Abstract. Analyses of discharge series, precipitation fields and flood producing atmospheric circulation patterns reveal that two governing flood regimes exist in the Mulde catchment in south-eastern Germany: frequent floods during the winter and less frequent but sometimes extreme floods during the summer. Differences in the statistical parameters of the discharge data can be found within the catchment from west to east. The discharges are compared to a number of landscape parameters that influence the discharge in the subcatchments. Triggering circulation patterns were assigned to all events of the annual maximum discharge series in order to evaluate which circulation patterns are likely to produce extreme floods. It can be shown that the cyclone Vb-weather regime (TM, TRM) generates the most extreme flood events in the Mulde catchment, whereas westerly winds produce frequently small floods. The Vb-weather pattern is a very slowly moving low pressure field over the Gulf of Genoa, which can bring large amounts of rainfall to the study area. It could also be shown that even with the two flood regimes estimates with the annual maximum series provide a safer flood protection with a larger safety margin than using summer maximum discharge series for extreme summer floods only. In view of climate change it is necessary to integrate knowledge about catchment characteristics, the prevailing flood regime or the trends of weather patterns in the estimation of extreme events.

1 Introduction

Limited data on extreme and thus rare flood events complicate the accurate estimation of design discharges (e.g. Francés, 2001; Benito et al., 2004; Merz and Thieken, 2005). Numerous approaches have been developed for flood estimation, which include statistical approaches such as flood frequency analysis (FFA), the use of envelope curves as well as rainfall-runoff modelling with hydrological models. The focus in this study is set on the FFA.

The most common methods for FFA use annual maximum series (AMS) and peak over threshold series (POT) (Institute of Hydrology, 1999). The AMS and POT series can also be extracted for summer or winter seasons, when, for instance, one flood process type (e.g. floods triggered by snow melting) is of special interest. Several distribution functions such as the Gumbel, Weibull, Generalized Extreme Value, or the Pearson type III can be fitted to the data (Hosking and Wallis, 1997; Institute of Hydrology, 1999). Although these functions and possibilities exist as to which data to integrate, large uncertainties still remain when estimating extreme events. There is much debate about the length of the data series. Short series may not capture the entire flood variability and very long series may not reflect stationary conditions (e.g. Bárdoosy and Pakosch, 2005; Khaliq et al., 2006). Moreover, it is questionable whether or not an AMS is stationary when the discharges reflect different flood producing processes. Independence, homogeneity and stationarity are required characteristics of the data to legitimate flood frequency analysis (Stedinger, 2000; Kundzewicz and Robson, 2004). However, often these criteria are not satisfied due to climatic change and/or anthropogenic influence (Webb and Betancourt, 1992; Klemêš, 1993; Jain and Lall, 2000; Sivapalan et al., 2005; Svensson et al., 2005; Khaliq et al., 2006). Independence is almost always given, when analyzing annual maximum series, whereas partial series have to be carefully examined in order to avoid miscounting one flood event as two. Usually, a threshold of several days is included in the extraction of the data, which defines the minimal time between two floods to ensure independence of the events. This threshold can comprise up to 30 days depending on the catchment area and discharge conditions. Stationary conditions seldom exist due to changes in climate, land-use or in...
It can accumulate large amounts of moist and warm air over the Mediterranean Sea, which is transformed into large precipitation amounts that fall along the northern slopes of the Alps and mountain ranges in Central and Eastern Europe. It is therefore interesting to analyze the relationship of circulation patterns and flood generation in the study area.

More information about flood generating processes can be gained when extending the study from one gauge station to the hydrological behaviour of sub-catchments and neighbouring regions (Harlin and Kung, 1992; Merz et al., 2006; Ouarda et al., 2006). Harlin and Kung (1992) extract for each sub-catchment the most extreme measured events and simulate the simultaneous occurrence of the floods which has not been observed yet. Of special interest for the flood hazard estimation of ungauged areas is also the regional FFA which incorporates flood process information from neighbouring catchments (e.g. Stedinger, 1983; Hosking and Wallis, 1997; Institute of Hydrology, 1999). Regionally valid distribution functions are fitted to data of preferably independent gauges within a region, which exhibit, in general, better fits (Merz, 2006).

In this paper the flood discharge characteristics of the Mulde catchment in south-eastern Germany are analyzed according to stationarity, their spatial distribution of the statistical moments and the relationship between landscape characteristics and flood peaks. Additionally, the relationship between the dominating weather pattern in Europe and the flood generation in this catchment is discussed. The following questions will be answered based on this analysis: Which landscape components (geology, soil, groundwater flow, land-use, precipitation) contribute to the flood discharge regime? Can seasonal or spatial differences be distinguished? Do specific circulation patterns exist which trigger large events? And finally, are the requirements for the flood frequency analysis with AMS for this catchment fulfilled?

2 Study area and data

2.1 Study area

The Mulde catchment is a sub-catchment of the Elbe River basin in south-eastern Germany. The southern boundary is marked by the mountain ranges of the Erzgebirge, which coincides with the Czech – German border. The catchment has a total area of 6171 km² (at the gauge Bad Düben) and has three large sub-catchments (Zwickauer Mulde, Zschopau, Freiberger Mulde), which drain the upper, mountainous part of the catchment (Fig. 1). Within only 20 km, the tributaries Zschopau and Freiberger Mulde disembogue near the gauge Erln (gauge 13, Fig. 1) into the Zwickauer Mulde and form the Vereinigte Mulde (“Joined Mulde”), which disembogues near the city of Dessau into the Elbe River.

The elevation ranges from 52 m to 1213 m a.s.l. with approx. 2/3 of the area being lowlands and 1/3 mountains.
(500–1213 m a.s.l.) (Fig. 1). The mountain ranges in the south cause fast runoff responses to rainfall events in the tributaries, whereas in the major part of the catchment slower runoff responses dominate. The annual precipitation ranges from 500 mm in the lowlands to 1100 mm in the mountain ranges.

The landscape characteristics of the catchment such as geology, soil, hydro-geology and land-use parameters were evaluated to gain information about the variability of the discharge behaviour. Therefore, the catchment was split into three zones, which correspond to the three large sub-catchments (Fig. 1).

The region has a long history of large flood events. First written documents about floods, the corresponding water levels and damage can be found from the 9th century onward and more detailed documents starting from the 14th century (Pohl, 2004). It is noteworthy that large winter floods with ice blockage as well as summer floods from torrential storms or long lasting frontal rains caused high damages on infrastructure and agriculture, often with fatalities.

During the last 100 years, three extreme flood events occurred in the study area, namely in July 1954, July 1958 and August 2002. These events will be analyzed in more detail in this paper. All of them were caused by large torrential storms. The floods in 1954 and 2002 were triggered by Vb-weather systems. Both flood events in the fifties caused high damage in different parts of the catchment, whereas in 2002 the entire catchment was affected. This flood caused a damage of 11.6 Billion € in Germany alone (DKKV, 2004; Thieken et al., 2006). As a consequence of the flood history, flood defence measures play an important role and have been extended until the present day (DKKV, 2004). Numerous flood retention basins and dams were constructed, which are mainly located in the upper part of the catchment, and significantly influence the discharge downstream.

2.2 Data

2.2.1 Discharge data

Over 60 discharge and water level gauges exist in the Mulde catchment. The earliest measurements at regular intervals began in 1910 at two gauges. In order to evaluate the influence of a dam before including data from the downstream discharge gauge into the dataset, daily differences of inflow versus outflow of five large dams for the period 1991–2002 were compared. More information from the dam authorities was not available. Inflow and outflow flood peaks were compared and the downstream stations were excluded from the dataset if the flood peak differences were greater than 10%, and if there were at least five affected flood events during this 10 year period. Additionally, daily time series of discharge gauges that are in the immediate vicinity of a dam were compared to daily discharge data from neighbouring gauges at other tributaries. Time series of discharge gauges that did not reflect the hydrograph at the compared gauge station were excluded from the dataset. AMS (hydrological year from November to October) were extracted from daily maximum discharges.

A subset of discharge gauges was selected for this analysis which met the following criteria:

- the time series must have a length of at least 40 years,
- the sub-catchment area is larger than 100 km$^2$,
- the flood AMS exhibits no trend,
- the discharge gauges are distributed across the catchment and have a distance of at least 3 km between each other.

15 discharge gauges meet these criteria; they are listed in Fig. 1 and Table 1. For better readability, the gauge stations are listed in all tables in the same order beginning with those located in the south-west (Zwickauer Mulde), then progressing north and east (Zschopau, Freiberg Mulde) and ending with gauges located in the Vereinigte Mulde (cf. Fig. 1).

2.2.2 Precipitation Data

Precipitation data were available from the German Weather Service (DWD) at 49 stations in and around the Mulde catchment (see Fig. 2). The data cover the time period between 1952 and 2002 on a daily basis. Daily areal precipitation was calculated based on cubic interpolation for each of the 15 sub-catchments (corresponding to the discharge stations) for the comparison of precipitation and discharge.

2.2.3 Atmospheric circulation patterns

Information about the predominant European circulation pattern for each day was available from the “Catalogue of Großwetterlagen in Europe 1881–2004” (Gerstengarbe and Werner, 2005). The catalogue distinguishes three large circulations, which are divided into 30 different circulation patterns (one is classified to be a “transition class”) (Table 2). The Vb-weather system is represented by the patterns TM (low Middle Europe) and TRM (Trough Middle Europe).

The circulation patterns comprise the zonal circulation form, the mixed circulation form as well as the meridional circulation form. For every day a circulation pattern is assigned to be the dominant one for Europe. Through the specific distribution of lows and highs over Europe, it may therefore be possible that the dominant circulation pattern of a particular day is not necessarily representative for the Mulde catchment. This is for instance the case, if the Mulde catchment is still under the influence of a weakened low, which is however already situated above Eastern Europe, whereas the dominating European circulation pattern is above Western Europe. However, other than this catalogue, more detailed meteorological data for the study area were not available.

3 Methodology

3.1 Flood frequency analysis

The distribution-free and non-parametric Mann-Kendall test for Trend (one-sided test; significance level: $\alpha=0.05$) was used for the detection of trends in the data. Since small trends in the data may not be detectable, for instance by the Mann-Kendall test (Bárdossy and Pakosch, 2005), a regional test of stationarity was conducted with all 15 data sets (Lindström and Bergström, 2004). To this end, several data series from the same region, that cover the same period of measurements, are tested jointly (also with the Mann-Kendall test). For comparison, the discharge data were divided by the MAF (mean maximum annual flood discharge) of the respective series. AMS of 13 gauge stations with data from 1936 to 2002 and of two gauges with data from 1961 to 2002 were included.

Independence of the data was ensured by using AMS data, which were also checked for possible dependent values around the turn of a hydrological year. For this, a threshold time of 7 days between two AMS floods was included, which guarantees the independence of two close-by flood events, since the time of concentration for this basin is smaller than 7 days.

Flood frequency analyses were performed with seven different distribution functions (Gumbel, Weibull, 2-parametric LogNormal, Generalized Extreme Value (GEV), General Logistics (GL), 3-parametric LogNormal, and Pearson type III) with both the Method of Moments and with the L-Moments (Hosking and Wallis, 1997; Institute of Hydrology, 1999). The GEV and GL distribution functions (both with L-Moments) revealed the best fits based on the Kolmogorov-Smirnov-Test and visual examination relative to the empirical probabilities (Test hypothesis: $F(x)=CDF$ for all $x$ with $\alpha=0.05$). Emerging consensus can be found in many studies worldwide that the GEV distribution reveals the best fits (Pearson, 1991; Onoz and Bayazit, 1995; Vogel and Wilson, 1996; Douglas and Vogel, 2006). The Institute of Hydrology (1999) also describes the “theoretical and historical importance” of the GEV. Hence, subsequent analyses were performed using the GEV.

3.2 Spatial distribution of flood characteristics

The spatial distributions of the statistical moments of the AMS, such as skewness and coefficient of variation, were analyzed to detect possible differences among sub-catchments. The spatial extent and distribution of the three most extreme flood events (July 1954, July 1958, August 2002) were analyzed in more detail. For every event and gauge station, return periods (GEV, L-Moments) were calculated. These estimates were then assigned to each river segment upstream of the 15 gauge stations in order to analyze the flood characteristics in a spatially explicit manner.

Moreover, the AMS of 11 gauge stations with data from 1929 to 2002 (74 years) were studied with respect to the spatial distribution and magnitude of flood events. To this end, the number of different flood events per year in the catchment was analyzed. If all 11 gauges have their highest discharge of a certain year on the same day (+/− 1 day), the number of flood events for that year will be one. The other extreme is that all gauges have their highest peak at another time of the year. In that case, the number of flood events for that year is 11.

3.3 Relationship between precipitation maxima and discharge maxima

The relationship between precipitation maxima and discharge maxima was studied in more detail. Areal precipitation was calculated for the three large sub-catchments (Zwickauer Mulde: gauge Wechselburg; Zschopau: gauge Lichtenwalde; Freiberger Mulde: gauge Nossen) and the Vereinigte Mulde at the gauge Golzern. Precipitation sums of 24 h, 48 h and 72 h of the flood events were compared to discharge maxima. The four discharge stations are distributed over the entire catchment and represent the large sub-catchments. Rainfall AMS were extracted from the precipitation data and then compared on a seasonal basis to the discharge AMS to determine, how many large precipitation events are reflected in the discharge AMS.

3.4 Circulation pattern and flood generation

Daily data of circulation patterns between 1911 and 2002 were analyzed in order to obtain an overview about the seasonal distribution and frequency of the circulation patterns in Europe. Additionally, the circulation patterns, which are triggering the AMS discharges, were assigned to the AMS flood data of the gauge Golzern. The gauge at Golzern is representative for the entire catchment, because it comprises 88% of the catchment area. As the first gauge at the Vereinigte Mulde it represents the influence of the two large sub-catchments. Moreover it has a long time series (1911–2002) compared to nearby gauges such as Bad Düben or Erlin (both 43 years).

From the AMS data, empirical probabilities were assigned to the flood events and then combined with the circulation pattern data. With this information, it is possible to estimate the potential of a circulation pattern to generate a flood of a certain return period.
4 Results

4.1 Testing for trends in the flood AMS

The one-sided Mann-Kendall test for increasing trend (significance level $\alpha=0.05$) revealed no trends for all 15 gauge stations. The trend test for regional stationarity was performed with the normalized AMS of the 15 gauge stations. As Fig. 3 shows, the data exhibit a very small positive trend in the regional trend analysis. When the flood event from August 2002 was excluded from the data, the slightly positive trend became slightly negative. The Mann-Kendall test showed no trend (significance level $\alpha=0.05$). Therefore the data were used for flood frequency analysis.

4.2 Seasonal occurrence and magnitude of floods

Two dominant flood process types in the Mulde catchment can be extracted from the data. During March and April, a first peak in the discharge AMS occurs during snow melt and “rain on snow” flood events. The second peak occurs in July and August, when large torrential storms traverse the area (Table 3). At all 15 discharge stations winter floods (November–April) comprise a larger part of the AMS than summer floods. In the upper western part of the Erzgebirge (corresponding to the gauges at Aue, Niederschlema, Zwickau), the percentage of summer and winter floods in the AMS is almost equal (e.g. Aue: 46% summer floods; 54% winter floods), whereas in the eastern part of the catchment winter floods have larger percentage (59%–69%).

The winter floods are usually small events with a low return period. They constitute at all 15 gauges only 8–21% of the 20% of the largest floods. Summer flood events, on the other hand, are less frequent, but cover a larger proportion of extreme events (26–39%). In Fig. 4 the data of Table 3 are summed up for all 15 gauges. Additionally, the monthly distribution of the 20% largest flood events is shown. Again, it is visible that winter floods have a large percentage of the AMS, but the most extreme events occur during the summer. From these analyses we could conclude that summer flood events play a more important role for the flood hazard estimation of extreme events, which would necessitate the usage of Summer Maximum Series (SMS) instead of AMS. A comparison of return periods estimated with AMS and SMS for the three extreme flood events showed however that estimated return periods up to 270 years are at all 15 gauges much lower with AMS. As an example return periods (GEV) for the gauge Aue are shown for the three floods 1954: 48 (AMS), 65 (SMS); 1958: 7 (AMS), 10 (SMS); 2002: 115 (AMS), 143 (SMS). Thus, a larger discharge would be needed to estimate the same return period, e.g. a design discharge of 100 years when using AMS compared to SMS. Estimates for return periods larger than 270 years show, however lower values with SMS. Therefore, flood protection measures designed on the basis of AMS estimated return periods provide safety margins, even for extreme summer events up to 250 years.

4.3 Spatial distribution of flood characteristics

The AMS of 11 gauge stations with data from 1929 to 2002 (74 years) were studied with respect to the spatial distribution and magnitude of flood events. To this end, the number of different flood events per year in the catchment was analyzed. In 13 years of the 74-year period, one flood event occurred that affected all 11 sub-basins, whereas in 18 years no dominant flood event (i.e. four to seven flood events per year) could be identified. These are summer and winter events. In most years (27) three different flood events are related to AMS discharges.

In Fig. 5 six different flood events at the 11 analyzed gauges and their respective return periods are shown. The return periods were estimated with the GEV (L-Moments). The six flood events comprise the three largest events in the catchment (1954, 1958, 2002) and three small catchment-wide events. Events with discharges that correspond up to a 10-year peak discharge are mostly homogeneously distributed.

Normalized AMS from 15 stations (1936-2002)

Fig. 3. Regional trend test based on discharge data of 15 stations.

across the catchment. They have similar return periods at all gauges and exhibit a standard deviation of 1. This is shown for the floods in January 1938, October 1960 and August 1984. Events with discharges larger than a 10-year peak exhibit increasing spatial distinctions as well as increasing standard deviations. This is illustrated by the floods in 1954, 1958 and 2002. Depending on the location of the precipitation field, one or the other sub-catchment is more affected during a large flood event. Figure 6 shows the spatial distribution of the return periods that were calculated for the observed discharges of the three most extreme flood events (1954, 1958, 2002) in the Mulde catchment (upper part) and the corresponding areal precipitation events (lower part). The return period calculated for a certain gauge was assigned to the river segment upstream of the gauge. A marked spatial distribution can be seen. For the flood event in 1954, high
return periods were calculated for the western part of the catchment. This is explained by the rainfall event that had its centre in the western part. The floods in 1958 and 2002 were caused by precipitation events with their centres east of, or in the eastern part of the study area. Figure 6 illustrates the direct relationship between the location of the precipitation field and the flood return period for the three events.

More similar statistical moments were found along the tributary rivers rather than according to the elevation of the gauge locations. In the beginning the assumption was made that the gauges in the mountains of the Erzgebirge can be grouped together to exhibit similar statistical moments as well as the gauges in the lowlands. However, increasing values of the statistical moments occur from west to east that corresponds to the division of the sub-catchments. Figure 7 shows the spatial distribution of the skewness (A) and the coefficient of variation (B) for the 15 gauges. The sub-catchment of the Zwickauer Mulde and the western part of the Zschopau (gauges 1–6 in Table 1) are more homogeneous and differ significantly (CI 95%) in its statistical moments from the eastern part of the catchment. These results suggest a different distribution of the precipitation in the sub-catchments which in turn leads to differences in the discharge behaviour. Another possibility is that the landscape characteristics are largely responsible for these differences, which is discussed in the following section.

4.4 Landscape characteristics

The land-use is dominated forest covered mountains and intensively used agricultural lowland. The proportion of agriculturally-used areas increases from west to east and south to north, whereas the percentage of forest decreases. Urban areas only play a role in the sub-catchment Zwickauer Mulde with two larger cities (Zwickau, Chemnitz). Meadows and pastures are homogenously distributed across the area with a slightly larger area in the upper middle Erzgebirge.

Table 4 shows the main percentages of the analyzed landscape characteristics. It can be seen that no major differences in soil (type of soil with information on soil depth, texture, conductivity, etc.), bedrock, groundwater flow and land-use can be distinguished among the three large sub-catchments. As we can see landscape characteristics, such as soil and hydro-geology, do not vary much between the sub-catchments. Although there are slight differences in the land-use, there is much evidence in the literature that during extreme events the land-use only plays a minor role (e.g. DKKV, 2004). Thus, the dominant influence seems to be exerted by precipitation and weather characteristics, which is discussed in the following two sections.
4.5 Relationship between precipitation AMS and discharge AMS

AMS of precipitation and discharge were therefore compared to determine how well precipitation and discharge AMS coincide. Different precipitation AMS were extracted from sums of one, two and three days. A time lag of two days between the precipitation event and the discharge peak was allowed. Table 5 shows exemplarily for four discharge stations the percentages of agreement for summer and winter separately.

During the winter, the precipitation events are not so clearly and directly reflected in the discharge data (agreement 7–26%). One reason for this can be found in the topography of the catchment. During the winter time, large amounts of the precipitation can fall as snow in the Erzgebirge and the water is stored in the snowpack. The discharge generation is delayed until melting starts. Therefore, the triggering circulation pattern, which may have brought a major snow cover, cannot be directly related to the corresponding discharge peak. On the contrary, a direct connection between a large summer rain event and a large discharge can be found in the summer throughout the catchment (agreement 59–89%). Based on these findings the question was posed if large summer flood events can also be related to a specific circulation pattern. This question will be answered in the following section.
Table 4. Percentages of the dominating landscape characteristics.

Fig. 6. Estimated return periods (GEV, L-Moments) for the floods in 1954, 1958, 2002 (period 1929–2002 (above)) and the corresponding precipitation fields (below). Note that for a better illustration of the spatial distribution the classes of discharge return periods and precipitation amounts differ.

4.6 Circulation pattern and flood generation

First of all, daily information about the dominating European circulation pattern between 1911 and 2002 were analyzed. For the entire period, westerly winds (WA–WW) cover about 25% of the total circulation patterns; high pressure weather regimes (all circulation patterns beginning with the letter “H”) cover about 27%. The proportion of the Vb-weather regime (TM and TRM) is relatively low with 6.5%.

The analysis of the discharge AMS at the gauge Golzern shows that approx. 60% occur during the winter time and 40% during the summer time. Only 19 out of the 30 circulation patterns (cf. Table 2) play a role in creating AMS discharges in the Mulde catchment. Thus, 11 out of 30 CPs have not created an AMS discharge within the 92 years. In the winter (November–April), the cyclonal western and northwestern patterns (WA–WW; NWZ) play the dominant role in flood generation, because they account for 84% of the AMS winter discharges and 100% for the floods from November until February (see Fig. 8). The summer AMS discharges are
Fig. 7. Skewness (A) and coefficient of variation (B) of the discharge AMS for the 15 gauges.

Fig. 8. Monthly distribution of AMS discharges at Golzern and the assigned circulation pattern.
generated by several different CPs, though mainly by westerly cyclones (WA–WW), north-east cyclones (NEZ) and the troughs over central Europe (TM, TRM). Figure 9 illustrates the distribution separately for summer and winter.

To answer the question, which circulation pattern is likely to generate large floods in the Mulde catchment, the flood potential was calculated as the probability for a flood quantile $H_{Q_T}$, given a certain CP:

$$P(H_{Q_T}|CP) = \frac{n_{H_{Q_T}}}{n_{CP}}$$

where $n_{H_{Q_T}}$ is the number of flood events larger than $H_{Q_T}$ (e.g. the 10-year flood) that have been triggered by a certain circulation pattern $CP$, whereas $n_{CP}$ is the number of days with the corresponding circulation pattern. It is important to note that already for small return periods (5 years) the Vb-weather regime (TM, TRM) has the highest
flood potential (Fig. 10). These circulation patterns occur seldom, however they are associated with high discharge peaks. Their flood potential is even more pronounced for floods of larger return periods. Weather patterns, such as the westerly and north-western cyclones, which are responsible for most of the winter AMS discharges, play only an important role for return periods of max. 10 years.

There exist also Vb-weather regimes that generated floods with low return periods at the gauge Golzern. However, they often caused high damage in other catchments in Europe and had their precipitation centre outside the Mulde catchment. This is for example the case for the flood in April 1930 in Bavaria, the August 1984 flood in Switzerland, and the flood in July 1997 in the Odra catchment, when the Czech Republic and Poland were heavily affected (Grünewald et al., 1998; Wasserwirtschaftsamt Bayreuth, 2006).

Analyses of the other gauge stations as well as historical records of large floods in the Mulde catchment show similar results with the highest floods being generated by Vb-weather regimes. From this analysis we can conclude that although Vb-weather pattern do not occur often in the European weather regime they carry a large flood risk in the Mulde catchment.

trigger large flood events in the region of interest and possible trends of these. With the combined information of catchment characteristics, flood behaviour and weather patterns, the uncertainty in the estimation of extreme events can be reduced.

Acknowledgements. We thank the GeoForschungsZentrum Potsdam (GFZ) and the Helmholtz Association of National Research Centres for their financial support. The study was part of the Helmholtz Young Scientists Group “Information and modelling systems for large scale flood situations” at GFZ. We dedicate our special thanks to the authorities that provided data.
