## Abstract

The volatile organic compound (VOC) emission rates of Scots pine (*Pinus sylvestris* L.) were measured from trees growing in a natural forest environment at two locations in Finland. The emission rate measurements were carried out using a dynamic flow through technique with samples collected on adsorbent tubes and analyzed using thermodesorption followed by a gas chromatograph with a mass-selective detector (GC-MS). The standard emission potentials (at 303.15 K and  $1000 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ ) were calculated for the measured compounds using non-linear regression to fit the experimental data to temperature and light dependent emission algorithms.

The observed total VOC emission rates varied between 21 and 874 ng/g(dw)\*h and 268 and 1670 ng/g(dw)\*h in southern and northern Finland, respectively. A clear seasonal cycle was detected with high emission rates in early spring, a decrease of the emissions in late spring and early summer, high emissions again in late summer, and a gradual decrease in autumn.

The main emitted compounds were  $\Delta^3$ -carene (southern Finland) and  $\alpha$ - and  $\beta$ -pinene (northern Finland), with approximate relative contributions of 60–70% and 60–85% of the total observed monoterpene emission rates, respectively. Sesquiterpene ( $\beta$ -caryophyllene) and 2-methyl-3-buten-2-ol (MBO) emissions were initiated in early summer at both sites. The observed MBO emission rates were between 1 and 3.5% of the total monoterpene emission rates. The sesquiterpene emission rates varied between 2 and 5% of the total monoterpene emission rates in southern Finland, but were high (40%) in northern Finland in spring.

Most of the measured emission rates were found to be well described by the temperature dependent emission algorithm. The calculated standard emission potentials were high in spring and early summer, decreased somewhat in late summer, and were high again towards autumn. The experimental coefficient  $\beta$  ranged from 0.025 to 0.19 (average 0.10) in southern Finland, with strongest temperature dependence in spring

and weakest in late summer. Only the emission rates of 1,8-cineole were found to be both light and temperature dependent. However, there were irregularities with the performance of the exponential temperature algorithm, and our results suggest that especially during the spring recovery period of the vegetation there may be several different processes contributing to the VOC emissions of Scots pine.

## 1. Introduction

Scots pine (*Pinus sylvestris* L.) is one of the most common tree species in the boreal forests, and e.g. in Finland its volatile organic compound (VOC) emissions dominate the annual biogenic VOC emissions (Lindfors and Laurila, 2000; Lindfors et al., 2000). The monoterpene emission characteristics of Scots pine have been described in several studies (Janson, 1993; Rinne et al., 1999, 2000; Staudt et al., 2000; Janson et al., 2001; Komenda and Koppmann, 2002). Janson and de Serves (2001) have also measured high acetone emission rates from Scots pine. So far sesquiterpenes have not been detected in the emissions of Scots pine although other boreal tree species, such as Norway spruce (*Picea abies* L.) and Downy birch (*Betula pubescens* L.) emit large amounts of sesquiterpenes during summer (Hakola et al., 2000, 2003). 2-methyl-3-buten-2-ol (MBO) has been observed to be a main component in the air in a pine forest in Colorado (Goldan et al., 1993). Harley et al. (1998) have also measured high MBO emission rates from the needles of several pine species but it has not previously been reported in the emissions of Scots pine in boreal forests.

Once emitted, both sesquiterpenes and MBO are very reactive, the sesquiterpenes especially so, with an atmospheric lifetime of only a few minutes so that they can not be measured in ambient air samples (Hakola et al., 2000, 2003). In daytime, the main sink of MBO is assumed to be the reaction with OH radicals but it also reacts with ozone and nitrate radical, producing acetone, aldehydes, formic acid, and organic, carbonyl and peroxy nitrates (Finlayson-Pitts and Pitts, 2000, and references therein) thus affecting local photochemistry and atmospheric ozone formation. Sesquiterpenes react read-

ily with atmospheric ozone, and they have a high potential to form secondary organic aerosol (Hoffmann et al., 1997; Jaoui et al., 2003). Bonn and Moortgat (2003) suggest that sesquiterpene ozonolysis could be involved in the atmospheric new particle formation observed frequently in several locations including Hyytiälä, Finland (Mäkelä et al., 1997; Boy and Kulmala, 2002). The new particle formation and growth processes are, however, probably uncoupled (Kulmala et al., 2000), and the oxidation products of the sesquiterpenes are expected to mainly affect the growth of the particles (see, e.g. Kulmala et al., 2004). Sesquiterpenes also affect tropospheric ozone concentrations, by participating in ozone formation when enough nitrogen oxides are present or acting as ozone sink in a very clean environment, where some of the ozone deposition may be attributed to sesquiterpene reactions (Kurpius and Goldstein, 2003). Currently, the sesquiterpene emission rate data of boreal tree species is very limited.

We have measured the VOC emission rates of Scots pine in two locations in Finland. The seasonal development of the emissions was studied over a period of six months. Also the sesquiterpene and MBO emission rates were measured. The light and temperature dependence of the emissions was studied by darkening experiments and by fitting the experimental data to the light and/or temperature dependent emission algorithms commonly used in biogenic emission modelling (Guenther et al., 1993; Guenther, 1997).

## 2. Materials and methods

The VOC emission rates of Scots pine (*Pinus sylvestris* L.) were measured in southern Finland in Hyytiälä (61°51' N, 24°17' E) and in the Finnish Lapland in Sodankylä (67°22' N, 26°39' E). In Hyytiälä the measurements were carried out from March to October in 2003. During the QUEST II (Quantification of Aerosol Nucleation in the European Boundary Layer) campaign (24 March to 14 May 2003) the emission rates were measured daily in the afternoon. Several samples were usually taken per measurement session at 30 min to 2 h intervals. During three intensive campaign days the

measurements were conducted during the whole day. After the campaign the emission rates were measured during 1–2 days every month until October 2003. We also conducted experiments where the plant was covered from light. The measured tree was growing in a natural forest environment, with an average tree height of 14 m. The samples were collected at a height of about 11 m. The measured branch received direct sunlight only for a couple of hours in a day. Altogether 132 regular samples (no artificial light conditions) were taken during the measurement period. In Sodankylä the VOC emissions of Scots pine were measured in spring and early summer 2002. The measurements were carried out during five days, starting at the end of April and continuing until the beginning of June, with a total of 22 samples. The tree measured in Sodankylä was younger than the one in Hyytiälä, with a height of about 5 m, and it was growing in a sunny forest environment. The same branch was used for the measurements until the tree started to grow new needles, after which a different branch was sampled each time.

The emission rates were measured using a dynamic flow through technique. The measured branch was enclosed in a Teflon cuvette with a volume of approximately 20 l. The cuvette was equipped with inlet and outlet ports and a thermometer. The photosynthetically active photon flux density (PPFD) was measured just above the cuvette. The flow through the cuvette was about 8 l per min. Ozone was removed from the inlet air using MnO<sub>2</sub>-coated copper nets. The samples were collected onto adsorbent tubes simultaneously from both the inlet and outlet ports. The emission rate ( $E$ ) is determined as the mass of compound per needle dry weight and time according to

$$E = \frac{(C_2 - C_1)F}{m} \quad (1)$$

Here  $C_2$  is the concentration in the outgoing air,  $C_1$  is the concentration in the inlet air, and  $F$  is the flow rate into the cuvette. The dry weight of the biomass ( $m$ ) was determined by drying the needles at 75°C until consistent weight was achieved.

The samples were collected on adsorbent tubes filled with Tenax-TA and

Carbopack-B. The sampling time was 30–120 min. The adsorbent tubes were analyzed using a thermodesorption instrument (Perkin-Elmer ATD-400) connected to a gas chromatograph (HP 5890) with HP-1 column (60 m, i.d. 0.25 mm) and a mass-selective detector (HP 5972). Samples were concentrated in the thermodesorption instrument in a cold trap ( $-30^{\circ}\text{C}$ ). The analytical system did not allow the separation of myrcene and  $\beta$ -pinene; their amount was therefore expressed as a sum and quantified as  $\beta$ -pinene. Quantification was achieved with five-point calibration using liquid standards in methanol solutions. Standard solutions were injected onto adsorbent tubes that were flushed with helium (flow 100 ml/min) for 5 min in order to remove methanol. The detection limits for the monoterpenes were 5–20 pptv, depending on the sampling time.

The standardized emission potentials (at 303.15 K and  $1000 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ ) were calculated for the measured compounds using nonlinear regression to fit the experimental data to the temperature and light dependent emission algorithms presented by Guenther et al. (1993) and Guenther (1997).

### 3. Results and discussion

#### 3.1. Observed emissions

In Finland Scots pine has two genotypes that differ in the emitted monoterpene composition. One genotype mainly emits  $\Delta^3$ -carene while the other does not emit  $\Delta^3$ -carene at all (Hiltunen, 1968). The trees measured in the present study turned out to be of different types. The tree growing in Sodankylä emitted no  $\Delta^3$ -carene, and 60–85% of its emission consisted of  $\alpha$ - and  $\beta$ -pinene and myrcene, whereas the emission of the tree measured in Hyytiälä mainly consisted of  $\Delta^3$ -carene (60–70%). The average noontime emission rates observed in Sodankylä and Hyytiälä during their respective measurement periods are presented in Fig. 1.

The observed total VOC emission rates were of the same order of magnitude at both

© EGU 2004

locations, varying between 268 and 1670 ng/g(dw)\*h in Sodankylä and between 21 and 874 ng/g(dw)\*h in Hyytiälä. The very low emissions in Hyytiälä in the beginning of April 2003 (Fig. 1, lower panel) are explained by a cold spell with temperatures close to or below zero during the two days. In general, the emissions observed in Sodankylä were higher than those in Hyytiälä. In Hyytiälä, a clear seasonal cycle was detected with high emission rates in early spring, a decrease of the emissions in late spring and early summer, high emissions again in late summer, and a gradual decrease in autumn.

There were also changes in the composition of the emissions during the measurement period. In Sodankylä, the April emissions were dominated by  $\alpha$ - and  $\beta$ -pinene, with approximate relative contributions of 35% and 40% of the observed total monoterpene emission rates, respectively. In May and June the contribution of  $\beta$ -pinene was reduced to the 5% level, while  $\alpha$ -pinene remained the most abundant emitted compound (55–80%) throughout the measurement period. In Hyytiälä, the contribution of  $\alpha$ -pinene was at the 10% level in early spring, after which it doubled and stayed around 20% until October. The contribution of  $\Delta^3$ -carene, on the other hand, was approximately 70% in March and April, after which it dropped slightly, and was around 60–65% during the rest of the measurement period.

In the early summer, sesquiterpene ( $\beta$ -caryophyllene) and 2-methyl-3-buten-2-ol (MBO) emissions were detected at both sites, although the emission rates were very low. In Sodankylä the MBO emission rates were approximately 1–2% of the total monoterpene emission rates, and in Hyytiälä, they stayed between 2–3.5% of the total monoterpene emissions from the onset of the emissions until the cessation in September. The observed  $\beta$ -caryophyllene emission rates, on the other hand, were about 40% and 2% of the observed total monoterpene emission rates in June in Sodankylä and Hyytiälä, respectively. Later in summer the  $\beta$ -caryophyllene emissions in Hyytiälä were slightly higher, reaching approximately 5% of the observed total monoterpene emissions in August. The sesquiterpene emissions in Hyytiälä also ceased in September.

### 3.2. Light dependence of emissions

To study the light dependence of the monoterpene emissions of Scots pine we conducted an experiment in which the measured branch was covered from light and samples were collected from the darkened cuvette. The experiment was started at 7 a.m. on 7 August. Hourly emission samples were first collected from the selected branch under normal light conditions during the day. The cuvette was covered from light at 6.30 p.m. and sampling was continued throughout the night and for several hours after the removal of the cover at 7 a.m. on 8 August.

The emissions measured during the experiment are shown in Fig. 2. The emission rates of all monoterpenes had already decreased from the high midday values when the cuvette was darkened and they continued to do so also in the complete darkness (Fig. 2, upper panel), but only the emissions of MBO and 1,8-cineole disappeared almost completely (Fig. 2, lower panel). The  $\beta$ -caryophyllene emission rates, on the other hand, stayed at the approximate average level of the rates measured when the cuvette was receiving light (Fig. 2, lower panel). After the cover was removed, however, both the MBO and  $\beta$ -caryophyllene emission rates rapidly increased to quite high values for a few hours before adjusting approximately to the level of the previous day. The 1,8-cineole emission rates also recovered after the cover was removed, but there was no sudden emission burst. The MBO emissions increased immediately after removing the cover, whereas the  $\beta$ -caryophyllene emissions started to increase about an hour later together with the 1,8-cineole emissions.

The results of this experiment suggest that MBO emission rates may be dependent on the light intensity as well as the temperature, as proposed by Harley et al. (1998). This could also be true for the 1,8-cineole emissions, but assuming the stomata will close in the darkness, the outcome of the experiment could also mean that some of the compounds are released to the atmosphere through the stomata. Thus the rapid burst of some of the compounds immediately after removing the cover could be explained by the sudden opening of the stomata when exposed to light.

### 3.3. Calculated emission potentials

As the darkening experiment did not yield conclusive evidence of the light dependence of the emissions, the existence of dependencies was further studied using emission modelling techniques.

When modelling the biogenic VOC emissions for e.g. emission inventory purposes or for local photochemistry studies, two mechanisms are generally considered: the temperature controlled volatilization of hydrocarbons from storage pools inside the leaf (Ciccioli et al., 1997; Guenther et al., 1993; Hauff et al., 1999; Lamb et al., 1985; Schuh et al., 1997), and the direct emissions of newly synthesized hydrocarbons, which are under enzymatic control and strongly dependent on leaf temperature and light intensity (e.g. Monson et al., 1995). Monoterpenes are usually described as storage pool emissions, while isoprene is thought to be emitted directly after the synthesis and not stored inside the plant. However, several authors have reported both light and temperature controlled emissions of terpenoids other than isoprene from some plant species, including Scots pine (e.g. Hansen and Seufert, 2003; Shao et al., 2001; Schuh et al., 1997; Staudt et al., 1997; Steinbrecher and Hauff, 1996; Steinbrecher et al., 1999; Seufert et al., 1997; Komenda et al., 1999).

In this work we have calculated the emission potentials of Scots pine in Sodankylä and Hyytiälä by fitting the experimental data to the temperature and light dependent emission algorithms proposed by Guenther et al. (1993) and Guenther (1997). The observed emission rate ( $E$ ) is parameterised as

$$E = \gamma E_0, \quad (2)$$

where  $E_0$  is the emission rate at standard conditions (303.15 K, 1000  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ), henceforth called the standard emission potential, and  $\gamma$  is a non-dimensional environmental correction factor which includes the effects of temperature and light conditions.

For pool emissions the environmental correction factor is (Guenther et al., 1993)

$$\gamma_P = \exp(\beta(T - T_S)). \quad (3)$$

Here  $T$  (K) is the leaf temperature and  $T_S$  is the leaf temperature at standard conditions.  $\beta$  is an empirical coefficient, which is usually set at 0.09 (Guenther et al., 1993). In this work, however, we carried out nonlinear regression in order to fit also the  $\beta$  coefficient individually for each compound.

The environmental correction factor for the direct emissions of newly synthesized compounds is of the form

$$\gamma_S = C_T C_L, \quad (4)$$

where  $C_T$  is the temperature correction and  $C_L$  is the light correction. These are parameterised as (Guenther, 1997)

$$C_L = \frac{\alpha C_{L1} L}{\sqrt{1 + \alpha^2 L^2}} \quad (5)$$

$$C_T = \frac{\exp([C_{T1}(T - T_S)]/RT_S T)}{C_{T3} + \exp([C_{T2}(T - T_M)]/RT_S T)}. \quad (6)$$

Here again  $T$  (K) is the temperature and  $T_S$  is the standard temperature.  $L$  is the photosynthetically active photon flux density (PPFD,  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ),  $R$  is the universal gas constant, and  $C_{L1}$ ,  $C_{T1}$ ,  $C_{T2}$ ,  $C_{T3}$ ,  $T_M$  and  $\alpha$  are empirical constants given by Guenther (1997).

To obtain the standard emission potentials the measured emission rates were fitted to both the temperature dependent pool algorithm (Eq. 3) and the combined light and temperature dependent algorithm (Eq. 4) using nonlinear regression. Since not only the emission rates but also the spectrum of the emitted compounds showed significant variation during the measurement period, the data from Hyytiälä was divided into seasonal data sets according to the average thermal seasons. In the southern parts of

Finland thermal spring (defined as the period with the smoothed daily average temperature between 0 and +10C) usually starts in late March and lasts until early May, while thermal summer (daily average temperature above +10C) extends from mid-May to September, according to the statistics of the Finnish Meteorological Institute. In this analysis the summer period was further divided into early (20 May through 11 June) and late (24 June through 8 August) summer. The rest of the measurements (9 September through 15 October) were considered to represent autumn. The data from Sodankylä, on the other hand, was so sparse and scattered that no seasonal grouping was possible, and thus each month was treated separately.

Most of the measured emission rates were well described by the temperature dependent pool algorithm (Eq. 3), whereas the combined temperature and light algorithm (Eq. 4) generally performed poorly in the nonlinear regression analysis. The standard emission potentials obtained by fitting the temperature algorithm to the spring, early summer, late summer, and autumn data from Hyytiälä, with the corresponding  $\beta$  coefficient values and the nonlinear regression statistics are given in Table 1. The standard emission potentials obtained by fitting the temperature algorithm to the April, May and June data from Sodankylä with the  $\beta$  coefficient values and regression statistics are given in Table 2. Only nonzero measured emission rates were included in the analysis. Also cases where the regression statistics are poor are shown in order to facilitate an evaluation of the performance of the algorithm during different seasons and with different compounds.

According to the results, the temperature algorithm was not as successful in describing the spring emissions as those during the other seasons in Hyytiälä. In Sodankylä there are so few data that one should be very careful in evaluating the applicability of the algorithm based on this analysis, but also there the performance of the algorithm improves towards summer. It is quite probable, in fact, that in addition to the temperature there are other processes during the spring recovery period of the vegetation, perhaps related to the plant developmental stage or the environmental conditions (e.g. strong irradiance in connection with rather low temperatures and low water availability),

**VOC emissions of  
Scots pine**

© EGU 2004

which also affect the emission patterns (Bäck et al., in preparation, 2004<sup>1</sup>).

In addition to the general tendency of poor spring performance, there are also differences related to the different compounds. For example in Hyytiälä limonene is extremely poorly described in spring and early summer while the algorithm performs reasonably well in predicting limonene emissions in late summer and autumn.  $\beta$ -phellandrene, on the other hand does not seem to be captured by the algorithm at all, and its performance with sabinene and terpinolene becomes poorer as the summer progresses. However, these compounds are only minor constituents of the total monoterpene emission and their emission data are therefore more uncertain, bringing an added uncertainty also to the nonlinear regression analysis.

In general it can be said that for most of the modelled monoterpenes, the standardized emission potentials were high in spring and especially early summer, decreased somewhat in late summer, and were high again towards autumn. This type of seasonal behaviour with higher spring emission potentials has also been observed elsewhere (Janson, 1993; Komenda and Koppmann, 2002).

In Hyytiälä the  $\beta$  coefficient values obtained for the different compounds ranged from 0.025 to 0.19, with an average of 0.10 (Table 1). The average value is close to the empirical value 0.09 which is usually assigned to the coefficient in biogenic emission modelling studies (Guenther et al., 1993; Guenther, 1997). The highest coefficient values, indicating the strongest temperature dependence, were obtained in early summer (average 0.15), while the dependence was weakest in late summer (average 0.07). In Sodankylä the coefficient values were between 0.036 and 0.56, with an average of 0.14 (Table 2).

Harley et al. (1998) have reported high emission rates of MBO from several pine species. They also found that these emissions were both temperature and light dependent, whereas in this study the MBO emissions appear to be well described by the

<sup>1</sup> Bäck, J., Hari, P., Hakola, H., Juurola, E., and Kulmala, M.: Can the spring-time dynamics of monoterpene emissions in Scots pine needles be related to photorespiration, in preparation, 2004.

temperature dependent pool algorithm ( $R^2$  between 0.78 and 0.98). Fitting the measured MBO data to the combined temperature and light dependent algorithm (Eq. 4) resulted in a very poor agreement ( $R^2$  below 0.10).

The 1,8-cineole emissions measured in Hyytiälä in 2003, on the other hand, were well described by the light and temperature dependent algorithm (Eq. 4), yielding a standard emission potential of  $68 \pm 4 \text{ ng g(dw)}^{-1} \text{ h}^{-1}$  over the whole measurement period ( $R^2$  of 0.84; 14 observations). The 1,8-cineole emissions in Sodankylä in June 2002 were also well described by the temperature and light dependent algorithm (Eq. 4), with a standard emission potential of  $246 \pm 27 \text{ ng g(dw)}^{-1} \text{ h}^{-1}$  ( $R^2$  of 0.80; 3 observations). Thus, we may tentatively identify Scots pine as a light and temperature dependent 1,8-cineole emitter. However, our data is very limited – for example in Hyytiälä cineole was observed in only 14 of the 132 samples, and more measurements are needed, especially in the late summer conditions when the emissions were highest.

In Hyytiälä,  $\Delta^3$ -carene was the main compound emitted by Scots pine throughout the study period. The observed and modelled  $\Delta^3$ -carene emissions for the spring, early and late summer and autumn measurement periods are presented in Figs. 3a and b. Even though the seasonal emissions are rather well predicted by the model based on the simple temperature algorithm (statistics in Table 1), there is some discrepancy, especially in spring. The high emissions of 25 March, in particular, are not captured by the model. As pointed out above, light dependent monoterpene emissions have been found by several authors (e.g. Hansen and Seufert, 2003; Shao et al., 2001; Schuh et al., 1997; Staudt et al., 1997; Steinbrecher and Hauff, 1996; Steinbrecher et al., 1999; Seufert et al., 1997; Komenda et al., 1999). We therefore also applied the light and temperature dependent emission model (Eq. 4) to the  $\Delta^3$ -carene data of 25 March. The results are shown in Fig. 4, together with the predictions of the average seasonally fitted temperature algorithm, and a dedicated temperature algorithm fitted to the data of 25 March only. The light and temperature dependent algorithm (denoted “L, T” in the figure) captures the daily emission cycle rather well ( $R^2$  of 0.89), whereas the dedicated temperature algorithm (T(25/03/2003)) underpredicts the morning and noontime

emissions and overpredicts the afternoon and early evening emissions. However, the standard emission potential given by the dedicated temperature algorithm is too large to be realistic, and the corresponding  $\beta$  coefficient is also very high. The average spring algorithm (T(spring 2003)), on the other hand, is only able to produce one third of the observed daily maximum emission while also overpredicting the late afternoon emissions.

In search for an explanation for this type of sudden emission bursts in spring one could argue that while monoterpenes are usually emitted from storage pools, the pools might be empty after winter, and when the plant starts to synthesize monoterpenes the emission might at first occur in concert with the light dependent production. Then as the season progresses and the pools start to fill, the emission becomes saturated and assumes the more stable temperature dependent pattern. However, our present data is too limited to deduce the origin of this irregular emission behaviour.

Even though the emission burst of 25 March remains unexplained, these results suggest that there may be several different processes which all contribute to the  $\Delta^3$ -carene emissions of Scots pine. As there were also other irregularities in the modelled monoterpene emissions when compared to the observations, such processes may apparently be active or inactive at different times during the growing season, bringing an added uncertainty to e.g. regional emission models where annual, seasonal, or other average standard emission potentials are used.

#### 4. Conclusions

The VOC emission rates of Scots pine were measured in Hyytiälä in southern Finland and in Sodankylä in the Finnish Lapland. A clear seasonal pattern of the emissions was observed, with very high emission rates in spring, relatively lower emissions in early summer, high emissions again in late summer, and a gradual cessation in autumn. Also the spectrum of the emitted compounds showed seasonal variation. In Hyytiälä the main emitted compounds were  $\Delta^3$ -carene and  $\alpha$ -pinene. No  $\Delta^3$ -carene was ob-

served in Sodankylä where the main emitted compounds were  $\alpha$ - and  $\beta$ -pinene and limonene. Sesquiterpene and MBO emissions, initiating in June, were also observed in both locations.

In summer the emission rate variability was well explained by the temperature variation and the temperature dependent emission algorithm could be applied in assessing the standard emission potentials for most of the measured compounds. However, the temperature algorithm did not perform well in spring, and our results suggest that especially during the spring recovery period of the vegetation there may be several different processes contributing to the monoterpene emissions of Scots pine. Apparently, such processes may also be active or inactive at other times during the growing season, bringing an added uncertainty to e.g. regional emission models where annual, seasonal, or other average standard emission potentials are used.

For most of the monoterpenes, the calculated standard (30°C) emission potentials were high in spring and especially early summer, decreased somewhat in late summer, and were high again towards autumn. This is in accordance of the seasonal behaviour observed in other similar studies (Janson, 1993; Komenda and Koppmann, 2002). The average  $\beta$  coefficient value obtained in Hyytiälä was 0.10, which is very close to the empirical value of 0.09 usually applied in biogenic emission modelling studies (Guenther et al., 1993; Guenther, 1997).

Scots pine was tentatively identified as a light and temperature dependent 1,8-cineole emitter. However, more data is needed to properly assess the standard emission potentials, especially in late summer when the emissions were highest.

Sesquiterpenes were emitted during summer months only, therefore it is not likely that they would cause the new particle formation events observed in Hyytiälä during spring (Kulmala et al., 2001) – however, their oxidation products can participate in the growth processes of the newly formed particles later in the summer. The sesquiterpene emissions were not dependent on light, but increased with increasing temperature.

Scots pine is also a low MBO emitter. These emissions initiated in June and were dependent on temperature while the light and temperature dependence reported in

VOC emissions of  
Scots pine

V. Tarvainen et al.

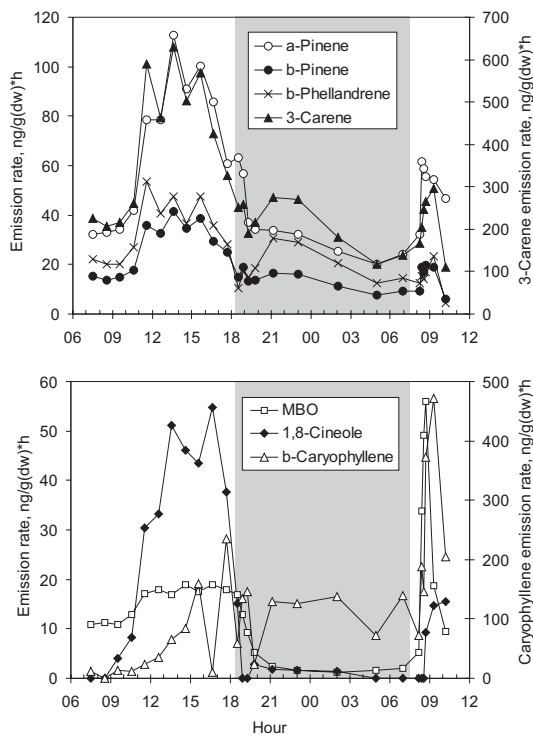

**Fig. 1.** Average noontime emission rates measured in April–June 2002 in Sodankylä and in March–October 2003 in Hyytiälä. Other monoterpenes comprises camphene, sabinene, 1,8-cineole, linalool, and bornyl acetate in Sodankylä, and camphene, sabinene,  $\beta$ -pinene+myrcene, terpinolene, limonene, 1,8-cineole,  $\beta$ -phellandrene, terpinolene, and bornyl acetate in Hyytiälä. The average temperature during the measurements (solid diamonds) is shown on the right hand axis. Note that the x-axis is not in scale because the averages for each measurement day are shown at regular intervals.

VOC emissions of  
Scots pine

V. Tarvainen et al.

**Fig. 4.** Measured and modelled  $\Delta^3$ -carene emissions in Hyytiälä on 25 March 2003 (upper panel). The light and temperature dependent algorithm (Eq. 4) is denoted by T, L. The temperature algorithm (Eq. 3) is denoted by T. T (25/03/2003) is fitted to the data of 25 March only, while T (spring 2003) refers to the seasonally fitted algorithm (same as in the upper panel of Fig. 3a). The error bars indicate the 95% confidence limits of the nonlinear regression fit to T,L. The lower panel shows the temperature and the photosynthetically active radiation (PPFD). The standard emission potentials (30°C) obtained with the different models and the corresponding parameters are given under the figure.
