## Abstract

Precise knowledge of the angle between the meteor vector velocity and the radar beam axis is one of the largest source of errors in the Arecibo Observatory (AO) micrometeor observations. In this paper we study  $\sim 250$  high signal-to-noise ratio (SNR) meteor head-echoes obtained using the dual-beam 430 MHz AO Radar in Puerto Rico, in order to reveal the distribution of this angle. All of these meteors have been detected first by the radar first side lobe, then by the main beam and finally seen in the side lobe again. Using geometrical arguments to calculate the meteor velocity in the plane perpendicular to the beam axis, we find that most of the meteors are travelling within  $\sim 15^\circ$  with respect to the beam axis, in excellent agreement with previous estimates. These results suggest that meteoroids entering the atmosphere at greater angles may deposit their meteoric material at higher altitudes explaining at some level the missing mass inconsistency raised by the comparisson of meteor fluxes derived from satellite and radar observations. They also may be the source of the observed high altitude ions and metallic layers observed by radars and lidars respectively.

## 1. Introduction

The Arecibo Observatory (AO) 430 MHz radar detects  $\sim 10\,000$  events daily, and measures their radial velocity with great accuracy. We obtain this high accuracy by measuring the Doppler shift of the meteor head-echoes, which are radar reflections from a plasma travelling with the meteoroid. The largest source of error in these observations arises from the lack of precise knowledge of the position of the meteoroid as it flies through the 305 m diameter radar beam, and their exact angle of entry. Very precise Doppler measurments of the line-of-sight meteor velocity give estimates with less than 1% errors for radial velocities between a few km/s to  $\sim 70$  km/s. We have argued in the past, based on dynamical arguments and geocentric meteor velocity measurments (Meisel et al., 2002; Janches et al., 2003), that, although unknown, the relative angle

between the radar beam and the meteoroid vector velocity must be small, less than  $15^\circ$ . We will refer to this angle as the meteor off-axis angle for the rest of this paper. Ongoing theoretical studies of the altitude at which micrometeor initial ablation occurs (Janches and ReVelle, 2003) show that if micron-sized particles travel at angles larger than  $\sim 30^\circ$  with respect to the vertical, then the ablation will begin at higher altitudes before reaching the small AO radar volume. Knowledge of this angle is crucial for the precise radiant determination needed for orbital calculations (Janches et al., 2001; Meisel et al., 2002). A small error will also be introduced in our meteoroid size estimates (Janches et al., 2000b) and calculations of meteoric mass flux into the upper atmosphere due to these meteoroids (Mathews et al., 2001; Raizada et al., 2003). These issues will be discussed in more detail later in this paper.

Figure 1 shows velocity distributions obtained at AO with the dual-beam radar system during the 04:00–06:00 hr AST interval of 21 January 2002. Although our observations covered the whole night, we present and discuss only the distributions between 04:00 and 06:00 hrs AST, the period during which the meteor rate detected by the AO radar is maximum ( $\sim 40$  events per minute; Janches et al., 2003) and the result reported here is clearest. The high event rate is due to the fact the AO radar points towards the so-called apex, the direction of the Earth's motion in its orbit around the Sun, where particles caught by the Earth, as well as head-on collisions, are present, unlike the antapex direction where a particle must travel sufficiently fast to reach the Earth from behind in its orbit (Janches et al., 2000a). The “North” (Fig. 1a) velocity distribution was detected by the AO Gregorian feed (GF) when it was pointed  $15^\circ$  from the zenith looking north of AO and the “South” distribution (Fig. 1c) was obtained when the antenna was pointed  $15^\circ$  from the zenith looking south of AO. Figure 1b shows the distribution from the detections of the line feed (LF) looking vertical at AO. The complete description of these velocity distributions is presented in Janches et al. (2003). From these figures the dependence of the distribution shape with topocentric declination (which is a function of radiant ecliptic latitude) can be seen. While the “North” velocity distribution has a single peak, the “South” distribution is clearly bimodal with very few events with velocities of

the order of 30 km/s. The “Vertical” distribution seems to be a mixture of the “North” and “South”, where the bimodal characteristics are still present, but with some 30 km/s objects. As pointed out in [Janches et al. \(2003\)](#), these differences in the distributions as well as the lack of events with velocities of the order of 30 km/s cannot be due to an instrumental bias, because we are using the same instrument (the GF) to monitor two different areas of the sky. If the absence of meteors were due to an instrumental bias, then the effect should be present in both the “North” and “South” distributions.

In order to further explore this issue, we performed a simple simulation where uniform random distributions in meteor vector velocity are assumed. We then calculate the line-of-sight velocity for the different pointing directions presented in Fig. 2. Note that the “North” and “South” simulated velocity distributions are identical, while the “Vertical” distribution decreases with increasing velocity. It is deduced from this simulation that the particles that produced the meteors detected at Arecibo are not traveling in random directions and that for each pointing direction there is a preferred radiant distribution. We suggest the scenario where a filtering effect occurs in which, for a particular pointing direction, the radar detects mainly particles with vector velocities within a narrow angular range with respect to the beam axis. In the next section we describe the methodology used to determine an upper limit to this angular range. We present and discuss the results in Sect. 3 and explore the posibles causes of this effect and give the major implications on our general micrometeor results.

## 2. Methodology

For this study, we use a sample of 265 (out of ~40 000) radar meteor head-echoes that show the largest (<1000) signal-to-noise ratio (SNR) detected at AO during the nights of 21 January and 25 June 2002. Figure 3 displays the range-time-intensity (RTI) plot of one of these events. Note that the meteor return in this figure shows three parts. The first and last part are the return detected by the radar first diffraction lobe while the middle and strongest part is the detection of the meteor while traveling through the

main beam. All the meteors in the subset discussed here show this characteristic. If we assume that the meteor travels through the center of the main beam (Fig. 4) we can calculate from the duration of the event how long it took to cross the length of the main beam ( $\sim 300$  m). From this calculation, we can estimate the largest tangential velocity that the meteor would have as

$$V_T = \frac{0.3 \text{ km}}{T_{MB}}, \quad (1)$$

where  $V_T$  is the tangential velocity and  $T_{MB}$  is the duration of the meteor in the radar main beam. The estimation of the meteor off-axis angle is trivial once we know the tangential and radial component of the meteor velocity and is given by

$$\alpha = \tan^{-1}\left(\frac{V_T}{V_r}\right), \quad (2)$$

where  $V_r$  is the radial velocity. Note that if the meteor does not travel through the center of the main beam, then the distance it travels is shorter hence the tangential velocity appears artificially higher and  $\alpha$  is smaller too: that is why this estimate represents the upper limit for the off-axis angle.

### 3. Discussion

The distribution of estimated meteor off-axis angles from the methodology described in the previous section is presented in Fig. 5 (red dashed line). This histogram contains 265 events discussed in this paper. A gaussian curve is fitted to the distribution and is given by

$$f(\alpha) = A_0 \times \exp\left(-\frac{(\alpha - \bar{\alpha})^2}{\sigma^2}\right),$$

where  $\bar{\alpha}$  is the mean angle and  $\sigma$  is the standard deviation. The fitted parameters for the curve presented in Fig. 5 are given in Table 1. In addition, Table 1 shows the fits

for the data sets with same radar pointing characteristics. The results presented in Table 1 show that, independently of antenna feed or radiant observed, the detected angular distribution is identical for the three directions and both feeds, suggesting that there is a filtering process which prevents particles with large off-axis angles to reach the radar volume between the 80 and 120 km of altitude. Figure 6 (red dashed line) displays the meteors per unit solid angle. This figure suggests that AO cannot detect meteors with small off-axis angle ( $<7^\circ$ ) which makes no physical sense. This effect is an artifact of the assumption that all the events are travelling through the radar beam center. In order to correct for this effect, we perform a further correction by randomly choosing the meteor position within the radar beam. The results of this correction are shown in both Figs. 5 and 6, as solid black lines. Gaussian curves were also fitted to these results and their parameters are presented in Table 1. We can see from Fig. 5 that for the corrected distribution the average off-axis angle is  $15^\circ$ . Taking the 1/e point in the gaussian curve (black solid line) in Fig. 6, which looks as expected, we can estimate that most of the events are within  $15^\circ$  the radar beam axis.

We now explore the different causes that could produce this effect. We first note that a particle traveling at  $\sim 50$  km/s at an off-axis angle of  $90^\circ$  will spend  $\sim 6$  ms inside the AO radar main beam. Since the IPP used in our observations is 1 ms, there is no reason why these events should fly undetected through the beam. In fact, we measure a small sample of meteors which show low line-of-sight velocities and short durations and possibly some of these events are fast particles crossing the beam perpendicularly. However, it is difficult to distinguish between meteors and space debris when the line-of-sight velocity is lower than the Earth's escape velocity (11.2 km/s). An other possibility is that the head echo is aspect sensitive, that is the radar return is stronger for meteor traveling at low off-axis angles. However, Close et al. (2002) reported for the first time high polarization ratio measurements of meteor head-echoes utilizing ALTAIR, suggesting that the meteor head-echo is approximately spherical in shape (i.e. the radar cross section is isotropic). Theoretical results reported by Janches and ReVelle (2003) present the initial ablation altitude dependence with meteoroid entry angle

given by the meteor energy equation approximated for small particles (Whipple, 1951; Ceplecha et al., 1998). They calculate the altitude dependence of absolute meteor velocity and find good agreement with the AO observations for off-axis angles lower than  $30^\circ$ . The results presented here are in excellent agreement with those results and previous estimates using dynamical arguments (Meisel et al., 2002). If this is the dominant case, then the filtering effect is produced mainly because particles with large off-axis angle would interact with sufficient atmosphere so that they ablate or stop before reaching the small radar volume centered at  $\sim 100$  km of altitude. This would imply that a portion of the incoming meteoric material is ablated and deposited at higher altitudes than the so called meteor ablation zone. Estimation of the meteoric mass detected by the AO radar gives  $\sim 2000$  tons per year over the whole Earth for particles in the  $0.5\text{--}100\ \mu\text{m}$  size range (Mathews et al., 2001; Raizada et al., 2003). This estimate raised some controversies since it is lower than a widely used estimate given by Love and Brownlee (1993) but in better agreement, although still lower than other estimates (Ceplecha et al., 1998; Rietmeijer, 2000). For the same particle mass range detected at AO ( $10^{-5}\text{--}10\ \mu\text{g}$ ), these estimates were mainly derived from satellite measurements which are much higher ( $\sim 500$  km) than the altitudes at which radar meteor activity is maxima ( $\sim 105$  km). Hughes (1978) showed that there is a large discrepancy between the rates detected by satellite and by classical meteor radars. If a portion of the meteor influx is deposited at high altitudes as these results suggest, then it could explain at least at some level the missing mass discrepancy raised by the comparison between conventional meteor radars and satellite measurements. In addition, Tepley et al. (2003) report lidar observations of  $\text{Ca}^+$  layers at altitudes near 120 km which are correlated to Ne layers observed with the AO radar in ISR mode, and appear to be descending from above this zone. Höffner and Friedman (2004) report lidar measurements at high altitude ( $>110$  km) K, Ca,  $\text{Ca}^+$ , Fe and Na layers. The authors note that despite the different seasonal characteristics between the different low altitude metallic layers, these high altitude ones show similarity along the year and different locations and they are likely formed from direct meteoric deposition. Given all these facts, we are

led to conclude that micron-sized particles which enter the atmosphere at large angles will ablate at higher altitudes and could be regarded to some degree as the source for the ions which produce the descending layers and high altitude metallic layers.

[Chau and Woodman \(2003\)](#) using observations performed with the Jicamarca radar at 50 MHz showed that the detected particles have radiants within a narrow angular range around the apex direction. [Sulzer \(2004\)](#) confirm these results using regular incoherent scatter radar of the ionosphere performed at Arecibo. This “preferred” directionality on the meteor radiant distribution helps also explaining at some degree the differences observed in the meteor geocentric velocity distributions resulted from AO observations (Fig. 1 [Janches et al., 2003](#)) in the sense that the “South” distribution results from observing close to the ecliptic plane right into the meteor flow, while the “North” distribution is the same flow but shifted by a cosine factor. However, the dependency of the hourly meteor rate with ecliptic latitude reported by [Janches et al. \(2003\)](#) suggests that the difference are more likely from a combination of both effects argue here, atmospheric filtering and geometrical, as well as additional characteristics of the dust distribution at 1 AU. Finally, due to the pointing characteristics of the AO system during the observations presented here, the “South” distribution represents absolute velocities and the bi-modal characteristics suggests the presence of two populations of particles in the AO detections: a slow and less dominant with asteroidal orbital characteristics and a faster and more dominant, which orbits are mainly retrograde ([Janches et al., 2001](#)). The fast distribution can either be the results of particles of cometary origin or small charged particles that have been accelerated by electromagnetic effects with the interplanetary magnetic field ([Morfill and Grün, 1979](#); [Janches et al., 2001](#)). In any case, the fundamental result of this paper is that for a particular pointing direction, events are travelling within a narrow angular distribution with respect to the beam axis, and that the lack of knowledge of the precise path of the particles through the very narrow AO 430 MHz beam does not introduce significant error to our dynamical mass estimates or our orbital results ([Janches et al., 2001](#); [Meisel et al., 2002](#)).

## 4. Conclusions

In this paper we presented  $\sim 250$  high signal-to-noise (SNR) ratio meteor head-echoes observations obtained using the dual-beam 430 MHz Arecibo Observatory (AO) Radar in Puerto Rico. Using the known diffraction pattern of the telescope, we applied a geometrical calculation in order to estimate the distribution of the meteor off-axis angle (i.e. angle between the vector velocity and the radar beam axis). We find that meteors mostly travel with radiants within  $\sim 15^\circ$  with respect to the radar beam axis, in excellent agreement with previous estimates. This uncertainty does not introduce significant error to our general results of meteoric mass estimates and orbital characteristics of the dust.

D. Janches et al.

**Fig. 3.** Range-time-intensity (RTI) plot showing a meteor event that begins at  $\sim 93$  km and shows a range extent that corresponds to the  $45 \mu\text{s}$  uncoded radar pulse. The interpulse period (IPP) is 1 ms and the sample rate is  $1 \mu\text{s}$  (150 m). The red line is a representation of the radar beam pattern indicating when the meteor crosses the side lobes or the main beam.

**Radiant distribution  
of micrometeors**

D. Janches et al.

**Fig. 4.** A cartoon representing the radar beam seen from above and a meteor crossing the beam through the center. The red part of the meteor path represents the portions of the meteor that are detected by the radar while the black ones are the interval when no return was recorded. See Fig. 3.
