsolini and Grant, 2000). Due to limited spatial resolution in the model, filaments/laminae could not be resolved in the experiment. However, it was shown in a case study, that the final stage of a streamer can develop in a filament-like structure, as detected in fine-scale resolution transport studies by e.g. Waugh (1993) and Manney et al. (1998). The stretching and thinning of a tropical-subtropical streamer was found close to the edge of the polar vortex, taken here to be the region where maximum wind speeds with the strongest spatial gradient exist. The theoret-

ical and modeling studies of Appenzeller and Holton (1997) and Manney et al. (1998) found the formation of ozone laminae throughout the stratosphere, which would support the findings of this paper. Manney et al. (1998) suggested three different formation mechanisms for ozone laminae depending on the altitude region of occurrence: in the higher stratosphere for example ozone laminae formed due to the differential advection of trace gases, which was also found in the presented case study. The results of earlier studies (Chen et al., 1994; Waugh, 1996) showing a relation between the occurrence of tropical-subtropical streamers and a shift of the polar vortex towards lower latitudes were confirmed with this study. In the process study, the "formation" of tropical-subtropical streamers was found to be higher anti-correlated with the meridional wind components and an equatorward shift of the polar vortex than with an increase of the zonal wind component and the zonal wave numbers-1 and -2.

When comparing this study to other streamer climatologies (Langbein et al., 2001; Eyring et al., 2003), a good correspondence between the general distribution of streamers is found only when a similar criterion method was chosen. The method used to identify streamers determines to a large extent the results of the climatology. In this study, the streamer climatology based on the method of zonal anomaly, was the best approach to identify streamers in the horizontal plane. Nevertheless, method deficiencies due to an artificial counting of streamers can arise in regions with strong horizontal gradients in the passive tracer field: (a) the tropical tropopause region due to a too cold and high tropical tropopause in the model; (b) the subtropics and (c) the polar vortex edge. These artifacts are visible through an enhanced zonal band in the relative frequency field, which did not effect the region of comparison (20–70° N/S). Another explanation for the deviations could be the use of different passive tracers in the different model studies. Langbein et al. (2001) and Eyring et al. (2003) used chemical N_2O fields in contrast to the idealized, zonally stratified passive tracer without any sources and sinks in this model study.

The higher occurrence of tropical-subtropical streamers compared to polar vortex streamers indicates, that the subtropical barrier is more permeable than the polar vortex barrier in the T42 FUB-CMAM. This model behaviour is in very good correspondence with observed characteristics of the transport barriers (e.g. Plumb, 2002; Neu et al., 2003). In this model study and in CRISTA observations polar vortex streamers seem to be weaker phenomena than tropical-subtropical streamers. The use of a constant threshold number during one winter season could therefore have impacted the detection of stratospheric streamers. Testing the passive tracer fields for the start and the end points of the advection periods reveal a loss of the maximum tracer concentrations of up to 20% at high latitudes in dynamical perturbed winters, which could result in a less readily detection of polar vortex streamers at the end of them. Future investigations of the occurrence of streamer-like and filament-like structures based

on data with higher vertical and horizontal resolutions would benefit from using a combination of the vertical gradient and zonal anomaly method.

It should be noted that possible model deficiencies could also have an effect on the reliability of the results: the model climatology; the quality of the transport scheme; the use of an idealized zonally stratified tracer and the lower spatial resolution of the FUB-CMAM compared to high resolution transport calculations (e.g. Norton, 1994).

6 Summary

To investigate the influence of large-scale structures on the variability of transport processes in mid-latitudes, a global streamer climatology for 10-years was calculated using the FUB-CMAM with increased horizontal resolution. Unique to this study, the streamer climatology was divided into tropical-subtropical and polar vortex streamers, using a full climate middle atmosphere model including the troposphere, stratosphere and mesosphere.

Stratospheric streamers are regularly simulated with the FUB-CMAM and are in good correspondence with the observed features to date. They are characterized as having more than 10–20 km thickness in the vertical, a width between 500 to 2000 km and a length of more than 10 000–20 000 km during the development stage. They can even span a whole latitudinal belt, as was also analysed for polar vortex filaments by e.g. Waugh et al. (1994a) and Manney et al. (2001). Their duration is between 1–3 weeks and they decay in 1–2 weeks in the model simulations, which is in good agreement with CRISTA observations. Stratospheric streamers have thus to be distinguished from filaments/laminae, defined after Reid and Vaughan (1991). However, a streamer can eventually develop into a filament-like structure (e.g. Waugh, 1993; Manney et al., 1998).

An overall result of the streamer climatology is that tropical-subtropical streamers have a higher frequency than polar vortex streamers. This result indicates that the subtropical barrier is more permeable than the polar vortex barrier in the model, which is in good correspondence with observations (e.g. Neu et al., 2003). During the existence of the Arctic polar vortex, the maximum occurrence of tropical-subtropical streamers is up to 30% per 10 years during winter and spring in the middle and upper stratosphere of the NH, where the ultra-long planetary waves are intensified. Synoptic maps reveal two maxima in the subtropics, one over East Asia and the other over the Atlantic.

Interesting for total ozone concentrations in mid-latitudes are tropical-subtropical transport processes in the lower stratosphere, which are likely to play a significant role in its observed negative trend (e.g. WMO, 2003; Grewe et al., 2004). It is found, that the transport out of the tropics is greater in the middle stratosphere than in the lower stratosphere, as was also observed by e.g. Chen et al. (1994) and Waugh (1996). Our investigation of the lower stratosphere revealed the highest occurrence of up to 10% in 10 years of tropical-subtropical streamers from October to February over East Asia/Pacific with a secondary maximum over the Atlantic. These results are in good correspondence with assimilations from the 1990s, if a similar streamer criterion is chosen (Langbein et al., 2001). Observational based studies showed an increase of ozone minima over Europe in the lowermost stratosphere since the late 1980s, indicating an increase of subtropical air intrusions into mid-latitudes over Europe (Reid et al., 2000; Bojkov and Balis, 2001), which was confirmed by the study of Koch et al. (2002).

When interpreting these results one has to bear in mind, that the model generaly simulates weak easterly winds in the tropical lower stratosphere. During the easterly phase of the QBO a steeper subtropical tracer isoline slope is observed suggesting a suppressed role of isentropic mixing by eddies particularly in the lower stratosphere (Gray and Russell III, 1999). The same authors also showed a distinct difference between lower and middle stratosphere transport processes in the subtropics with the latter showing an increasing role of isentropic mixing at higher levels which is in good correspondence with the main findings of this paper.

Further observational and modeling studies are needed to understand more about the role of streamers in contrast to filaments/laminae in the stratosphere and in particular their role on the observed mid-latitude ozone decrease. Of particular interest would be to investigate the occurrence of such streamers in transient climate simulations to detect possible trends and influences on the mid-latitude total ozone distribution. An earlier model study with the FUB-CMAM investigating past and present climate changes due to prescribed stratospheric ozone decrease and greenhouse gas increases (Langematz et al., 2003) did not show a statistically significant increase in planetary wave activity, which would have an impact on the occurrence of stratospheric streamers. Until now, a reliable prediction of planetary wave activity and possible future trends for the inter-annual variability during Arctic winter is not feasible, given the large spread in the results of future simulations with coupled chemistry climate models (WMO, 2003).

This study used a new approach, separating stratospheric streamers (broad, large-scale, tongue-like structures) of trace gases or potential vorticity from filaments/laminae (thin, smaller-scale, finger-like structures) first detected in ozonesonde profiles. Specific transport climatologies based on observations have concentrated on the effect of transport processes induced by smaller-scale phenomena. In the 10-year climatology, stratospheric streamers are regularly simulated with the FUB-CMAM and are in good correspondence with the so far observed features. Tropical-subtropical streamers mark the entry of ozone-poor air from the tropics into mid-latitudes in the lower stratosphere. Polar vortex streamers mark the entry of chemically processed

air from polar into mid-latitudes in the stratosphere above $\sim$20 km altitude. Considering only the meridional "passage" from subtropical and polar air masses, these processes can significantly contribute to the observed total ozone trend in mid-latitudes since the 1980s (Fioletov et al., 2002), as was shown with ozone measurements over two Swiss stations in mid-latitudes (Calisesi et al., 2001; Koch et al., 2002). According to the frequent, spatial occurrence of stratospheric streamers presented in this model study, our results imply that streamers are likely to play a non-negligible role in determining horizontal transport processes in the stratosphere and can therefore impact total ozone decrease in mid-latitudes.
