## Abstract

Three years of continuous measurements of aerosol optical properties and simultaneous aerosol number size distribution measurements at Pallas GAW station, a remote subarctic site in the northern border of the boreal forest zone, have been analysed. The scattering coefficient at 550 nm varied from 0.2 to 94.4 Mm<sup>-1</sup> with an average of 7.1±8.6 Mm<sup>-1</sup>. Both the scattering and backscattering coefficients had a clear seasonal cycle with an autumn minimum and a 4–5 times higher summer maximum. The scattering was dominated by submicron aerosols and especially so during late summer and autumn. The Ångström exponent had a clear seasonal pattern with maximum values in late summer and minimum values during wintertime. The highest hemispheric backscattering fraction values were observed in autumn, indicating clean air with few scattering particles and a particle size distribution strongly dominated by ultrafine particles. To analyse the influence of air mass origin on the aerosol optical properties a trajectory climatology was applied to the Pallas aerosol data. The most polluted trajectory patterns represented air masses from the Kola Peninsula, Scandinavia and Russia as well as long-range transport from Britain and Eastern Europe. These air masses had the largest average scattering and backscattering coefficients for all seasons. Higher than average values of the Ångström exponent were also observed in connection with transport from these areas.

## 1. Introduction

There is a growing evidence that the Earth's radiation budget, and thus climate, is affected through radiative forcing caused by changes in the concentration and composition of aerosol particles (Lohmann and Feichter, 2005; Ramanathan et al., 2001; Charlson et al., 1999; Hansen et al., 1997). However, owing to their high spatial and temporal variability (seasonal dust storms or biomass burning), the globally and annually averaged climatic forcing by aerosols is associated with large uncertainties (IPCC,

2001).

Aerosol optical properties and their relation to other aerosol properties are key factors in investigating the direct radiative effects by atmospheric aerosols. The most important particles in this respect are submicron accumulation mode particles (Charlson et al., 1999). However, supermicron sea salt and dust may also have an important role in scattering in certain conditions (O'Dowd and Smith, 1993). Measurements concerning aerosol optical properties have been made in the marine boundary layer (Hegg et al., 1996), at a few coastal sites (O'Dowd and Smith, 1993; Sheridan and Ogren, 1999; Delene and Ogren, 2002; Anderson et al., 1999), in the free troposphere (Sheridan and Ogren, 1999), in Arctic regions (Virkkula et al., 1998; Treffeisen et al., 2004; Beine et al., 1996), and in areas with a high sulfate burden (Koloutsou-Vakakis et al., 2001; Delene and Ogren, 2002). High Arctic aerosol loadings, i.e. Arctic haze, have also been investigated (Treffeisen et al., 2004; Heintzenberg et al., 2003; Beine et al., 1996). In addition to field measurements, aerosol optical properties have been studied with airborne in-situ measurements as well as from satellites (Bodhaine et al., 1991; Kaufman et al., 2002).

Although the optical properties of particles with different size have been studied widely, there is still a need for measurements from remote or moderately polluted areas. In this study we present results from simultaneous aerosol scattering and size distribution measurements conducted at a remote continental subarctic site. The data covers three years of continuous measurements. Our purpose is to illustrate 1) how the aerosol optical properties (scattering and backscattering coefficients, Ångström exponent, hemispheric backscattering fraction) vary seasonally and with air mass origin, and 2) how the optical properties are related to the properties of measured aerosol number size distributions.

## 2. Instrumentation and methods

### 2.1. Site description

The Finnish Meteorological Institute (FMI) has participated in the Global Atmosphere Watch (GAW) programme since 1994 and maintains the Pallas-Sodankylä GAW station. The main measuring station (Fig. 1, 67°58′ N, 24°07′ E) is located on a top of fjeld (an Arctic hill) Sammaltunturi, at the height of 560 m above sea level, and ca 300 m above the surrounding area. The measuring site is very suitable for tropospheric measurements due to the absence of large local and regional pollution sources. The distance to the nearest town, Muonio, with some 2500 inhabitants, is 19 km to the west. The second nearest town, Kittilä (6000 inhabitants) is 46 km to the south-east. The closest major pollution sources are the smelters Nickel and Montshegorsk in Russia, located about 350 km away from Pallas, Nickel to the northeast and Montshegorsk to the east. A detailed description on the site is given by Hatakka et al. (2003).

### 2.2. Instrumentation

The scattering ( $\sigma_{sp}$ ) and backscattering coefficients ( $\sigma_{bsp}$ ) were measured with an integrating nephelometer (model 3563, TSI, Inc., St. Paul, Minnesota). The measurements at Pallas have been going on continuously since February 2000. The instrument measures scattering ( $\sigma_{sp}$ ) and backscattering coefficients ( $\sigma_{bsp}$ ) in three wavelengths, 450, 550 and 700 nm. The instrument illuminates the sample volume from the side and measures the light scattered by aerosol particles and gas molecules in the direction of the photomultiplier tube integrating the scattering over angle of 7–170°. The instrument is described in detail by Anderson et al. (1996) and Bodhaine et al. (1991). Calibration of the nephelometer is carried out at least twice per year by using CO<sub>2</sub> (purity 4.0) as high span gas and filtered air as low span gas. The averaging time is set to 5 min. The zero signal is measured once an hour.

The inlet of the main sampling line is about 3 m above the roof of the measurement

EGU

station building, about 7 m above the ground. Calculated (Baron and Willeke, 2001) cut off diameter of the inlet nozzle and sample transport lines was about  $5\ \mu\text{m}$ . More detailed description of the inlet system is found in Komppula et al. (2005).

The sample air is heated to station indoor temperature (about  $20^\circ\text{C}$ ) prior to entering the nephelometer. The heater inside the nephelometer was not activated until December 2003. The heater decreases condensation inside the measurement chamber. Before turning the heater on, the mean relative humidity ( $RH$ ) was  $18\pm 10\%$ , the maximum hourly mean  $RH$  being 60%. After turning the heater on, the mean  $RH$  was  $9\pm 3\%$  and the maximum hourly mean  $RH$  was 23%.

The particle number size distribution in the range 7–500 nm was measured with a Differential Mobility Particle Sizer (DMPS). Continuous DMPS measurements were started on 13 April 2000. The instrument and measuring arrangements have been described in detail by Komppula et al. (2003).

The total aerosol number concentration was measured with a Condensation Particle Counter (CPC, TSI model 3010). These measurements have been going on since 28 June 1996. The CPC measures particles larger than about 10 nm. Concentration of particles larger than  $0.5\ \mu\text{m}$  was measured with a Laser Particle Counter (LPC, TSI model 7550) between October 1998 and April 2004. The instrument measures number concentration of aerosol particles in two size channels,  $D_p > 0.5\ \mu\text{m}$  and  $D_p > 5.0\ \mu\text{m}$ .

Other measurements in Pallas include trace gas measurements and meteorological parameters. In this analysis we used  $\text{SO}_2$  concentration as well as visibility measured with a Vaisala FD12P weather sensor. The detection limit of the  $\text{SO}_2$  measurements, carried out with Thermo Electron 43S, is  $0.1\ \mu\text{g m}^{-3}$ . The weather measurements are made with an automatic weather station (Hatakka et al., 2003).

### 2.3. Data processing

Measurement data were analysed for the period from 9 November 2001 to 9 November 2004. The data associated with abnormal peaks, calibrations or visits at the station were rejected, as were also the cases when the zero mode was not activated, values

Interactive Discussion

when the  $RH$  inside the nephelometer exceeded 40%, or the station was inside clouds.

Nonidealities due to nonlambertian and truncation errors were corrected using the method described by Anderson and Ogren (1998). Nonlambertian errors are most important for sub-micron particles whereas truncation errors are most important for  $>1\ \mu\text{m}$  particles (Anderson and Ogren, 1998). Nonlambertian error is the slightly noncosine-weighted intensity distribution of illumination light provided by the opal glass diffusor of the nephelometer. Truncation error is the geometrical blockage of near-forward-scattered light for angles below about  $7^\circ$ .

For 5-min averages applied here, the detection limits for total scattering coefficients are 0.44, 0.17, and  $0.26\ \text{Mm}^{-1}$  for 450, 550, and 700 nm, respectively (Anderson et al., 1996). For backscattering, the detection limits are 0.29, 0.11, and  $0.21\ \text{Mm}^{-1}$  for 450, 550, and 700 nm, respectively. Values below these detection limits were excluded. Hourly averages were calculated from valid results.

The Ångström exponent,  $\mathring{a}$ , is defined as the negative slope of the logarithm of scattering coefficient as a function of wavelength and is given by  $\sigma_{\text{sp}} = K\lambda^{-\mathring{a}}$ , where  $K$  is a constant. In practice,  $\mathring{a}$  is calculated from the equation

$$\mathring{a} = -\frac{\log \sigma_{\text{sp}}(700\ \text{nm}) - \log \sigma_{\text{sp}}(550\ \text{nm})}{\log 700 - \log 550}. \quad (1)$$

A large Ångström exponent implies an aerosol size distribution with scattering dominated by submicron particles, while a distribution dominated by coarse particles has typically smaller  $\mathring{a}$ . The hemispheric backscattering fraction,  $b$ , was obtained from  $b = \sigma_{\text{bsp}} / \sigma_{\text{sp}}$ .

### 2.4. Cluster analysis

To analyse the influence of air-mass origin on the optical aerosol measurements at Pallas, three-dimensional 5-day back-trajectories arriving at 925 hPa were calculated, using the kinematic model FLEXTRA (Stohl and Wotawa, 1995; Stohl and Koffi, 1998;

Stohl et al., 1999). The model utilizes meteorological data from the European Centre for Medium Range Weather Forecasts (ECMWF). The calculations were performed twice daily (00:00 and 12:00 UTC) during the period 1997–2003, resulting in a data set of 5112 trajectories.

The trajectories were classified into different flow patterns with the use of cluster analysis. Cluster analysis denotes a variety of multivariate techniques used to group similar objects together, whereby differences between individual elements within a cluster are minimized but differences between clusters are maximized (Romesburg, 1984). In the present study the Ward's minimum variance technique was used, provided in a Matlab standard statistical package. Seven transport patterns, representing the atmospheric flow to Pallas during the 7-year period 1997–2003, were identified. The clustering procedure and the resulting trajectory climatology are described in detail by Eneroth et al. (2005).

### 3. Results and discussion

#### 3.1. General features

Figure 2 shows daily mean scattering coefficients  $\sigma_{\text{sp}}$  at 550 nm covering the whole measurement period. The value of  $\sigma_{\text{sp}}$  varies widely – more than two orders of magnitude. This variation is embedded in the consistent seasonal cycle discussed below. Gaps in the data are mainly due to burned lamp or maintenance.

Statistical properties of the hourly mean values of the measured and calculated parameters are presented in Table 1. Based on three years of hourly averaged data,  $\sigma_{\text{sp}}$  at 550 nm varied in the range 0.2–94.4  $\text{Mm}^{-1}$  with an average of 7.1  $\text{Mm}^{-1}$  and a standard deviation (STD) of 8.6  $\text{Mm}^{-1}$ . These values are lower than those (10.4±11.1  $\text{Mm}^{-1}$ ) measured between October 1997 and September 2000 in Barrow, Alaska (Delene and Ogren, 2002), but higher than those measured in Ny-Ålesund, Svalbard (5.0±3.9  $\text{Mm}^{-1}$ ) during the Arctic haze period in spring 1994 (Beine et al.,

Interactive Discussion

1996).

The seasonal variation of various optical parameters can best be seen from the monthly-average data, which is shown in Fig. 3. Both the scattering and backscattering coefficients display a clear seasonal cycle with an autumn minimum and a 4–5 times higher summer maximum. These two parameters started to rise early in spring, reaching their highest values in summer. After July the values decreased very rapidly and stayed relative constant during the autumn. The autumn scattering minimum may be related to the fact that both cloudiness and precipitation have their maximum in autumn, and therefore the air is expected to be cleaner. The scattering coefficient usually reached its maximum in July and minimum in October. The backscattering coefficient behaved in the same way, though with lower absolute values. At Barrow, Alaska,  $\sigma_{sp}$  was lowest in summer and highest (10–15 times higher than summer values) in winter (Delene and Ogren, 2002). High values at Barrow in winter are related to a winter maximum in submicron sulfate aerosol and sea-salt aerosol mass concentration, indicating periods of Arctic haze as well as high sea-salt mass concentrations.

The Ångström exponent also had a clear seasonal variation with a minimum in spring and a 2–4 times higher maximum in late summer. Based on the absolute values of  $\hat{a}$ , we conclude that scattering is dominated by submicron aerosols in Pallas, and especially so during late summer and autumn. The hemispheric backscattering fraction  $b$  at 550 nm varied by roughly a factor two between the months but does not show a consistent seasonal pattern.

### 3.2. Relationships between the measured quantities

The scattering and backscattering coefficients were found to be strongly correlated to each other. The ratio of these two quantities, the hemispheric backscattering fraction  $b$ , was also found to be dependent on the magnitude of  $\sigma_{sp}$  (Fig. 4). For  $\sigma_{sp} > 1 \text{ Mm}^{-1}$ , the value of  $b$  decreased gradually with increasing  $\sigma_{sp}$ , being mostly below 0.2 when  $\sigma_{sp} > 10 \text{ Mm}^{-1}$ . This kind of pattern is consistent with observations made by Delene

**Measurements of optical properties**

V. Aaltonen et al.

and Ogren (2002) at four different sites in Northern America. Interestingly,  $b$  started to increase very rapidly with decreasing  $\sigma_{sp}$  in very clean air ( $\sigma_{sp} < 1 \text{ Mm}^{-1}$ ). A closer look at the particle size distribution data revealed that these cases were characterized by very low accumulation mode particle number concentrations, as well as a particle size distribution strongly dominated by ultrafine particles.

Figure 5 displays  $\sigma_{sp}$  as a function of the particle number concentration in different modes, including the accumulation mode (particle diameter 95–500 nm), aitken mode (25–95 nm) and nucleation mode (7–25 nm). Aerosol particles in the accumulation mode have the highest scattering efficiency at measured wavelengths. This can be seen as a clear correlation between  $\sigma_{sp}$  and the number concentration of accumulation mode particles (Fig. 5a). The relation between  $\sigma_{sp}$  and the number concentration of nucleation mode particles displays an envelope type pattern (Fig. 5b), with high values of  $\sigma_{sp}$  being always associated with low nucleation mode particle number concentration and vice versa. This kind of behaviour can be explained in two ways: 1) no major primary sources (such as traffic emissions) for nucleation mode particles observed at Pallas exist, and 2) atmospheric new-particle formation at Pallas takes place only in clean air masses originating from the North Atlantic or the Arctic Ocean (Komppula et al., 2003). No clear connection between  $\sigma_{sp}$  and the aitken mode particle number concentration (Fig. 5c), or between  $\sigma_{sp}$  and total particle number concentration (Fig. 5d), could be seen.

The scattering coefficient  $\sigma_{sp}$  correlated strongly with the particle number concentration measured by the LPC (Fig. 6d,  $R^2=0.71$ ), which is consistent with the results by Virkkula et al. (1998) at another Finnish Arctic site. This correlation is higher than that of  $\sigma_{sp}$  with the number concentration of accumulation mode particles ( $R^2=0.60$ ), but lower than that of  $\sigma_{sp}$  with 400–500 nm particles ( $R^2=0.87$ ) or with 300–400 nm particles (Fig. 6c,  $R^2=0.92$ ). By looking at particles larger than a certain threshold size, rather than by looking at specific size ranges, a complementary picture emerges. For example, the correlation between  $\sigma_{sp}$  and  $>200 \text{ nm}$  particles was 0.85 (Fig. 6a), that between  $\sigma_{sp}$  and  $>300 \text{ nm}$  particles was 0.93 (Fig. 6b), and that between  $\sigma_{sp}$  and

EGU

>400 nm particles was 0.87. No correlation could be seen between  $\sigma_{sp}$  and concentration of 100–200 nm particles. Probably most of the particles in the accumulation mode are too small to effectively scatter the atmospheric radiation in the visible range. When using the backscattering coefficient instead of scattering coefficient, a behaviour similar to that in Figs. 5 and 6 was observed.

The highest values of  $\sigma_{sp}$  ( $>40 \text{ Mm}^{-1}$ ) were observed in air with Ångström exponents  $\tilde{a}$  in the range 1.3–2.3 and with  $\text{SO}_2$  concentrations typically smaller than a few  $\mu\text{g}/\text{m}^3$  (Fig. 7). This indicates that these episodes were dominated by submicron particles from various combustion sources. The largest regional pollution source affecting Northern Finland is the Kola Peninsula industrial area some 350 km east from Pallas. During periods of air mass transport from this area the highest  $\text{SO}_2$  concentrations ( $>10 \mu\text{g}/\text{m}^3$ ) are observed at Pallas (Virkkula et al., 1998; Ruuskanen et al., 2003). Although higher than averages, the values of  $\sigma_{sp}$  were mostly below  $10 \text{ Mm}^{-1}$  in air clearly affected by Kola Peninsula sources. Taken together, these things suggest that the episodes showing the highest values of scattering are associated with long-range transported particulate pollution originating from Central or Eastern Europe rather than by local or regional pollution.

### 3.3. Long-range transport

Figure 8 shows the calculated climatology for trajectories arriving at Pallas at 925 hPa. The clusters are depicted by mean trajectories. The cluster mean represents the average pathway of trajectories in that cluster and describes potential source areas within a 5-day transport time to Pallas. Each cluster is assigned an identification number (1–7). Clusters 3–5 represent transport across the Arctic Basin, clusters 2 and 6 from the Eurasian continent, and clusters 1 and 7 from the Atlantic. The mean trajectory length for each of the clusters is shown in Fig. 8. The highest mean wind speeds, i.e. the longest trajectories, are found in connection with transport over the Atlantic (clusters 1 and 7). Clusters 2, 4 and 6 are associated with the lowest mean wind speeds. Figure 8

EGU

also shows the mean frequency of occurrence of the transport clusters. However, this frequency of occurrence co-varies with the seasonal changes of the general circulation patterns (Eneroth et al., 2005).

To study the influence of long-range atmospheric transport on the observed optical aerosol properties at Pallas, the aerosol data were correlated with cluster membership. The data was divided into seven separate groups according to the trajectory climatology. The mean value of the hourly means between  $\pm 1$  h of the arrival time of the trajectory was calculated and used in the analysis.

In terms of aerosol properties, the cleanest air conditions were associated with clusters 3 and 7 containing trajectories originating from the Arctic Ocean and the North Atlantic, respectively. These clusters had the lowest average scattering and backscattering coefficients ( $\sigma_{sp}$  at 550 nm for clusters 3 and 7 were  $3.2 \pm 3.3 \text{ Mm}^{-1}$  and  $4.0 \pm 3.4 \text{ Mm}^{-1}$ , respectively) as well as accumulation mode particle number concentrations for all seasons. The same clusters also showed high nucleation mode particle number concentrations during spring and late summer, which is an indication of new particle formation (Komppula et al., 2003). The most polluted conditions were associated with cluster 1 representing air mass transport from Scandinavia and Britain, and cluster 6, representing air mass transport from Russia and Eastern Europe. Cluster 6 also includes trajectories from the polluted Kola Peninsula area. Clusters 1 and 6 showed the largest average scattering and backscattering coefficients ( $\sigma_{sp}$  at 550 nm were  $12.2 \pm 16.8 \text{ Mm}^{-1}$  and  $16.2 \pm 9.1 \text{ Mm}^{-1}$ , respectively) as well as the largest accumulation mode particle number concentrations for all seasons. Furthermore, these clusters were associated with year-round low nucleation mode particle number concentrations. Figure 9 shows monthly variations of  $\sigma_{sp}$  at 550 nm,  $\dot{a}$  as well as  $b$  at 550 nm for clusters 6 and 3, illustrating polluted and clean air conditions at Pallas, respectively.

From Fig. 9 it can be seen that the Ångström exponent has a clear seasonal pattern for all clusters, with maximum values in autumn and minimum values during winter. The high autumn values of  $\dot{a}$  could possibly be related to the maximum cloud frequency observed in Pallas at that time of the year. When clouds are present, the relative amount

**Measurements of optical properties**

V. Aaltonen et al.

of large sea-salt and dust particles is likely to be reduced, causing an increase in the value of  $\hat{a}$ . On average, the values of  $\hat{a}$  were found to be somewhat higher in connection with clusters 1, 2 and 6 compared to the other transport patterns. This may be due to the dominance of submicron pollution-related particles in these air masses. The highest values of the hemispheric backscattering fraction was observed in autumn for all clusters, indicating clean air with few scattering particles and particle size distribution emphasized by ultrafine particles. No clear linkage between atmospheric circulation and the observed aiten mode and total particle number concentrations was found.

#### 4. Summary and conclusions

Three years of continuous measurements of aerosol optical properties have been analysed at Pallas GAW station, a remote subarctic site in the northern border of the boreal forest zone. The measurements were analysed as a function of aerosol size distribution and atmospheric long-range transport. The seasonal variation of the data was also studied. The scattering coefficient at 550 nm varied from 0.2 to 94.4  $\text{Mm}^{-1}$  with an average of  $7.1 \pm 8.6 \text{Mm}^{-1}$ . Both the scattering and backscattering coefficients had a clear seasonal cycle with an autumn minimum and 4–5 times higher summer maximum. Also the Ångström exponent varied over the year, having a minimum in spring and 2–4 times higher maximum values in late summer. The scattering was dominated by submicron aerosols in Pallas, and especially so during late summer and autumn. The ratio between the backscattering and scattering coefficients was very high at small scattering coefficients. These cases were characterized by very low accumulation mode particle number concentrations, as well as particle size distributions strongly dominated by ultrafine particles.

The scattering coefficient correlated strongly with the number concentration of accumulation mode particles, even though most accumulation mode particles were too small to effectively scatter at the measured wavelengths. The relation between  $\sigma_{\text{sp}}$  and nucleation mode particle number concentration displayed an envelope type pattern,

EGU

with high values of  $\sigma_{sp}$  being associated with low nucleation mode particle number concentration and vice versa. This kind of behaviour is due to the fact that atmospheric new-particle formation at Pallas takes place only in clean air masses originating from the North Atlantic or the Arctic Ocean.

5 Aerosol data was inspected in terms of trajectory clusters, each of which representing different regions of air masses origin. The cleanest air mass conditions were observed in connection with trajectories coming from the Arctic Ocean and the North Atlantic, showing the lowest average scattering and backscattering coefficients as well as the lowest accumulation mode particle number concentrations all year-round. The most polluted air masses were associated with air mass transport from the Kola Peninsula, Scandinavia and Russia as well as Britain and Eastern Europe. These trajectory clusters had the largest average scattering and backscattering coefficients as well as the largest accumulation mode particle number concentrations for all the seasons.

10 Our results demonstrate that aerosol optical properties, including scattering and backscattering coefficients and Ångström exponent, depend strongly on the aerosol number size distribution. In the future, we will focus on 1) optical closure studies based on the aerosol number size distribution, chemical composition, and optical parameters such as index of refraction and the  $RH$  dependence of scattering, and 2) column closure experiments including aerosol optical depth attained by surface measurements and estimations of vertical distribution of extinction coefficient and  $RH$ .

**Table 1.** Statistics of aerosol optical parameters. The averages are expressed as arithmetic means (AM), and variations as standard deviations (STD). Scattering and backscattering coefficients are given in unit  $\text{Mm}^{-1}$ , while DMPS and LPC number concentrations are given in particles  $\text{cm}^{-3}$ .  $\text{SO}_2$  concentrations are given in  $\mu\text{g}/\text{m}^3$ .

Parameter	N	AM	STD	Percentiles
