Abstract

A pronounced ENSO cycle occurred from 1986 to 1989, accompanied by distinct dynamical and chemical anomalies in the global troposphere and stratosphere. Reproducing these effects with current climate models not only provides a model test but also contributes to our still limited understanding of ENSO's effect on stratosphere-troposphere coupling. We performed several sets of ensemble simulations with a chemical climate model (SOCOL) forced with global sea surface temperatures. Results were compared with observations and with large-ensemble simulations performed with an atmospheric general circulation model (MRF9). We focus our analysis on the extratropical stratosphere and its coupling with the troposphere. In this context, the circulation over the North Atlantic sector is particularly important. Observed differences between the El Niño winter 1987 and the La Niña winter 1989 include a negative North Atlantic Oscillation index with corresponding changes in temperature and precipitation patterns, a weak polar vortex, a warm Arctic middle stratosphere, negative and positive total ozone anomalies in the tropics and at middle to high latitudes, respectively, as well as anomalous upward and poleward Eliassen-Palm (EP) flux in the midlatitude lower stratosphere. Most of the tropospheric features are well reproduced in the ensemble means in both models, though the amplitudes are underestimated. In the stratosphere, the SOCOL simulations compare well with observations with respect to zonal wind, temperature, EP flux, and ozone, but magnitudes are underestimated in the middle stratosphere. The polar vortex strength is well reproduced, but within-ensemble variability is too large for obtaining a significant signal in Arctic temperature and ozone. With respect to the mechanisms relating ENSO to stratospheric circulation, the results suggest that both, upward and poleward components of anomalous EP flux are important for obtaining the stratospheric signal and that an increase in strength of the Brewer-Dobson circulation is part of that signal.

1   Introduction

On a global scale, the most important (and potentially predictable) mode of interannual climate variability is El Niño/Southern Oscillation (ENSO). It affects not only climate in tropical regions, but also in the extratropics and in the stratosphere. While the climatic influence in the Pacific-North American sector is well known and understood (e.g., Alexander et al., 2002), the effects in other parts of the world are less well established. Understanding these effects is important, e.g., with respect to seasonal climate forecasting. As to the stratosphere, the ENSO signal is relevant as it affects the ozone layer as well as stratospheric dynamics (Brönnimann et al., 2004).

The ENSO signal in the stratosphere is neither well known nor completely understood. Many El Niño events are accompanied by a weak and warm polar vortex both in models and observations; a signal that appears in the upper stratosphere in early January and then propagates downward and dominates the lower stratosphere in late winter (e.g., van Loon and Labitzke, 1989; Sassi et al., 2004; Manzini et al., 2006; Brönnimann et al., 2004; see also Taguchi and Hartmann, 2006[1]). In climate models, ENSO affects stratosphere-troposphere coupling (e.g., Pyle et al., 2005) and stratospheric chemistry (e.g., Sassi et al., 2004). However, the signal is not reproduced in all model studies (see references in Manzini et al., 2006) and in observation-based studies it has been found difficult to separate the ENSO signal from other effects such as the Quasi-Biennial Oscillation (QBO) or volcanic eruptions. The effect on Arctic ozone has only rarely been addressed.

The circulation in the Arctic stratosphere is closely related to the tropospheric circulation in the North Atlantic-European sector (e.g., Hartmann et al., 2000; Baldwin and Dunkerton, 2001; Ambaum and Hoskins, 2002) and hence understanding the stratospheric ENSO signal requires an understanding of the ENSO climate signal in

---

[1]Taguchi, M. and Hartmann, D. L.: Changes in the occurrence frequency of stratospheric sudden warmings with ENSO-like SST Forcing as Simulated by WACCM, J. Climate, submitted, 2006.

the North Atlantic-European area. The latter, however, is a matter of ongoing discussion. In statistical studies, several authors found a symmetric signal that resembles the North Atlantic Oscillation (NAO) and supposedly results from a downwind propagation of a wave disturbance from the Pacific-North American sector in the form of a station-
5　ary wave-train, possibly maintained by a transient-eddy feedback (e.g., Fraedrich and Müller, 1992; Fraedrich, 1994). However, others found an asymmetric signal (e.g., Wu and Hsieh, 2004) or a signal that is strong for La Niña but weak or absent for El Niño (e.g., Pozo-Vázquez et al., 2005). This is important with respect to the interpretation of the stratospheric signal. Hence, trying to reproduce the ENSO signal in the North
10　Atlantic-European area and the stratosphere with climate models not only serves as a model test but also promotes our understanding of ENSO mechanisms.

In this study we analyse the effects of a pronounced El Niño/La Niña cycle on the circulation of the extratropics and the northern stratosphere using ensemble simulations with a chemical climate model (CCM). Ensemble simulations provide multiple
15　realisations of numerical predictions of the atmospheric state, which allows analysing probabilities and frequency distributions. The observed state ideally should fall within the ensemble spread. Although standard for atmospheric general circulation models (AGCMs), ensemble simulations are less common for CCMs and, to our knowledge, have not yet been systematically used for addressing ENSO effects. We compare
20　our results with observations as well as with existing large-ensemble simulations performed with an AGCM. The latter comparison is interesting not only with respect to the tropospheric signal, but also with respect to the robustness of the stratospheric signal, as the AGCM does not include chemistry (and thus no chemical feedback on the circulation) and resolves only the lower stratosphere.

25　Before models can be analysed with respect to inter-event variability or combinations of influences, they should be able to reproduce a standard ENSO cycle. For our study we therefore chose an ENSO cycle that follows the "canonical" case with respect to the observed circulation anomalies in the Pacific-North American and North-Atlantic European sectors and the stratosphere. However, the "canonical" case is primarily a

statistical construct and rarely occurs in nature. With respect to the ENSO signal in the stratosphere (but also at the Earth's surface), volcanic eruptions as well as the QBO have a disturbing or modulating effect. The same might be true for anthropogenic influences, most importantly ozone depletion. Nevertheless, a close to "canonical"

5 ENSO cycle occurred 1986–1989, which comprises an average El Niño in the winter 1986/87 and a relatively pronounced La Niña in the winter 1988/89. The cycle was undisturbed by volcanic eruptions, the two opposite ENSO events both occurred during easterly phases of the QBO, and greenhouse gas concentrations, aerosol loadings, and stratospheric chlorine loading were not very different for the two events.

10 One or both events have been studied by many others using oceanographic and atmospheric data (e.g., Kousky and Leetma, 1989; McPhaden et al., 1990; Miller et al., 1988) and models (e.g., Hoerling et al., 1992; Hoerling and Ting, 1994; Sardesh-mukh et al., 2000). Climate effects in Europe have also been addressed (e.g., Palmer and Anderson, 1993; Fraedrich, 1994; Claud et al., 1999; Sardeshmukh et al., 2000;

15 Compo et al., 2001; Mathieu et al., 2004). The latter studies have demonstrated that atmospheric circulation over the North Atlantic-European sector during this ENSO cycle was in relatively good agreement with the "canonical" ENSO effects found in other studies (e.g., Fraedrich and Müller, 1992; Merkel and Latif, 2002; Brönnimann et al., 2004). Hence, this ENSO cycle provides a good opportunity to assess the ability of cur-

20 rent models to reproduce the ENSO effects and in addition helps to better understand the observed dynamical and chemical effects in the polar stratosphere.

The paper is organised as follows. Section 2 describes the observational data sets used and the set-up of the model experiments. In Sects. 3.1 and 3.2 we analyse the results for the troposphere and for the stratosphere, respectively. Discussion and

25 conclusions are presented in Sects. 4 and 5, respectively.

EGU

2 Observational data and model description

The CCM SOCOL (for details see Egorova et al., 2005) combines a modified version of the AGCM MAECHAM4 (Manzini et al., 1997) and the chemistry-transport model MEZON (Rozanov et al., 1999; Egorova, 2003). The radiation scheme is based on the ECMWF radiation code (Fouquart and Bonnel, 1980; Morcrette, 1991). The model was run with a horizontal resolution of T30 and 39 levels (model top at 0.01 hPa). A 26-year long transient simulation (Rozanov et al., 2005) was used as climatology (termed S0) and for each of the two winters an ensemble of 11 simulations was performed (S1). A second ensemble of 11 simulations per winter (S2) was performed with a slightly modified version of the model, which used the SPARC stratospheric aerosol data (Thomason and Peter, 2006) instead of the NASA-GISS data (Sato et al., 1993) and in which the QBO was nudged (Giorgetta, 1996). All simulations were started from S0 in August 1986 and 1989, respectively (in the case of S1), or in January 1986 and 1989, respectively (S2, in order to allow another seven months of spin-up with the modified model). Initial conditions for the ensemble members were obtained by perturbing global CO_2 concentration within 0.01% for one month (August 1986 and 1989, respectively). The final simulations were then performed from September to March in each winter. Meteorological variables were stored at 12-h intervals and chemical variables as monthly means (S1, based on the original 2-hourly data) or at 12-h intervals (S2).

For comparison we used existing runs performed with the AGCM MRF9. A detailed description of the MRF9 model may be found in Kumar et al. (1996) and references therein. The simulations are described in more detail in Sardeshmukh et al. (2000) and Compo et al. (2001). The model was run at a T40 horizontal resolution with 18 sigma levels. The model top was at 50 hPa, which imposes important constraints when analysing the stratosphere. As climatology we used a set of 90 runs performed with climatological SSTs (M0). For each of the two winters, a total of 180 simulations were performed. Apart form the initial conditions, also the starting month varied. We chose sets of 45 simulations per winter that start in November and were performed through

The 1986–1989 ENSO cycle in a chemical climate model

S. Brönnimann et al.

March (M1). Table 1 gives an overview of the model experiments.

In order to address the circulation of the troposphere and stratosphere we used ERA40 reanalysis data (Uppala et al., 2005), which are somewhat incorrectly referred to as observations in the follwing (we performed all comparisons also with NCEP/NCAR reanalysis data (Kistler et al., 2001), but refer to these comparisons only occasionally). For precipitation we used the Global Precipitation Climatology Project (GPCP) Version 2 data (Adler et al., 2003). The signal in stratospheric ozone was analysed in TOMS Version 8 total ozone data (Nimbus-7) and SAGE II (Version 6.2) ozone profiles. In addition, we also used the CATO assimilated ozone data (Brunner et al., 2006) on an equivalent latitude coordinate system, which allows focussing on changes in the diabatic mean circulation and chemical effects. The overlapping period of all data sets, i.e., 1979–2002, was used as a reference period.

Results from the two models and observations are compared mostly with respect to late-winter (January to March) averages, when a consistent signal is expected over the North Atlantic and in the lower stratosphere (e.g., Gouirand and Moron, 2003; van Loon and Labitzke, 1989; Sassi et al, 2004; Manzini et al., 2006). Note that the expected signal is different, in fact opposite in many respects, in November and December (e.g., Mariotti et al., 2002; Moron and Plaut, 2003; Manzini et al., 2006). In order to correctly interpret the stratospheric signal, it is important that the tropospheric signal is reproduced correctly. Hence, we first analysed 1000 hPa temperature and geopotential height (GPH) as well as precipitation. In order to address the stratospheric signal we analysed temperature, zonal wind, GPH, ozone as well as the components and divergence of the Eliassen Palm (EP) flux (Andrews et al., 1987).

EGU

3 Results

3.1 The troposphere

Figure 1 displays observed anomalies of temperature and GPH at 1000 hPa as well as precipitation for January to March 1987 and 1989. The two winters exhibit the well known ENSO imprint in the North Pacific area such as a strong (weak) Aleutian low for El Niño (La Niña), accompanied by high (low) temperatures in Alaska. Temperature anomalies in northeastern Europe were strongly negative for the El Niño winter and positive for the La Niña winter. The 1000 hPa GPH field shows a pronounced negative (positive) NAO pattern in the two winters. This is in excellent agreement with the "canonical" effect of ENSO on Europe in late winter. The El Niño winter also resembles the strong 1940-1942 case (Brönnimann et al., 2004). A strong precipitation signal is found especially for the La Niña winter, with negative anomalies throughout the Mediterranean area and positive anomalies in northwestern Europe. The El Niño case shows anomalies of opposite sign, but slightly weaker in amplitude. In general, the results show a close to symmetric response for these two winters with respect to most of the features, and they again suggest that 1986–1989 was a "classical" ENSO cycle with respect to its effect on the circulation over the North Atlantic-European sector.

   Comparisons between simulations and observations for the two individual winters are not possible in a strict sense (and therefore not shown here) because of the different climatologies used. Nevertheless, it is interesting to note that similar to the observations, both models show a response that is close to symmetric around the respective climatology in the two winters. Model results (ensemble means) are compared to the observations in Fig. 2 in the form of the difference between the El Niño winter (1987) and the La Niña winter (1989). The amplitudes of the anomalies are generally smaller in the ensemble means than in the observations, which is expected due to averaging. The patterns, however, are relatively well reproduced by both models. For El Niño minus La Niña, all experiments show cold winters in northeastern Europe, stretching all across northern Eurasia, and a dipole pattern in 1000 hPa GPH resembling the neg-

The 1986–1989 ENSO cycle in a chemical climate model

S. Brönnimann et al.

ative mode of the NAO (see Compo et al., 2001, for a discussion of related changes in subseasonal variability). In the SOCOL experiments as well as in the observations (but not in M1) the anomaly centres lie close to Iceland and the Azores.

For precipitation (Fig. 2), all experiments reproduce the observed decrease in Norway and the increase in the Mediterranean area. The precipitation signal over the Atlantic reflects a southward shift in the Atlantic storm track for El Niño relative to La Niña, which was also shown by Compo and Sardeshmukh (2004). As for the other fields, the magnitudes of the precipitation anomalies is underestimated. Nevertheless, in all three fields (temperature, GPH, and precipitation) the main differences between El Niño and La Niña found in the observations are also statistically significant (t-test, $p < 0.05$) in the model experiments.

Several features, on the other hand, are not well reproduced in the SOCOL model. This concerns in particular surface air temperature over the sea ice north of Alaska (also in MRF9). Also, the warming signal for El Niño minus La Niña stretching from Sudan to the Middle East is not well reproduced (again by both models).

In addition to the significance of the ensemble mean differences, it is advisable also to look at the distribution functions (see also Melo-Goncalvez et al., 2005). Figure 3 shows histograms of temperatures at a grid point near Dalarna, Sweden (60°N/15°E), which is close to the location of the maximum 1000 hPa temperature difference in the observations (note, however, that the grid point is close to the Baltic Sea, where SSTs were prescribed). In order to obtain a larger sample we merged S1 and S2, which show a similar mean response, into one figure. First of all, it becomes obvious that the models differ both with respect to absolute values as well as variability. The surface temperature is lower in SOCOL compared to MRF9. On the other hand, the variability is much higher in SOCOL than in MRF9. The observed temperatures are indicated as coloured lines. Here we use both ERA40 and NCEP/NCAR reanalysis data. They are within the ensemble spread only for SOCOL (S1+S2) in the winter 1987, but outside the ensemble spread in all other cases. While the models reproduce the sign of the difference between the two winters, they clearly underestimate the magnitude.

However, it should be noted that the two observation-based data sets (i.e., two de-pictions of the same "realisation") also show quite substantial differences and that the observed magnitude amounts to 8–10°C. This is extreme for a 3-month average. In fact, long temperature records from nearby stations sites (not shown) indicate that the two winters were both close to the record minima and maxima, respectively.

With respect to the interpretation of ensemble means, it is clear that the modelled temperature signal shown in Fig. 2 does not arise from a few outliers, nor does it mask a bimodal behaviour. MRF9 seems to show a slightly skewed distribution (longer tail towards low temperatures) for La Niña, but this feature is not robust when analysing nearby grid cells.

3.2 Stratospheric dynamics and chemistry

In the following, we focus on the stratospheric dynamics and chemistry. Figure 4 displays the results for GPH and temperature at 100 hPa, representing the lowermost stratosphere. For El Niño minus La Niña, temperatures were low and GPH high above the eastern tropical Pacific (see also Claud et al., 1999). At midlatitudes, a clear wave structure is visible in the 100 hPa GPH field, with its main anomaly centres in the North Pacific and central Europe. Temperatures were high over northern Eurasia, but low over the North Atlantic, similar as in the case of the 1940–1942 El Niño (Brönnimann et al., 2004). The main feature at high latitudes is a weak and meridionally expanded polar vortex, which is consistent with statistical analyses (van Loon and Labitzke, 1987) and model studies (Sassi et al., 2004; Manzini et al., 2006) and again similar to the 1940–1942 case (Brönnimann et al., 2004). In line with a weak polar vortex and again in agreement with the above mentioned studies, ERA40 temperatures were much higher in 1987 compared to 1989 over much of the Arctic. This is in part due to a major warming in January 1987.

The models reproduce the patterns in tropical temperature and GPH anomalies fairly well. MRF9 underestimates the magnitudes in both fields, whereas SOCOL slightly overestimates the GPH response. Both models also show a similar wave-structure

3974

EGU

as the observations in temperature and GPH over the North American-Pacific sector. Further downstream, over the North Atlantic, the wave-pattern is shifted westward in the models compared with the observations. The cooling over the North Atlantic is pronounced and significant in M1 and S2. In the high Arctic, however, the observed temperature signal is not well reproduced in the ensemble means. No significant effect is found except over eastern Siberia. The weak polar vortex in 100 hPa GPH is better reproduced, with a statistically significant signal in all ensemble sets. However, the magnitude is again smaller than in the observations, especially in the MRF9 model. The fact that even MRF9 with a low model top shows a significantly weaker polar vortex confirms that this is a very robust part of the stratospheric ENSO signal.

This is not similarly true for stratospheric temperatures, as is discussed in more detail in the following. We analysed the zonal mean signal in temperature, zonal wind, ozone, and EP flux as a function of latitude and altitude. This was done only for the SOCOL model, but not for MRF9, which due to its low model top is not expected to realistically reproduce processes related to wave-mean flow interaction in the middle stratosphere.

Figures 5 and 6 show zonal mean zonal wind and temperature as a function of latitude and altitude. In addition to the differences between 1987 and 1989, their mean value is also shown for S1 for the comparison of absolute values (S1 and S2 are almost identical with respect to the mean value). SOCOL reproduces the structure as well as the magnitude of the zonal wind fairly well at all levels from the surface up to the middle stratosphere. The structure of the zonal mean temperature (Fig. 6) is also well reproduced, but absolute values are too low in the tropopause region and in the polar vortex. The differences between El Niño and La Niña agree well with the observations in a qualitative sense. In the zonal winds (Fig. 5) both simulations (S1 and S2) show a stronger subtropical jet and a weakened polar vortex (more so in S1 than S2), which is very similar to the ENSO signal found in statistical analyses of reanalysis data (e.g., Chen et al., 2003). Note that the subtropical jet is displaced southward in the models during El Niño compared with La Niña, but not in the observations. The magnitudes of the anomalies also agree well in the troposphere, but in the stratosphere they are

clearly too small in both simulations, especially in the middle stratosphere. Significance is limited to the lowermost stratosphere and troposphere.

A similar result is found for the zonal mean temperature differences between El Niño and La Niña (Fig. 6). The observations show a pronounced signal in the Arctic lower stratosphere. In S1, the pattern is well reproduced, but not its strength, whereas in S2 the pattern is less well reproduced. The Arctic temperature response in the model is significant below 200 hPa. At higher levels, within-ensemble variability is too large for obtaining significant results. Both S1 and S2 show a significant warming of the subtropical tropopause and lower stratosphere which is not seen in the observations. This is probably related to the southward displacement of the subtropical jet in the model (Fig. 5) that is not seen in the observations.

In order to understand the modelled Arctic temperature response in the stratosphere, we analysed 12-hourly series of temperature at the North Pole (10 hPa and 100 hPa) in the individual ensemble members as well as in ERA40 (Fig. 7). The reanalysis data for 1986/87 show a strong disturbance (major midwinter warming) in January. While at 10 hPa, temperatures dropped again during February and reached very low values in March, the disturbance at 100 hPa persisted into spring. In 1988/89, in contrast, the polar stratosphere was undisturbed and cold well into February, but the final warming then was very pronounced. In the SOCOL experiments major warmings appear in most of the simulations in both winters, sometimes already in late November or December. The large day-to-day variability causes a large within-ensemble variability, which hampers the statistical analysis of ensemble means.

In addition to zonal wind and temperature we also analysed the EP flux as a measure of the planetary-wave driving of the stratospheric circulation. Figure 8 shows zonal means of the upward and meridional components of the EP flux as well as its divergence, again for the mean of the two winters and their difference (note that we have averaged EP flux from November to February, thus allowing a four-to-eight week lead with respect to the temperature, zonal wind, and ozone). For the mean values, the EP flux shows an excellent agreement with observations with respect to vertical and latitu-

The 1986–1989 ENSO cycle in a chemical climate model

S. Brönnimann et al.

EGU

dinal structure as well as absolute values. This does not only hold for the divergence of the EP flux, but also for its vertical and meridional components. The differences between El Niño and La Niña are also well reproduced. The observations show a negative anomaly in EP flux divergence in most of the extratropical stratosphere, which is also found in both sets of simulations. An analysis of the EP flux components implies two contributions: an increase in the vertical component as well as an increase (in the lower stratosphere) of the poleward component of the EP flux. For both components the anomalies are again well reproduced by both sets of simulations.

Further comparisons were performed with respect to ozone. The simulated total ozone difference (January-to-March average, El Niño minus La Niña, Fig. 9) shows a very good agreement with TOMS observations with respect to the main structure in the tropics and midlatitudes. Total ozone was reduced over the tropics, especially the tropical Pacific, but enhanced over the midlatitudes with a pronounced imprint of the planetary wave structure. These main features are also significant in the model simulations, though underestimated in the ensemble mean. A similar tropical ENSO pattern was also found in other analyses of TOMS data and chemical climate models (e.g., Steinbrecht et al., 2005). Over the polar region (where no TOMS data are available) S1 shows an increase and S2 a decrease in total ozone, but neither is significant.

We also analysed the zonal mean vertical distribution of ozone in the SOCOL model and compared it to SAGE II data (Fig. 10, left). Prominent features in the observations are high concentrations in the midlatitude lower stratosphere and in the polar vortex and low ozone concentrations in the tropical middle stratosphere. Both S1 and S2 also show an ozone decrease in the tropical stratosphere, but more pronounced and through the entire lower and middle stratosphere. The midlatitude signal is well reproduced both with respect to altitude and magnitude of the signal. These anomalies are all statistically significant in the ensemble means. However, the ozone increase in the polar middle stratosphere is only reproduced by S1 and is not significant.

In order to obtain a better picture of the ozone anomalies at middle and high latitudes we plotted ozone differences as a function of equivalent latitudes (Fig. 10, right).

S. Brönnimann et al.

EGU

This allows focussing on the effects of chemistry and of the meridional circulation by removing the planetary wave imprint (which, as discussed above, is well reproduced by SOCOL). CATO was used as the corresponding observational data set. The transformation to the equivalent latitude coordinates was only possible for S2, which, as discussed above, fits worse with the observations in the stratosphere than S1. The El Niño minus La Niña difference in CATO is larger than in the SAGE II data and shows a different vertical structure of the signal in the tropics and in the subtropical middle stratosphere. The most pronounced feature is again the ozone increase poleward of 65° equivalent latitude (which is not reproduced by S2), providing clear evidence for a strong ozone increase in the Arctic lower stratosphere. Outside the Arctic the agreement between S2 and CATO is relatively good. This concerns especially the tropical lower stratosphere, the subtropical middle stratosphere, and the midlatitude stratosphere. Hence, even after removing the (well reproduced) planetary wave imprint from the zonal mean ozone field, S2 agrees well with observation-based data except for the Arctic.

4 Discussion

At the Earth's surface, SOCOL reproduced the main anomalies of the two winters 1987 and 1989 relatively well with respect to most analysed features, even though the magnitudes of the anomalies are underestimated. Most importantly, both analysed models reproduced the changes in the circulation over the Pacific-North American and North Atlantic-European sectors, i.e., a strengthened Aleutian low and weakened Icelandic low, which is important with respect to the stratospheric signal (Brönnimann et al., 2004). The model results are in good agreement with studies performed with other models (e.g., Mathieu et al., 2004). Note that the results do not imply a causal relationship between the extratropical anomalies and ENSO, as SST fields were prescribed globally. For the same reasons, care should be taken when drawing conclusions on predictability (see van Oldenborgh, 2005). What would be necessary to address these

issues are sensitivity experiments prescribing only the tropical or only the Indo-Pacific SSTs and setting the remaining SSTs to climatology (or using a mixed-layer ocean), which is beyond the scope of this paper.

However, the model simulations and comparison with observations do allow conclusions with respect to the processes behind ENSO effects on the stratosphere and stratosphere-troposphere coupling, given the consistent tropospheric ENSO response. SOCOL reproduced the observed anomalies of lower stratospheric temperature, GPH as well as total ozone in the tropics. This is the typical ENSO pattern that is directly related to the longitudinal shift of the region of intense atmospheric convection (Hatsushika and Yamazaki, 2001). All sets of simulations also reproduced the planetary wave imprint in the midlatitude lower stratosphere that appears in the fields of GPH, total ozone (in SOCOL), and to some extent temperature.

Of special interest with respect to the polar stratosphere are the features that are supposedly caused by wave-mean flow interaction. Brönnimann et al. (2004) suggested that El Niño (relative to La Niña) increases the planetary wave activity propagating from the troposphere to the stratosphere (see also Sassi et al., 2004; Manzini et al., 2006). Increased upward propagating planetary wave activity, which accompanies the negative NAO mode, is expected to lead to a weak polar vortex, higher temperature of the Arctic stratosphere in spring, and more major midwinter warmings (Taguchi and Hartmann, 2006[1]). At the same time, the meridional circulation is expected to be strengthened, transporting more ozone from the tropical source regions to the extratropics, which would lead to higher ozone column at mid latitudes and especially in the polar vortex, where the descent is enhanced (see Randel et al., 2002). In addition, reduced chemical ozone depletion (because of the warmer temperatures) would further increase the Arctic ozone column (Sassi et al., 2004).

The observations are in very good agreement with this hypothesis. They not only exhibit all of the features discussed above (for El Niño minus La Niña a weak and warm polar vortex, a major midwinter warming, more ozone at mid latitudes and in the polar vortex and less ozone, in the tropics, most pronounced in the CATO data), but also

show anomalous EP flux convergence in the stratosphere, which indicates strengthened planetary-wave driving. The SOCOL model reproduces most of these features and hence compares reasonably well, at least qualitatively, with the observations and with other modelling studies (see e.g., Sassi et al., 2004; Manzini et al., 2006). However, the signal in the stratosphere, especially in the middle stratosphere and in the polar vortex, is too weak when compared with observations and some of the prominent features in the observations that are supposedly caused by ENSO are not significant in the ensemble mean.

The agreement between S1, S2, and observations is very good for the components and the divergence of the EP flux. This result implies that the observed and modelled weakening of the polar vortex during El Niño is largely due to wave-mean flow interaction (see also Manzini et al., 2006). It is interesting to note that not only the vertical component of the EP flux (and thus the amount of wave energy that reaches the stratosphere) contributes, but also the meridional component (and thus the degree to which this wave energy is refracted poleward). This is in agreement with the results of Chen et al. (2003) who distinguish between two modes of interannual EP flux variability: a tropospheric mode that is strongly related to the Northern Annular Mode (or NAO) and controls upward propagation of planetary wave energy as well as a stratospheric mode which is strongly related to ENSO and the Pacific North American pattern and controls the poleward refraction of wave energy. The modes are defined as a tropospheric and stratospheric dipole in the anomaly field of EP flux divergence, respectively (see Chen et al., 2003). Both dipoles also appear in the difference field of EP flux divergence in the ERA40 reanalysis and, somewhat less clear, in S1 and S2 (Fig. 8). Thus, in the "canonical" ENSO case, both patterns contribute.

With respect to ozone, all of the above results suggest a strengthening of the Brewer-Dobson circulation that leads to low ozone concentrations in the tropical lower stratosphere and high concentrations at mid latitudes and in the polar lower stratosphere (see also Sassi et al., 2004; Pyle et al., 2005). The chemical contribution at high latitudes has the same sign as the dynamical contribution, but is dependent on tempera-

The 1986–1989 ENSO cycle in a chemical climate model

ture and therefore probably underestimated by SOCOL. At midlatitudes, the planetary wave imprint in total ozone is important and is well reproduced by the model.

5   Conclusions

The main anomalies in atmospheric circulation and ozone observed during the "canonical" ENSO cycle 1986–1989 were successfully reproduced with the chemical climate model SOCOL. While some deficiencies could be identified with respect to the middle stratosphere, the ENSO signal in surface climate, especially the circulation over the North Atlantic-European region, as well as the imprint in the lower stratosphere agree well with observations. As such, the results provide insight into the mechanisms relating ENSO to stratospheric circulation changes. They suggest that both the upward and poleward components of anomalous EP flux are important for obtaining the stratospheric ENSO signal and that an increase in strength of the Brewer-Dobson circulation during El Niño is part of that signal.
