Abstract

Long-term variability of total ozone over Europe is discussed using results of a flexible trend model applied to the reconstructed total ozone data for the period 1950–2004. The data base used was built within the objectives of the COST action 726 “Long-term changes and climatology of UV radiation over Europe”. The trend pattern, which comprises both anthropogenic and “natural” component, is not a priori assumed but it is a result of a smooth curve fit to the zonal monthly means and monthly grid values. The trend values in 5-year and 10-year intervals in cold (October–next year April) and warm (May–September) seasons are calculated as the differences between the smooth curve values at the end and beginning of selected time intervals divided by length of the intervals. The confidence intervals for the trend values are calculated by the block bootstrapping. The statistically significant negative trends are found almost over whole Europe only in the period 1985–1994. Negative trends up to -3% per decade appeared over small areas in earlier periods when the anthropogenic forcing on the ozone layer was weak. The statistically positive trends are found only during warm seasons 1995–2004 over Svalbard archipelago. The reduction of ozone level in 2004 relative to that before the satellite era is not dramatic, i.e., up to $\sim -5\%$ and $\sim -3.5\%$ in the cold and warm subperiod, respectively. Present ozone level is still depleted over many popular resorts in southern Europe and northern Africa. For high latitude regions the trend overturning could be inferred in last decade (1995–2004) as the ozone depleted areas are not found there in 2004 in spite of substantial ozone depletion in the period 1985–1994.

1 Introduction

Negative trends in the ozone content in the atmosphere in the mid- and high latitude regions over both hemisphere and anticipated increase of the surface UV radiance (UVR) there triggered numerous studies on variability of UVR in different time scales

Interactive Discussion

and its influencing factors including ozone, aerosols, and clouds (Bais et al., 2007, and references herein).

The time series of the surface UV-B measurements longer than 2 decades are rather rare. 14 sites in the United States were analyzed by Weatherhead et al. (1997) and only one site, Belsk, in Europe by Borkowski (2000). Length of reliable data records is up to 10–15 year for most European UV observing stations. It is recognised that such period is not adequate to carry out trend analyses (Weatherhead et al., 1998). However, recent studies show possibilities to reconstruct the surface UVR using variables (total ozone, cloud/aerosol optical depth) directly affecting UVR (e.g., Kaurola et al., 2000; den Outer et al., 2000; Fioletov et al., 2001) The pyranometer and other meteorological data (sunshine duration and cloud cover) serve as proxies for the combined cloud/aerosols effects on UVR. Comparison of the European UV reconstruction models under the COST action 726 “Long-term changes and climatology of UV radiation over Europe” shows that past UV field can be accurately estimated using models taking into account only total ozone and pyranometric data (Koepke et al., 2006). The reconstructed datasets, which can extend backward in time to as early as the beginning of total ozone and pyranometer observations, would help to examine the UVR variability over Europe in periods without UV measurements.

Observations of the total (Sun + sky) solar irradiance integrated over the whole spectral range (~300–3000 nm) using pyranometers belong to standard measurements carried out at many meteorological stations. Since the late 1970s the global distribution of ozone has been available from satellite observations. Much less is known about stratospheric ozone during earlier periods. Current data archive centred at the World Ozone and Ultraviolet Data Center (WOUDC) in Toronto, Canada contain only few continuous total ozone records starting before International Geophysical Year in 1957. Thus for a purpose of the surface UV reconstruction over Europe (within the framework of the COST-726 action objectives) a statistical model has been developed to simulate daily total ozone values and the ozone data base covering Europe has been built since 1 January 1950 (Krzyścin, 2007). Here we present results concerning the long-term

variability of total ozone over Europe for the period 1950–2004. There were many studies focusing on trends in ozone but usually an anthropogenic component of the long-term variability was extracted from the data. Our objective is to estimate the long-term ozone forcing on the surface UV. Thus we calculate the trend component that comprises both the anthropogenic and “natural” effects.

2 Total ozone data base

Statistical model has been proposed within the framework of the COST-726 action to reproduce past total ozone variations over Europe to be used for surface UV simulation (Krzyścin, 2007). An assimilated data base of total column ozone measurements from satellites covering the whole globe, known as NIWA total ozone data base (named after affiliation of leading author Greg Bodeker – National Institute of Water and Atmosphere Research, Lauder, New Zealand) is used as input to our regression model. The NIWA data were homogenized by a comparison with the ground-based Dobson spectrophotometer stations. The data base was widely used in various studies of global ozone behaviour (Bodeker et al., 2001 and 2005; Fioletov et al., 2002; WMO, 2003 and 2007).

The COST-726 ozone reconstruction model consists of two-step regression. The first step is a regression of the monthly means of NIWA total ozone on various standard ozone explanatory variables, i.e., indices of the atmospheric circulation and meteorological variables (temperature, absolute vorticity). Next is a regression of the daily departures of NIWA total ozone from the total ozone monthly means. Here, the explanatory variables are deviations of daily values of meteorological variables from their monthly means. Finally, the modelled daily total ozone is obtained as a sum of terms being multiplication of regression constants and pertaining explanatory variables that were selected as important regressors using the multivariate adaptive regression splines (MARS) technique (Friedman, 1979). The quality of the data base is assured by a comparison of the reconstructed total ozone with the ground-based data from several Dobson stations functioning in the early 1950s and 1960s. The model explains

Interactive Discussion

~70–80% variance of the ozone data collected before the satellite era. Bias and the long-term drift between the reconstructed and measured Dobson ozone are within a range of $\pm 2\%$.

The reconstructed COST-726 ozone data base consists of daily total values since 1 January 1950 for a region: $\lambda=(25.625^\circ \text{ W}, 35.625^\circ \text{ E})$, $\phi=(30.5^\circ \text{ N}, 80.5^\circ \text{ N})$. The grid resolution is 1° in the latitudinal and 1.25° in the longitudinal direction (see grid structure in Fig. 1). The data base is available at address <http://tau.igf.edu.pl/~jkrzys> with separate files describing the data format and performance of the model.

The total ozone distribution over Europe in March and July shown in Fig. 1 and Fig.2, respectively, has been calculated averaging daily total ozone values taken from the data base. Top figures represent the overall long-term monthly means for the period 1950–1959. Bottom Figures provide the departures of the overall long-term monthly means for the period 1995–2004 relative to the 1950–1959 means in percent of the latter means. A substantial ozone depletion over Europe can be inferred from a comparison between the modelled ozone means in last and first decade of analyzed data. Further in the text we present results of trend analysis and visualize the spatial and temporal variability of the total ozone field over Europe.

3 Trend model

In previous studies of the total ozone trends authors focused on an extraction of component of the long-term variability being result of anthropogenic forcing (release of various chemicals like freons and halogens destroying the ozone layer), Chipperfield et al. (2007) and references herein. The natural variations of total ozone were parameterized and removed from the series, e.g. the 11-year solar signal, QBO, etc. Our approach is different when searching for the UV response to changing the ozone layer. We would like to estimate the long-term changes in total ozone comprising both anthropogenic and “natural” effects.

The long-term variability of total ozone was usually derived from a straight line fit to

Interactive Discussion

the whole analyzed time series or its subsets (e.g., Reinsel et al., 2002; WMO, 2003). A comparison of slopes of the regression lines enables to infer temporal variations of the long-term trend in last decades. Recently a concept of trend evaluation using a smooth curve fit to the ozone data has been evolving (Harris et al., 2003; Krzyścin et al., 2005; Oltmans et al., 2006; and Krzyścin, 2006). The trend means continuing and smooth change over a given time period. A difference between the curve's values at the end and beginning of the time period divided by the length of the period gives the trend value. A model using such concept is the so-called flexible trend model and it is also used here:

$$\Delta O_3(t_{m,K}) = F(t_{m,K}) + \text{Noise}(t_{m,K}) \quad (1)$$

where $\Delta O_3(t_{m,K})$ is the relative deviation of the modeled monthly means total ozone for calendar month m and year K relative to the long-term 1950–1978 monthly mean for month m in percent of the long-term mean, $F(t_{m,K})$ represents low frequency component, i.e., a trend component derived by smoothing of the data, $\text{Noise}(t_{m,K})$ is a noise component that is calculated as departures from the smoothed curve. The model is run separately for the cold and warm subset of the year for each grid point in the area shown in Fig. 1.

Various smoothing techniques are possible, for example, wavelets, locally weighted regression (LOWES), kernel, smoothing spline, etc. These procedures could be found in the present statistical software (e.g. S-Plus 4 Guide to Statistics, 1997). The most essential problem in the data smoothing for trend analysis is selection of a smoothness level, i.e., what scales of the time series variability should be retained for a trend determination. The level could be arbitrarily chosen for most of presently used smoothers. For example, Fig. 3 (top) shows possible candidates for trend components extracted from an application of the kernel smoother with different temporal bandwidths (from 2-year up to 55-year) to the relative deviations of monthly means of total ozone for the period 1950–2004, which were averaged over the band 40°–45° N. It is difficult to decide which curve provides a trend component.

Interactive Discussion

The wavelet analysis may facilitate the process of proper selection of the smoothness level. The wavelet multiresolution decomposition separates the series into components, and so-called “smooth” component is appropriate for trend analysis (e.g. Borkowski, 2002). Such component of the ozone time series together with the plot of the series obtained by the application of the kernel smoother with bandwidth 8-year are shown in Fig. 3 (bottom). In the performed multiresolution decomposition non-decimated wavelet transform was used because such a transform is translation invariant and in comparison with ordinary discrete wavelet transform provides better resolution at longer time scales (Bruce and Gao, 1996). Thus, it seems that the curve extracted by the kernel smoother with bandwidth 8-year could be treated as a trend component for 55-year time series. We decide to use such kernel smoother for all examined time series in spite of that wavelet smoother has some advantages over other smoother. The wavelets smoother requires equidistance data points, which are lacking for high latitude regions (no data during polar night) or seasonal data (time series of monthly means for selected calendar months; cold period, October-next year April; warm period, May-September).

The 95% confidence ranges for the trend curves calculated for zonal monthly means and monthly grid point values are derived here by the block bootstrapping. The bootstrap belongs to the category of nonparametric statistical methods. It is able to simulate the probability distribution of any statistics without making any assumptions related to the temporal or spatial covariance structure of the variables. Resampling with replacement of the original record provides a sample of potential time series. However, a construction of potential representatives of the original record must preserve the temporal structure of the original one. In our approach many hypothetical time series of $\Delta O_3(t_{m,K})$ are generated by a random resampling of the yearly blocks taken from $\text{Noise}(t_{m,K})$ time series,

$$\text{Noise}^*(t_{m,K}) = \text{Noise}(t_{m,K*}) \quad (2)$$

where $\text{Noise}^*(t_{m,K})$ is potential noise term in calendar month m and year K being the same as noise term in year K^* , K^* is randomly selected year between 1950 and 2004.

The same K^* is used for all months in year K . Resampling of blocks of data is known as the moving-blocks bootstrap first introduced by Kunsch (1989). Noise $^*(t_{m,K})$ term is added to the original smooth curve from (1) and a new hypothetical low frequency component, $F^*(t_{m,K})$, is extracted and stored. We analyze a sample of 1000 time series of $F^*(t_{m,K})$ and calculate several statistical characteristics related to the trend variability, i.e., mean change over 5-year and 10-yr intervals, value of the trend curve at the end of time series. These values are sorted in ascending order and point No. 25 and No. 975 define the 95% confidence range for the estimated values.

4 Results

The zonal monthly means are calculated averaging the daily data taken from the COST-726 total ozone data base over Europe. The relative deviations for the zonal monthly means are derived as differences between the zonal monthly means and the overall monthly means for the 1950–1978 (pre-satellite era of ozone observations) expressed as percent of the overall means. The trend curves are calculated by the kernel smoothing with bandwidth 8-year as it was discussed in previous section. In this section we focus on behavior of the smooth curves rather than on individual monthly data. Further in the text we discuss temporal and zonal changes in the trend patterns over Europe. Figure 4 and Fig. 5 show the trend curves extracted from the relative deviations of zonal monthly means for cold (October- next year April) and warm (May-September) seasons, respectively

It is seen that the statistically significant negative departures of zonal mean total ozone appeared in the mid 1980s. Until the end of the analyzed period ozone stays below its pre-satellite era values. It seems that the ozone lowering stops around 1995. No further thinning of the ozone layer during the last decade (1995–2004) over Europe could be inferred from the trend curve patterns. Some insights of a trend turnaround in the mid 1990s should be noted especially in higher latitudes ($\phi > 55^\circ$ for the cold periods, $\phi \geq 65^\circ$ for the warm period). A declining tendency could be hypothesized for

Interactive Discussion

zonal bands with $\phi \geq 60^\circ$, in two decades at the beginning of ozone record, during cold seasons. The width of 95% confidence range of the trend curve is enlarged at the end and beginning of the time series and for higher latitudes regions. Thus, these findings cannot be supported by a rigorous statistical test.

The trend curve is divided into moving 5-year blocks to find a trend variability. Thus, moving trend values will be calculated for time intervals: 1950–1955, 1951–1956, ..., 1998–2003, 1999–2004. The trend value (in %/10-yr.) in month $t_{m,K}$ is obtained as the difference between the trend curve values in this month and that 5-year earlier divided by the length of the time interval;

$$\text{Trend}(t_{m,K}) = 2(F(t_{m,K}) - F(t_{m,K-5yr})) \quad (3)$$

Figure 6 (cold seasons) and Fig. 7 (warm seasons) illustrate the trend variability for the same latitudinal bands as those used in Fig. 4 and Fig. 5. Pattern of the trend variability is similar almost in all zonal bands, i.e., maxima at the beginning, middle, and at the end of the data period, and minima in the 1960s–early 1970s, and in the 1980–early 1990s. Only the trend pattern for cold seasons in the 35° N band suggests steadily decline of total ozone throughout the whole time series. The 95% confidence range of the trend estimates increases from $\pm 1\%$ ($\pm 1.5\%$) per decade to $\pm 2\%$ ($\pm 4\%$) per decade from the lowermost to the uppermost zonal band during warm (cold) seasons. The mean trend values over the zonal bands (marked as thick line in Fig. 6 and Fig. 7) are not large, i.e., $\sim -1.5\%$ ($\sim -3\%$) per decade at the trend minima and $\sim 1.0\%$ ($\sim 3\%$) at the trend maxima during warm (cold) seasons. Thus, statistically significant negative trends are found for small parts of the analyzed 55-yr time series, i.e., between late 1980s and mid 1990s and for shorter periods between 1960s and 1970s. Statistically significant positive trends do not appeared over the analyzed bands. However, it is worth noting large upward tendency that is manifested at the end of time series over the high latitudinal regions especially during cold seasons. The trend is still negative in recent decade (1995–2004) over the 35° N band during cold seasons.

Figure 8 (cold seasons) and Fig. 9 (warm season) illustrate spatial variability of the ozone trend over Europe in decade blocks since 1955 and the ozone level at the end

Interactive Discussion

of data (2004). The ozone time series for each grid point are analyzed, and the trend values for 10-yr blocks are calculated using the same methodology which was applied for the zonal total ozone means. Dashed regions mark areas where the estimated values are not statistically significant at 95% confidence level. The confidence limits are derived by the block bootstrapping.

The statistically significant negative trends are found for larger European areas only in the period 1985–1994. Some regions with negative trends appeared in earlier decades but their areas were rather limited, for example, Great Britain and the eastern part of the Mediterranean Sea in warm seasons 1965–1974, Southern France, Spain, the western part of the Mediterranean Sea, and Northern Africa in cold seasons 1975–1984. The statistically positive trends are found only during warm seasons 1995–2004 over Svalbard archipelago. It is worth noting appearance of statistically significant trend in cold seasons 1994–2004 over the central/southern part of the Mediterranean Sea and Northern Africa. The ozone level at the end of time series is below pre-satellite (1978) mean level over the low and mid-latitude areas over Europe with the largest decline in the southern part of Europe (~4–5% decline during cold seasons) and central Europe (~3–3.5% decline during warm seasons). It seems that during last two decades substantial changes in the trend pattern occurred in the high latitudes regions of Europe especially in cold seasons as the ozone depleted areas disappeared there at the end of the data that was followed by a large ozone depletion in the 1985–1995. However, larger uncertainties of the statistical estimates for the high latitudes region do not allow to draw convinced (statistically significant) conclusion.

5 Summary and conclusions

Thinning ozone layer has focused interest of scientific community for almost two decades as expected increases of UVR reaching the Earth surface were linked with detrimental ecological aspects. The ozone trend analyses have been targeted to estimation of an anthropogenic component of the ozone trend. Many efforts have been put

to parameterize “natural” variations in ozone (e.g. Fioletov et al., 2002; Steinbrecht et al., 2003; Dhomse et al., 2005; Wohltmann et al., 2007). Thus resulting trend pattern after elimination of the “natural” fluctuations” are thought to be an effect of the anthropogenic forcing related to an increase of the atmosphere loading by human made substances destroying ozone layer. However, for an estimation of danger of thinning ozone layer we need also information of total ozone trend pattern comprising both the anthropogenic and “natural” forcing. Here, we present an analysis of the long-term variability of total ozone over Europe based on the reconstructed data extending back to 1 January 1950. The data base was built within the objective of the COST-726 project activity (Krzyścin, 2007). The basic idea of the proposed trend model is to fit proper smooth curve to the scattered monthly data and evaluation of the trend variability from the differences between the curve’s values at selected intervals. The confidence intervals for derived trend values are calculated by the block bootstrapping of the model residual term.

Inspection of the spatial/temporal long-term ozone variability over Europe suggests significant changes of the ozone field over Europe in recent decades. The scale of ozone depletion relative to the ozone level before the satellite era of observations is not dramatic. Maximum present decline (in 2004, the end of analyzed data) of the European total ozone is not dramatic, i.e., $\sim -5\%$ and $\sim -3.5\%$ in the cold (October–next year April) and warm (May–September) subperiod of the year, respectively. The statistically significant negative trends over large areas are mainly found in the mid 1980s up to mid 1995. For high latitude regions the trend overturning could be inferred in last decade (1995–2004) as the ozone depleted areas are not delineated there in 2004. It suggests a compensation of a large ozone depletion that happened before the mid 1990s over high north latitudes. Substantial thinning (up to -3% /per decade) of ozone layer could be found for some areas before 1980s, for example region along the Arctic circle in 1955–1964. Thus an importance of dynamical processes in forming the long-term pattern of the ozone variability should be stressed here (see also a positive trend of $\sim 2\%$ per decade over Svalbard archipelago in the 1995–2004 warm seasons).

Interactive Discussion

It is worth mentioning from perspective of protection against excessive UVR that present total ozone level over large areas of central and southern part of continental Europe in warm season, i.e., in period with naturally high surface UVR, is still ~3% below its level before 1980. Moreover, during cold season present ozone level is still depleted over many winter resorts over southern Europe and northern Africa. What is most alarming negative trend still exist in last decade for some isolated areas there, like the southern part of the Mediterranean Sea. Thus, further public informing of danger related to the UV overexposes is still vital issue.
