## Abstract

A synthesis inversion based on the atmospheric zoom model TM5 is used to derive top-down estimates of CH<sub>4</sub> emissions from individual European countries for the year 2001. We employ a model zoom over Europe with 1°×1° resolution that is two-way nested into the global model domain (with resolution of 6°×4°). This approach ensures consistent boundary conditions for the zoom domain and thus European top-down estimates consistent with global CH<sub>4</sub> observations. The TM5 model, driven by ECMWF analyses, simulates synoptic scale events at most European and global sites fairly well, and the use of high-frequency observations allows exploiting the information content of individual synoptic events. A detailed source attribution is presented for a comprehensive set of 56 monitoring sites, assigning the atmospheric signal to the emissions of individual European countries and larger global regions.

The available observational data put significant constraints on emissions from different regions. Within Europe, in particular several Western European countries are well constrained. The inversion results suggest up to 50–90% higher anthropogenic CH<sub>4</sub> emissions in 2001 for Germany, France and UK compared to reported UNFCCC values, but the derived EU-15 totals are relatively close to UNFCCC values (within 10–30%). The derived top-down estimate for Finland is distinctly smaller than the a priori estimate, suggesting much smaller CH<sub>4</sub> emissions from Finnish wetlands than derived from the bottom-up inventory.

## 1. Introduction

Atmospheric CH<sub>4</sub> is the second-most important anthropogenic greenhouse gas (after CO<sub>2</sub>) with a direct radiative forcing of 0.48 Wm<sup>-2</sup> (IPCC, 2001) and an additional indirect forcing of ~0.13 Wm<sup>-2</sup> due to chemically induced effects (tropospheric ozone and stratospheric water vapor)(Lelieveld et al., 1998). Furthermore, CH<sub>4</sub> has a significant influence on the oxidizing capacity of the atmosphere and hence the lifetime of other

trace gases, such as CO, NMHCs, and HCFCs.

General concern about increasing atmospheric levels of greenhouse gases has led to the United Nations Framework Convention on Climate Change (UNFCCC), which obligates signatory countries to report their annual greenhouse gas emissions, and the Kyoto protocol, which sets legally-binding emission reduction targets for the so-called Annex-1 parties by 2008–2012. The required total reduction of all Kyoto gases together (CO<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O, HFCs, PFCs, and SF<sub>6</sub>) for all Annex 1 parties is 5% below the 1990 CO<sub>2</sub> equivalent emissions, while the European Union has committed itself to reduce its total emissions by 8%. Emissions reported to UNFCCC are based on bottom-up inventories, and guidelines for compilation have been elaborated by IPCC (IPCC, 1996). Despite ongoing improvements of these bottom-up inventories, significant uncertainties remain, in particular for some source categories where emission factors may be highly variable (e.g. CH<sub>4</sub> emissions from landfill sites or N<sub>2</sub>O emissions from agricultural soils).

Thus, it is recognized that independent verification of reported national GHG inventories would be very useful (IPCC, 2000). Such a verification could in principle be provided by top-down approaches, based on measurements of atmospheric mixing ratios and inverse modelling.

Inverse techniques have been widely used on the global scale to derive the sources and sinks of the major greenhouse gases CO<sub>2</sub> (Bousquet et al., 1999a, b; Kaminski et al., 1999a, b; Gurney et al., 2002; Rödenbeck et al., 2003), CH<sub>4</sub> (Hein et al., 1997; Houweling et al., 1999; Bergamaschi et al., 2000; Dentener et al., 2003a), and N<sub>2</sub>O (Prinn et al., 1990). Only during the last few years attempts have been made to derive top-down estimates on national scales, mainly based on Lagrangian back trajectory or Lagrangian particle dispersion models (Vermeulen et al., 1999; Manning et al., 2003). The use of inverse modelling for verification of national bottom-up inventories has recently been discussed at an EU workshop (Bergamaschi et al., 2004).

The global inversions obtained until now generally provide a globally consistent picture; however, they have made little use of synoptic scale variations (usually they use

monthly mean values of atmospheric mixing ratios) and provided results only on relatively coarse model grids. In contrast, the studies based on Lagrangian models use short-term variability of meteorological conditions, but are focused on a limited spatial domain (e.g. Europe) and are not, or only weakly, coupled to the global tracer fields.

5 Here we present an inverse study of European national CH<sub>4</sub> emissions based on the recently developed atmospheric zoom model TM5, which allows us to overcome this scale gap. The zooming approach facilitates – at reasonable CPU costs – consistent high resolution simulations over Europe (1°×1°), two-way nested into the global model domain (with a resolution of 6°×4°).

10 Observational constraints are provided by high-frequency (quasi-continuous) measurements of atmospheric CH<sub>4</sub> mixing ratios at several western European monitoring sites (and some global sites), complemented by a comprehensive set of global flask measurements.

## 2. Inverse modelling setup

### 15 2.1. TM5 model

We use TM5, a two-way nested atmospheric zoom model (Berkvens et al., 1999; Krol et al., 2003, 2004). TM5 is an off-line model that uses meteorological fields from the ECMWF IFS model (6-hourly forecast, based on 4D-VAR analyses)(ECMWF, 2002). The global simulations are performed at a horizontal resolution of 6°×4°. The embedded European zoom domain is run at a resolution of 1°×1° (Fig. 3), and is surrounded by a somewhat larger 3°×2° zoom region in order to ensure smooth transition between the different domains. We employ the tropospheric standard version of TM5 with 25 vertical layers, which are defined as subset of the 60 layers of the current ECMWF operational model. About 5 vertical TM5 layers represent the boundary layer (up to ~1 km), 10 the free troposphere, and 10 the stratosphere. Advection is simulated using the slopes advection scheme (Russell and Lerner, 1981). For non

Interactive Discussion

resolved vertical transport by deep and shallow cumulus convection the parameterisation of Tiedtke (1987) is used. Vertical turbulent diffusion near the surface has been parameterised according to Holtslag and Moeng (1991), and in the free troposphere the formulation of Louis (1979) is applied. The model transport has been extensively validated using <sup>222</sup>Rn and SF<sub>6</sub>, and a detailed comparison with several other models has been performed within the EVERGREEN project (<http://www.knmi.nl/evergreen/>) (Goede et al., 2002). As an example we show <sup>222</sup>Rn and SF<sub>6</sub> simulations and observations from Schauinsland (Fig. 4), illustrating in particular the reasonable simulation of synoptic variations. In addition, an intensive SF<sub>6</sub> validation using a zoom grid over North America has recently been performed (Peters et al., 2004), showing in general good agreement.

Chemical destruction of CH<sub>4</sub> by OH radicals is simulated using pre-calculated OH fields based on CBM-4 chemistry (Houweling et al., 1998) and optimized with methyl chloroform. For the stratosphere, reactions of CH<sub>4</sub> with Cl and O(<sup>1</sup>D) radicals are also included, based on the 2-D photochemical Max-Planck-Institute (MPI) model (Bruehl and Crutzen, 1993).

The derived mean tropospheric CH<sub>4</sub> lifetime<sup>1</sup> vs. OH is 9.4 yrs, very close to the TAR recommended value of 9.6 years (IPCC, 2001).

## 2.2. Bottom-up inventories

Bottom-up inventories are used as a priori estimates of emissions. For all anthropogenic sources except rice paddies we use the International Institute for Applied Systems Analysis (IIASA) inventory for the year 2001, based on the Regional Air Pollution Information and Simulation (RAINS) model, which has recently been extended to include greenhouse gases (Klaassen et al., 2004). This inventory reports national annual totals and has been spatially disaggregated on 1° × 1° using the EDGAR 3.2 database

---

<sup>1</sup>Defined here as  $[\text{CH}_4]_{trop}/[d\text{CH}_4/dt]_{trop}$ , assuming that the troposphere extends from the surface up to 100 hPa.

Interactive Discussion

for year 1995 (Olivier and Berdowski, 2001). No seasonal variation in emissions is assumed for these sources, except biomass burning, which has been monthly disaggregated as described by Houweling et al. (1999). Monthly mean CH<sub>4</sub> emissions from rice paddies were taken from the Goddard Institute for Space Studies (GISS) data base (Matthews et al., 1991), with their annual total (79.7 CH<sub>4</sub>/yr) scaled down to 60 Tg CH<sub>4</sub>/yr. Monthly mean natural emissions from wetlands are based on Walter and Heimann (2000); emissions from wild animals and termites, as well as CH<sub>4</sub> uptake by soils are from the GISS data base (Fung et al., 1991). Emissions from the ocean were provided by Houweling et al. (1999). The bottom-up estimates per region are compiled in Table 1. The global and EU-15 annual totals for the different source categories are summarized in Table 2. Emissions from EU-15 contribute about ~4% of the global total emissions (~5% of the total anthropogenic emissions). The spatial distribution of CH<sub>4</sub> emissions is shown in Fig. 2. Within the zoom region over Europe the spatial resolution of the emission inventory and of the TM5 model are identical (1°×1°), outside Europe, however, the model is run at 6°×4°, i.e. summing up emissions over 24 1°×1° grid cells.

### 2.3. Inversion technique

We use the “synthesis-inversion”/Green’s function approach (Heimann and Kaminski, 1999; Enting, 2000), describing the total atmospheric CH<sub>4</sub> mixing ratio in space and time  $\mathbf{d}_{model}(\mathbf{x}, t)$  as linear combination of  $n_{para}$  model runs for emissions from different European and global regions and emissions from different months  $\mathbf{d}_{model,i}(\mathbf{x}, t)$ , including one background run (explained below):

$$\mathbf{d}_{model}(\mathbf{p}, \mathbf{x}, t) = \sum_{i=1}^{n_{para}} p_i \mathbf{d}_{model,i}(\mathbf{x}, t) \quad (1)$$

with scaling factors  $p_i$  (summarized as vector  $\mathbf{p}$ ).

The European domain has been disaggregated into individual countries for all EU-15 countries (except Belgium, Netherlands, and Luxemburg, which are treated as one region (BENELUX)), Norway and Switzerland. Eastern Europe is treated as two separate

Interactive Discussion

regions (North East Europe, South East Europe), and all non-European land masses are separated into larger regions (also based on national boundaries, but in most cases combining several countries). The definition of regions is illustrated in Fig. 1. The spatial distribution of countries and their fractional contribution to 1° × 1° grid boxes is based on Li (1996).

The temporal disaggregation is performed on a monthly basis, and the individual base functions represent the impact of the emissions from one region and one month. The photochemical sinks (OH, stratospheric O(<sup>1</sup>D) and Cl) are included in the base functions directly (in contrast to other approaches which separate CH<sub>4</sub> sources and sinks; Hein et al., 1997; Houweling et al., 1999).

This study is analyzing the year 2001. Global CH<sub>4</sub> mixing ratios have been initialised using results of a previous inversion. Furthermore, we introduce 2 spin-up months prior to year 2001 (in order to allow some adaptation to potential errors of the initialisation) and simulate also January 2002 (to account for the delayed influence of emissions at monitoring sites). Thus, a total of 2+12+1=15 base functions are calculated for each region. In addition, we calculate one base function for the influence of the model initialization, which accounts for the further development of the initial state of the atmosphere (at 1 November 2000). For this base function, only photochemical sinks are active, but no sources. Consequently, the total number of base functions is  $n_{para}=(15 \times 33 \text{ regions})+1=496$ . Output of each base function is sampled at hourly intervals, and for comparison with observations averaged to daily mean values.

For the inversion, we follow the Bayesian approach including the a priori knowledge from the bottom-up inventories with the usual definition of the cost function  $S$ :

$$S(\mathbf{p}) = \langle \mathbf{d}_{model}(\mathbf{p}) - \mathbf{d}_{data}, \sigma_d^{-1}(\mathbf{d}_{model}(\mathbf{p}) - \mathbf{d}_{data}) \rangle + \langle \mathbf{p} - \mathbf{p}_0, \sigma_{p_0}(\mathbf{p} - \mathbf{p}_0) \rangle, \quad (2)$$

where

$\mathbf{p}$  is a vector containing all model parameters (i.e. emissions from each region and month, and scaling of background base function); dimension  $n_{para}$   
 $\mathbf{p}_0$  is the a priori estimate of  $\mathbf{p}$ ; dimension  $n_{para}$

Interactive Discussion

$\mathbf{d}_{data}$  is a vector containing the observations (daily mean mixing ratios at monitoring sites); dimension  $n_{data}$

$\mathbf{d}_{model}$  is a vector containing the modelled mixing ratios corresponding to the available observations; dimension  $n_{data}$

$\sigma_d$  and  $\sigma_{p_0}$  are the covariance matrices of the observational data (dimension  $n_{data} \times n_{data}$ ) and a priori estimates of the parameters (dimension  $n_{para} \times n_{para}$ ), respectively, and

$\langle x, y \rangle$  denotes the scalar product. Vectors are identified by Bold Italics, matrices are in Bold Roman.

The minimum of the cost function is calculated according Tarantola and Valette (1982) as:

$$\mathbf{p} = \mathbf{p}_0 + \left[ \mathbf{G}^T \cdot \sigma_d^{-1} \cdot \mathbf{G} + \sigma_{p_0}^{-1} \right]^{-1} \cdot \mathbf{G}^T \cdot \sigma_d^{-1} \cdot [\mathbf{d}_{data} - \mathbf{G} \cdot \mathbf{p}_0] \quad (3)$$

with

$$\mathbf{G}_{ij} = \frac{\partial \mathbf{d}_{model,i}}{\partial \mathbf{p}_j} \quad (4)$$

and  $^{-1}$  denoting the inverse matrix and  $^T$  the transposed matrix. Dimension of  $\mathbf{G}_{ij}$  is  $n_{data} \times n_{para}$ .

The a posteriori covariance is given as:

$$\sigma_p = \left[ \mathbf{G}^T \cdot \sigma_d^{-1} \cdot \mathbf{G} + \sigma_{p_0}^{-1} \right]^{-1} \quad (5)$$

### 2.3.1. Parameter covariance matrix

For most bottom-up inventories the uncertainties are not specified in detail. Furthermore, correlations of emissions (e.g. of different grid cells or different regions) are usually not known or not specified, which makes a breakdown (or aggregation) of uncertainties for different spatial or temporal scales difficult. In the absence of this information we introduce a simple adhoc approach: We generally assume an uncertainty of

Interactive Discussion

100% per region and per month for each individual source category (for the categories listed in Table 2). An exception is enteric fermentation, for which an uncertainty of 50% per region and month is assumed. Furthermore, we assume a correlation  $r_{ij}$  between emissions of two consecutive months as follows:

$$r_{ij} = 0.9 * \frac{e_{\min}}{e_{\max}}, \quad (6)$$

where  $e_{\min}$  and  $e_{\max}$  are the minimum and maximum monthly emissions of the respective region and source category. Thus for source categories for which no seasonality is assumed, the correlation coefficient for emissions of consecutive months is 0.9, while for sources with seasonality the correlation is smaller. Emissions from different source categories are assumed to be uncorrelated; i.e. the uncertainty of total emissions per region and month is calculated as:

$$\sigma^2 = \sum_{i=1}^n \sigma_i^2 \quad (7)$$

(where  $\sigma_i$  are the uncertainties per source category).

Note that the relative contribution from different source categories within individual regions is determined by the a priori inventory only and not further optimized in the inversion.

Emissions of different regions are assumed to be uncorrelated (which is an assumption that is not strictly correct, as in many bottom-up inventories the same underlying assumptions (e.g. emission factors) are used for different countries). The assumed a priori parameter covariance matrix is shown in Fig. 8, with non-diagonal elements only within each region for emissions of different months. Note, however, that the a posteriori covariance matrix shows significant correlations between different regions (as will be further discussed in Sect. 3.2).

Using the correlation coefficients the uncertainty of total emissions per year can be calculated from the monthly uncertainties as:

$$\sigma^2 = \sum_{i=1}^n \sum_{j=1}^n r_{ij} \sigma_i \sigma_j \quad (8)$$

( $i, j$ : sum over all months; applicable both for a priori and a posteriori uncertainties).

### 2.3.2. Data covariance matrix

The data covariance matrix  $\sigma_d$  contains the uncertainties of observations and their correlations. It plays an important role in the inversion, giving high weight to observations with low uncertainty and vice versa.

We generally assume a measurement uncertainty of  $\Delta\text{CH}_{4\text{meas}}=3$  ppb for all data from all sites. However, similar to an approach described by Rödenbeck et al. (2003), we also include an estimate of the potential model error in the data covariance matrix. We consider the following contributions:

$\Delta\text{CH}_{4\text{mod}1,i}$ : The standard deviation between observations and model results of hourly values. This accounts for potential deficiencies of the model to simulate the daily cycle correctly.

$\Delta\text{CH}_{4\text{mod}2,i}$ : If not enough hourly observations are available to characterize the diurnal cycle, the standard deviation of hourly model results only is taken instead of  $\Delta\text{CH}_{4\text{mod}1}$ .

$\Delta\text{CH}_{4\text{mod}3,i}$ : To estimate the potential representativeness error, we calculate the spatial gradient of modelled  $\text{CH}_4$  mixing ratios at the monitoring sites, using all (horizontally and vertically) adjacent model grid cells.  $\Delta\text{CH}_{4\text{mod}3,i}$  is calculated as the daily average of the average gradient in all directions.

The final data uncertainty is calculated as:

$$\Delta\text{CH}_{4\text{data},i} = \sqrt{\Delta\text{CH}_{4\text{meas},i}^2 + [\max(\Delta\text{CH}_{4\text{mod}1/2,i}, \Delta\text{CH}_{4\text{mod}3,i})]^2} \quad (9)$$

Interactive Discussion

(index  $i$  is used here as data index, i.e. it refers to one particular daily average).

For most NH stations the calculated model uncertainties are typically much larger than the measurement uncertainty  $\Delta\text{CH}_{4\text{ meas}}$ , while high-latitude SH stations are dominated by  $\Delta\text{CH}_{4\text{ meas}}$ .

Due to different temporal resolution of parameters (monthly emissions) and observations (daily mean values), the cost function is strongly biased towards the observations. The dimension of parameter space is  $n_{\text{para}}=496$ , while typical dimensions of the observation space (e.g. scenario S1, see below) are in the order of  $n_{\text{data}}\approx 6500$ . In order to reduce this bias, we introduce a weighting factor for the observations:

$$[\Delta\text{CH}_{4\text{ data},i}]^2 \rightarrow \frac{1}{\alpha_i} [\Delta\text{CH}_{4\text{ data},i}]^2 \quad (10)$$

Taking into account the different sampling frequency of continuous measurements (averaged to daily mean values) and flask samples (typically one sample per week), we assign different weighting factors for the two sample types. The default values chosen are  $\alpha_{i\text{ FM}}=1/2$  for flask samples and  $\alpha_{i\text{ CM}}=1/6$  for daily averages from continuous measurements. The rationale of choosing a ratio of 3 for the weighing factors of the two sampling types is that the timescale for synoptic variations is typically  $\sim 3$  days and that air masses originating from the same region(s) contain similar information (i.e. correlated information for different days of particular event). The impact of these weighting factors has been investigated in some sensitivity experiments (see Sect. 3.2).

Except for some test experiments (see Sect. 3.2), the correlation between observations has been assumed to be zero (i.e. there are only diagonal terms in the data covariance matrix).

### 2.4. Observations

Observations were used from various networks or groups. Measurement sites are compiled in Table 3. Continuous observations at 5 German sites are from the operational network of the German Umweltbundesamt (UBA). Further continuous European

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

observations have been provided by ECN (at Cabauw (CBW), the Netherlands, which is also part of the CHIOTTO/CARBOEUROPE-IP network), RAMCES/LSCE (at Saclay (SAC), France), the AGAGE network (Mace Head (MHD), Ireland, and further global sites)(Prinn et al., 2000), and the WDCGG data base (at Kollumerwaard, the Netherlands (KOL) and at Izana, Tenerife (IZO))(WMO, 2003). Furthermore, we use weekly CH<sub>4</sub> measurements from the NOAA/CMDL global cooperative air sampling network (Dlugokencky et al., 1994, 2003) and quasi-continuous measurements from two CMDL observatories at Barrow, Alaska (BRW) and Mauna Loa, Hawaii (MLO)(Dlugokencky et al., 1995)(CMDL data are available from: <ftp://ftp.cmdl.noaa.gov/ccg/>). We generally apply the NOAA/CMDL CH<sub>4</sub> calibration scale. Observations from the AGAGE network have been converted to the NOAA/CMDL scale by applying a factor of 0.988 (Prinn et al., 2000), and for observations at Kollumerwaard (KOL), which are calibrated versus a NIST standard, a conversion factor of 0.985 has been applied (WMO, 2003). All other observations are already reported versus the NOAA/CMDL scale.

#### 2.4.1. Data selection

Usually the full observational records are used except data which are flagged for technical problems or local contamination. However for a few sites we applied some additional data selection criteria:

For the two mountain sites Schauinsland (SIL) and Zugspitze (ZUG) sometimes upslope winds are observed, in particular during summer daytime. These upslope winds are normally not reproduced by the model, even not on the 1° × 1° resolution. Therefore, for these two sites only observations and model results between 20:00 and 09:00 LT are used. The impact of this data selection is investigated in some sensitivity experiments (Sect. 3.2).

Furthermore, we apply in some model experiments a data selection for MHD, based on the “pollution flag” provided by AGAGE network.

We generally omit Neuglobsow (NGB) and Trinidad Head (THC) from the inversion, as NGB is very much dominated by regional emissions and model results for THC

appear questionable as the corresponding  $6^\circ \times 4^\circ$  grid cells cover land masses with significant  $\text{CH}_4$  emissions and model results are unlikely to represent such coastal site correctly (Peters et al., 2004).

In addition to the abovementioned site-specific selection criteria we generally select outliers, identified by a first iteration of the inversion. All observations which differ from model results more than a certain threshold are rejected and not used for the second (final) inversion:

$$\text{selection criteria: } \left| \text{CH}_{4,model,i} - \text{CH}_{4,obs,i} \right| > \lambda \Delta \text{CH}_{4,data,i} \quad (11)$$

with  $\lambda=2$ .

This approach prevents single outliers from introducing a significant bias to the inversion.

The applied threshold to  $\lambda=2$  leads to a rejection of 12–14% of data points for the scenarios S1–S7 discussed in Sect. 3. Relaxing the threshold to  $\lambda=3$  strongly reduces the percentage of rejected data to  $\sim 4\%$ , but with an only very small effect on the a posteriori emission estimates.

### 3. Results and discussion

#### 3.1. Synoptic variability and regional signal

In the following we present the optimized model results along with observations for the European and global monitoring sites. An apparent advantage of the Green's function approach is that it directly provides the attribution of the atmospheric signal to the chosen regions. Figure 5 shows the full year 2001 for Schauinsland (SIL). Figures 6 and 7 show 2 months (September and October 2001) of further European and several global sites, respectively. Plots for the complete year 2001 (similar to Fig. 5) are available for all sites on our ftp server (<ftp://ftp.ei.jrc.it/pub/bergamas/CH4BR/>). The figures highlight those regions that contribute most to the atmospheric signal (based on the annual

emissions**P. Bergamaschi et al.

---

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

average). We define as “direct source contribution” of a certain region the CH<sub>4</sub> emitted in the same month in which the observation has been made plus the CH<sub>4</sub> originating from previous months, weighted with a decay function and a time constant of 31 days. This procedure avoids that CH<sub>4</sub> that was emitted several months ago and “lost its identity” after being cycled over the hemisphere is still attributed to a certain region. The “decayed part” is added to the background (based on the background base function describing the evolution of the initial state of the atmosphere). This total background is displayed in light grey in all figures. The contributions of the remaining regions, which are not among the top 6–10 contributors, are summarized in dark grey (“other”). Hourly observations are shown as black dots, and daily mean values by the black error bars, with the small error bar indicating the 1σ standard deviation of hourly values around the daily mean value, and the large error bar indicating the assigned overall “data uncertainty”, including also our estimate of the model uncertainty ( $\Delta\text{CH}_{4_{data}}$  according to Eq. 9). Grey data points are those which have been rejected by the iterative inversion.

### 3.1.1. European sites

In general, all European sites are characterized by considerable synoptic variability, i.e. variations due to varying origin of air masses, with typical time scales of a few days. Basing the inversion on daily mean values (instead of monthly means as used for most global inverse studies) directly exploits the information content of these synoptic events in order to derive the emissions from various regions or countries.

A very favourable monitoring site for this purpose is Schauinsland (SIL), located in the Black Forest (South West Germany) at an altitude of 1205 m (Fig. 5). During night-time, the site is usually above the boundary layer and thus dominated by the large-scale influence of Western European CH<sub>4</sub> sources. Some influence of upslope winds during daytime (in particular in summer) from nearby regional sources (mainly from the Rhine valley) has been eliminated in the analysis by selecting only night-time values for the inversion (see also Sects. 2.4 and 3.2). The strongest direct source signal is from France (13.6 ppb), followed by Germany (8.4 ppb). Further significant European contributions

originate from UK (4.5 ppb), BENELUX (2.4 ppb), and Switzerland (2.1 ppb). However, long range transport also plays an important role, particularly from North America (USA (6.8 ppb) and Canada + Alaska (3.3 ppb)), but also from Russia (3.9 ppb) and East Asia (3.4 ppb). As expected, the influence of these more distant regions is much less variable than that of European regions. The seasonal CH<sub>4</sub> cycle appears at this site (as at most other sites with significant direct source influence) mainly in the background, with typical background values of ~1800 ppb during winter and ~1750 ppb during summer. The annual average of the total direct source contribution is 65 ppb, however, during individual synoptic events, CH<sub>4</sub> elevations of 150–200 ppb can be reached.

Other European sites are shown in Fig. 6, ordered from North to South. The character of these sites is very different, ranging from sites with very strong total direct source contributions of >100 ppb (Kollumerwaard (KOL), Cabauw (CB4), Deusselbach (DEU), Saclay (SAC), Hegyatsal (HUN), and Black Sea (BSC)) to continental background sites (Zugspitze (ZUG), total direct source contribution 41.7 ppb) and several Atlantic background sites with typical total direct source contributions of 30–40 ppb (Ocean Station M (STM), Heimag (ICE), Terceira Islands (AZR), and Izana (IZO)).

All European sites show a considerable synoptic scale variability and concomitant change of region of influence. In addition, short-term variations of the background are considerable (in the order of 20–30 ppb), particularly visible at sites with small direct source contributions. This confirms the importance of coupling European simulations with a global model.

Some of the European sites (and the majority of global sites) employ only flask sampling, with typical sampling intervals of 1 sample/week. For sites with strong regional source contributions (e.g. HUN and BSC), the flask observations provide a fragmentary picture only. Nevertheless, even these observations are useful for further constraining the inversion (as will be shown in Sect. 3.2 and Table 6).

### 3.1.2. Global sites

A selected set of global sites is shown in Fig. 7 (for the complete set, see the figures available on our ftp server). In general, most global sites have a weaker total “direct source contribution” than the European continental sites, and hence more remote character. In the NH many global sites are in the range of ~30–70 ppb. The total direct source contribution decreases further at the tropical sites (10–30 ppb) and in the extra-tropical SH. All sites south of 45° S exhibit a total direct source contribution of <10 ppb, and the minimum is reached at SPO (3.1 ppb). The figure illustrates the consistency of modelled CH<sub>4</sub> mixing ratios with measurements throughout the globe, including the high latitude SH background sites. Although this study does not primarily focus on the global inversion, consistent global CH<sub>4</sub> fields are important as significant long range transport is seen at all European sites.

Several remote marine sites are significantly influenced by variations of the background rather than direct source influence (in particular in the tropics (e.g. Mauna Loa (MLO), Cape Kumukahi (KUM), Ragged Point (RPB)), where the average NS gradient of CH<sub>4</sub> mixing ratios is large).

Illustrative is the comparison of the two “adjacent” sites, MLO and KUM. Separated by less than 100 km, but very different in their altitude (3397m vs. 3 m a.s.l.), they show very different regional contributions. For example, the average contribution from USA is 9.1 ppb at KUM, but only 2.4 ppb at MLO, although the total direct source contribution is comparable at both sites (MLO: 25.6 ppb, KUM 31.6 ppb).

At Cape Grim (CGO), events with significantly elevated CH<sub>4</sub> mixing ratios are observed, which are usually not (or not well) reproduced by the model. Many of these events, however, are rejected by the iterative inversion procedure (according Eq. 11).

In general, the measurements at all European and most global sites are reproduced quite well, including the 3-D spatial gradient, the seasonal cycles and the short-term synoptic variability. Although the model simulations in Figs. 5–7 show the optimized (a posteriori) values, the favourable agreement with observations on short time scales is

remarkable given the limited number of degrees of freedom for the parameters (dimension model parameter space: 496; observation space: ~6500). This, along with the independent  $^{222}\text{Rn}$  and  $\text{SF}_6$  model validation, gives us confidence in the overall model performance and the use of daily mean values for the inversion.

### 5 3.2. A posteriori inventories and sensitivity experiments

A posteriori emissions are compiled for various scenarios in Tables 4 and 5 and summarized in Table 1. The base scenario is denoted S1, while scenarios S2–S4 use slightly different sets of sites and, in scenarios S5–S7, different weighting factors for the observations were applied. First we discuss some features which are apparent in all scenarios, while the influence of parameters which have been varied in the individual scenarios are discussed in the subsequent sections.

For the European regions, the strongest constraints are on emissions from Germany, France, BENELUX, UK, and Ireland due to the set of available observations, which is strongly biased towards Western European countries. Emissions from several of these countries are higher than a priori values, especially France, where the a posteriori emission increase is +71% (average of scenarios S1–S7), while smaller increases are derived for Germany (+8%), UK (+24%), and BENELUX (+8%). The a posteriori total for all EU-15 countries, however, is virtually identical to the a priori value, but with substantially reduced uncertainty (from 2.4 to 1.0–1.4 Tg  $\text{CH}_4/\text{yr}$ ). The a posteriori increase of the abovementioned countries is mainly balanced by a strong decrease of  $\text{CH}_4$  emissions from Finland, for which in scenarios S1–S4 values close to zero are derived (nominally even negative values, but these are not significantly different from zero or the pure anthropogenic part of the  $\text{CH}_4$  emissions (0.24 Tg  $\text{CH}_4/\text{yr}$  as derived from the bottom-up inventory; Table 1). This result suggests that emissions from the wetlands in Finland are much smaller than predicted by the a priori inventory (3.0 Tg  $\text{CH}_4/\text{yr}$ ).

As the direct signal from Finland at the observational sites available in this study is relatively weak (and flask sampling at Pallas started only at the end of 2001), this

Interactive Discussion

result has to be interpreted with some caution. However, comparison of observations and forward simulations for year 2002 (Fig. 9) further strengthens the hypothesis of distinctly lower Finnish emission.

Furthermore, all scenarios indicate somewhat smaller emissions for Sweden, which is also strongly influenced by natural wetlands.

On the global scale the most prominent features, compared to a priori values, are smaller emissions for North Africa, Russia, East Asia, and higher emissions for USA, South Africa, and India+neighbouring countries.

All scenarios lead to significant reductions of  $X^2$  from a priori values of 3.62–3.72 to 1.96–2.07 in the first iteration, and 0.76–0.80 in the second iteration (Table 4). This strong final reduction of  $X^2$  is mainly due to the rejection of outliers (while a posteriori emissions derived in both iterations usually do not differ very much).

### 3.2.1. Influence of different sets of sites

Compared to the base scenario S1, we omitted some European sites with very strong regional influence in scenarios S2 (without Deusselbach (DEU) and Saclay (SAC)) and S3 (without Zingst (ZGT), Kollumerwaard (KOL), DEU, and SAC) (see also Table 3). The most evident effect is an increase in German emissions, as, in particular, inclusion of DEU results in significantly smaller a posteriori German emissions (see below, and Table 6). As already mentioned, however, this leads to a redistribution of calculated emissions among the European countries, while the EU-15 total remains virtually unchanged.

A particularly critical site appears to be Mace Head (MHD), as the corresponding  $1^\circ \times 1^\circ$  grid largely covers land masses with significant  $\text{CH}_4$  emissions. Although the a posteriori  $\text{CH}_4$  mixing ratios agree quite favourably with the observations, situations with westerly winds from the Atlantic may be biased (with model results affected by Irish emissions, but not the observations). Thus the very low  $\text{CH}_4$  emissions derived for Ireland in scenarios S1–S3 are to some extent due to this effect. The  $^{222}\text{Rn}$  experiments showed that much better agreement with observations can be achieved if the

model is sampled at a virtual site, shifted by 2° to the west. Tentatively we also applied this shift to the CH<sub>4</sub> inversion while excluding observations with strong regional influence (denoted by “P” flag in the AGAGE data set), because the shifted model site is unlikely to reproduce regional pollution events correctly. The corresponding inversion scenario S4 shows – compared to S1–S3 – much higher CH<sub>4</sub> emissions for Ireland that are close to the a priori value. It is difficult to judge which type of sampling is more appropriate, since both approaches clearly imply some systematic biases which are difficult to quantify. Consequently, the exact attribution of the Mace Head observations to emissions in Ireland should be interpreted with care.

### 3.2.2. Influence of individual European sites

In order to further investigate the impact of individual sites we performed inversions using single European sites only. The results are compiled in Table 6 and further illustrate the different character of the different sites. Sites which are strongly influenced by regional emissions like Zingst (ZGT), Neuglobsow (NGB) and Deusselbach (DEU) lead to distinct reductions of calculated a posteriori uncertainties and frequently to significant shifts of the a posteriori fluxes. Clearly, the impact of these sites has to be viewed quite critically since their influence on derived emissions from a whole region might be too strong. This so-call aggregation error has been observed in global inversions, when big regions are used (Kaminski et al., 2001).

Saclay (SAC), despite its semi-urban character and proximity to Paris, has only a moderate impact on French a posteriori emissions (increase of emissions by 14%, reduction of uncertainty by 26%). Most other single sites, however, also lead to a small increase of computed emissions from France. Obviously, this effect is augmented in the inversion with the (more or less) complete set of sites in scenarios S1–S4.

Also, all single sites indicate reduced emissions from Finland, typically in the order of 1–20%. This effect is enlarged in the full inversion (scenarios S1–S4) leading to net emissions from Finland close to zero.

For most other countries, however, the analysis from the single site inversion is more

ambiguous; e.g. for Germany or BENELUX, both increased and decreased emissions were found (reflected in the full inversion by only small shifts of a posteriori emissions).

It is interesting to note that the flask sampling sites in Eastern Europe (Baltic Sea (BAL), Hegyatsal (HUN)) put significant constraints on emissions from Germany and the UK.

We also used the single site experiments to further check the impact of data selection procedures applied at a few sites (see Sect. 2.4).

For Schauinsland (SIL) the use of night-time data only indeed leads to slightly smaller derived CH<sub>4</sub> emissions from Germany. In the non-selected case the observed upslope winds during summer daytime (which are not reproduced in the model) need to be compensated in the inversion by artificially higher German emission. This effect, however, is relatively small (~7% difference of deduced German emissions), and even much smaller for Zugspitze (ZUG) (difference ~0.5%).

As already observed in the full inversion, the effect of shifting the site Mace Head (MHD) and selecting “non-polluted” data only, is considerable (difference of derived Irish emissions of 32%).

### 3.2.3. Influence of weighting factor for observations

As described in Sect. 2.3, a weighting factor is applied to reduce the strong bias of the inversion towards observation space. Using the default values of  $\alpha_{iFM}=1/2$  for flask samples and  $\alpha_{iCM}=1/6$  for daily averages of continuous measurements, the inversion is still dominated by the observations (“effective” dimension of observational space in scenario S1: 1702 (see Table 4) vs. dimension of parameter space ( $n_{para}$ ): 496). In scenarios S5 and S6 we further decrease the weighting of observations to  $\alpha_{iFM}=1/4$ ,  $\alpha_{iCM}=1/12$  (S5) and  $\alpha_{iFM}=1/6$ ,  $\alpha_{iCM}=1/18$  (S6), bringing the effective dimension of the observational space closer to the dimension of the parameter space. As expected, this leads to smaller reductions of calculated a posteriori uncertainties and, in general, to smaller shifts of a posteriori emissions compared to a priori values. It is interesting to note, however, that the latter not always increase or decrease monotonously towards

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

the a priori values with decreasing weighting factor. This is obviously due to the very complex structure of the cost function. With decreasing weight of observations, the a posteriori emissions from Finland increase slightly (compared to values close to zero in scenarios S1–S4). Even in scenario S6, however, the emissions from Finland are only 39% of the a priori estimate, which is a clear indication that the bottom-up estimate (which was dominated by estimated 3 Tg CH<sub>4</sub>/yr from wetlands) for Finland is likely too high.

Evidently the best choice of the weighting factors for the observations is not precisely defined and choosing them introduces a subjective component. We also tested the effect of including correlations in the data covariance matrix for observations of subsequent days. However, this leads to very small changes of a posteriori results only (results not shown). In numerical weather forecasting it has been observed that the use of positive observation error correlations reduces the weight given to the observations, and at the same time gives more relative importance to differences between observed values (Bouttier and Courtier, 1999). In our analysis, these two effects are balancing each other to some extent.

A final scenario, S7, uses the low weighting factors for observations and the reduced set of sites from scenario S3. Scenario S7, which can be considered as the most conservative scenario (putting relatively small weight on the observations, and omitting sites with large regional contributions), confirms the major principal features discussed for the other scenarios.

The lower weighting of observations leads to very small increases of  $X^2$  only, i.e. the fit to observations deteriorates only slightly (Table 4).

### 3.2.4. A posteriori correlation of emissions

While the a priori emissions of different regions are assumed to be uncorrelated, the a posteriori emissions exhibit clear anti-correlations between different regions (Fig. 8). For example, the a posteriori emissions from Germany are significantly anti-correlated with the emissions from France, BENELUX, UK, and North East Europe. The fig-

---

national and  
European CH<sub>4</sub>  
emissions**P. Bergamaschi et al.

---

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

ure shows that the anti-correlations in general extend over a relatively short temporal period (typically  $\pm 1$ – $2$  months); e.g. the emissions from Germany of one particular month are anticorrelated with the emission from the mentioned countries in the same months, or the preceding or following 1–2 months. Further prominent features are the anti-correlations of Ireland with UK and of Spain with Italy and France. This behavior is consistent with the abovementioned observation that, despite some differences for emissions from individual European countries in scenarios S1–S7, the EU-15 total emissions are relatively constant in all scenarios.

Furthermore, there are strong anti-correlations among the non-European global regions, For example, of tropical Asia with “India+neighboring countries” or of South Africa with South America and North Africa. In general, however, there are only weak anti-correlations between European and global regions, except for regions in the transition region from middle-west Europe to East Europe and Russia (including a weak anti-correlation between Finland and Russia). Also there are some weak anti-correlations between emissions from North America (USA, and Alaska+Canada) and some European countries.

### 3.2.5. Potential systematic errors

In the following we discuss the most important potential systematic errors which could affect the results of our study:

(1) In general, the Green’s function approach is based on predefined relatively large regions, and may suffer from the aggregation error (Kaminski et al., 2001). The Green’s function approach allows us to increase or decrease only the total emissions of the individual regions, but not to change the spatial emission distribution within the regions. The aggregation error is potentially most serious when including observations of strongly regional character (potentially leading to a shift in emissions of a whole larger region, although the influence area of these measurements might be much smaller). In fact scenarios S1–S4 show slightly different results (in particular for Germany and Ireland), however EU-15 total emissions are not affected significantly. Inverse approaches

---

**Inverse modelling of  
national and  
European CH<sub>4</sub>  
emissions**

---

P. Bergamaschi et al.

---

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

based on an adjoint model (Houweling et al., 1999; Kaminski et al., 1999a, b) or full 4DVAR data assimilation systems (Bouttier and Courtier, 1999; Engelen, 2004; Meirink et al., 2004) will allow a much higher degree of freedom in the parameter space (i.e. optimization of emissions from individual model grid cells), but will require, in practice, further constraints such as assumptions about spatial correlations between emissions of different grid cells (making the inverse system stiffer, and probably similar to Green's function systems with relatively small regions).

(2) The representativeness error describes discrepancies in the behavior of a model grid cell (or interpolated point within that grid cell) with the real observational point, e.g. due to local meteorology which is not resolved in the model or strong emission gradients within a grid cell, as is frequently found at the land-sea border (such as for coastal sites like MHD). We addressed this potential error by data selection procedures for some sites (SIL and ZUG) and the general use of the 3-D model gradient as proxy for the representativeness error (Eq. 9). For MHD, in particular, the analysis remained ambiguous. Unfortunately, for many sites only limited information is available for further analysis (such as meteorology and measurements of other tracers, including <sup>222</sup>Rn).

(3) Systematic errors in model transport have a direct impact on the inversion results, and the inversion tends to compensate for these errors by erroneous adaptation of emissions. The TM5 model was intensively validated and compared with other models within the EVERGREEN projects, and the main transport features (such as vertical mixing or interhemispheric transport) are well within the range of other standard models. However, the TM5 model may have some tendency to underestimate vertical exchange, and it has recently been observed that enhancing the vertical mixing within the model boundary layer may further improve agreement with SF<sub>6</sub> observations (Peters et al., 2004). Since most CH<sub>4</sub> monitoring sites in Europe are in the boundary layer, however, enhanced vertical mixing in the model would most likely imply somewhat higher European CH<sub>4</sub> emissions resulting from the inversion.

(4) The total global CH<sub>4</sub> budget derived by the inversion is mainly determined by the applied model OH field (plus the additional minor sinks). The derived emissions over

Europe, however, are strongly linked to observed and modelled synoptic events, and any change of global model OH fields is likely to have only a minor influence on the derived European emission.

(5) Some biases may be introduced by gaps in the observational records. In this study we did not apply further screening of observations but note that for several sites gaps exist within the analysis period, which may have some impact on the derived seasonal cycles of emissions. The requirement of contiguous observations, however, will be in particular important for multi year trend analyses (Rödenbeck et al., 2003).

(6) Furthermore, very different temporal resolution (monthly emissions vs. daily mean values of observations) and spatial scales (global vs. European zoom) may introduce some biases.

### 3.3. Comparison with other studies

#### 3.3.1. Comparison with UNFCCC

Average a posteriori emissions and their ranges from scenarios S1–S7 are compiled in Table 1 (together with both a priori and UNFCCC emissions). For comparison of a posteriori emissions with UNFCCC values it is important to keep in mind that inverse modelling provides estimates of total emissions, i.e. anthropogenic and natural emissions (including soil sink), while UNFCCC covers the anthropogenic sources only. For most EU-15 countries except Sweden and Finland, however, natural sources contribute only a small fraction of total emissions. The anthropogenic part of the a priori bottom-up inventory used in our study differs from UNFCCC values by up to 30–50% for several European countries (see Table 1), including the 3 largest EU-15 CH<sub>4</sub> emitters Germany, France, and UK. All inversion scenarios presented here (S1–S7) are increasing the CH<sub>4</sub> emissions of these 3 countries compared to our a priori estimate. Assuming that this increase is due to anthropogenic emissions only (i.e. subtracting the small a priori natural sources/sinks from the a posteriori total emissions), this would imply distinctly higher anthropogenic CH<sub>4</sub> emission compared to UNFCCC values (Germany:

national and  
European CH<sub>4</sub>  
emissions**P. Bergamaschi et al.

---

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[◀](#)[▶](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

3.9 Tg CH<sub>4</sub>/yr (+65% compared to UNFCCC), France: 4.5 Tg CH<sub>4</sub>/yr (+46%), and UK: 4.2 Tg CH<sub>4</sub>/yr (+91%), based on average values for scenarios S1–S7). For the EU-15 totals the discrepancy is much smaller. UNFCCC total (15.7 CH<sub>4</sub>/yr) is about 11% less than the anthropogenic part of the bottom-up inventory used in this study (17.6 CH<sub>4</sub>/yr).

5 The a priori total of 21.5 Tg CH<sub>4</sub>/yr does not change significantly in the inversion (S1–S7 average: 21.5 Tg CH<sub>4</sub>/yr). However, as discussed, the inversion is suggesting some redistribution within Europe, and in particular a significant reduction of emissions from Finland (with assumed 3 Tg/yr from wetlands in the a priori inventory). Therefore, the inversion indicates that a much smaller fraction of the total EU-15 CH<sub>4</sub> emissions may  
10 be of natural origin, which would increase the difference with the UNFCCC value. Assuming total EU-15 emissions of 21.5 Tg CH<sub>4</sub>/yr, with a natural contribution of 1 Tg, would be equivalent to 30% higher anthropogenic CH<sub>4</sub> emissions compared to the UNFCCC value. The comparison of inverse modelling results with UNFCCC values is also illustrated in Fig. 10 for Germany, UK, France, and BENELUX.

### 15 3.3.2. Comparison with other top-down studies

Figure 10 also shows top-down estimates of other studies over the period 1994 to 2001. The studies of Ryall et al. (2001), Manning et al. (2003, 2004) are based on NAME, a Lagrangian particle dispersion model (LPDM), and observations from Mace Head only. Vermeulen et al. (1999) use the Lagrangian back trajectory model COMET,  
20 and alternatively observations of Cabauw only (1993–1997), or a set of 4 European sites (Cabauw, Petten (NL), Heidelberg (D), London (UK), 1996). Roemer et al. (2000) use the LOTOS model, an Eulerian 3-D model on the European domain with initial and boundary conditions taken from the global TM3 model, and observations of 4 Dutch sites (Arnhem, Delft, Kollumerwaard, Cabauw) and Mace Head (1994). The studies  
25 based on NAME and COMET do not use an a priori emission inventory. However, they used very long integrations periods (1–6 years) and the assumption that over this period emissions per grid cell or source area are constant.

Considering all studies together, the majority of top-down estimates is reasonably

---

**Inverse modelling of  
national and  
European CH<sub>4</sub>  
emissions**P. Bergamaschi et al.

---

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Print Version](#)[Interactive Discussion](#)

close (~30–50%) to the UNFCCC bottom-up estimates (corrected with our estimate of natural sources and sinks) for the 4 displayed regions (Germany, UK, France, and BENELUX). There are, however also remarkable discrepancies. In particular striking is the fact that in all studies except that of Manning (2004), the sum of all 4 regions (for the study of Vermeulen et al. (1999) only the 3 regions Germany, UK, and BENELUX are available) is distinctly higher than the corresponding sum of UNFCCC estimates. As we had seen in our study (Sect. 3.2, and Fig. 8) the a posteriori emissions show clear negative correlations, leading typically to relatively robust results for sums of adjacent (coupled) regions. Therefore, the observation of higher sums for the 3–4 regions in the above studies is consistent with the higher emissions from Germany, UK, and France derived from our study. In contrast, however, Manning (2004) does not show higher sums for the 4 regions, but rather slightly smaller totals. Apparent in Manning (2004), however, is the coupling of these regions (i.e. considerable year-to-year variations, but relatively constant sums).

Model-independent top-down estimates can also be provided using <sup>222</sup>Rn measurements. Applying this technique, Levin et al. (1999) derive a mean CH<sub>4</sub> emission of 0.24±0.50 g CH<sub>4</sub> km<sup>-2</sup> s<sup>-1</sup> for a catchment area with radius of ~150 km around Heidelberg for 1995–1997. For a similar catchment area we obtain a mean CH<sub>4</sub> emission of 0.36±0.24 g CH<sub>4</sub> km<sup>-2</sup> s<sup>-1</sup> (scenario S1). We note however, that this comparison is problematic because the <sup>222</sup>Rn derived value may be biased towards dominant wind directions (and emissions show considerable variability on small scales, e.g. between 1°×1° grid boxes). Furthermore, the applied synthesis inversion does not optimize the spatial emission distribution within the predefined regions.

#### 4. Conclusions

The presented analysis provides a consistent picture of the European and global 3-D distribution of atmospheric methane. For most sites an overall good agreement with observations is achieved, including the simulation of synoptic events arising from the

short-term ( $\sim 1$ –5 days) variability of meteorological situations.

The atmospheric  $\text{CH}_4$  signal has been attributed directly to recent emissions of different European and global regions, on top of a global background (which is also evolving dynamically in space and time).

In particular quasi-continuous observations close to source regions provide significant constraints on the emissions. Largely driven by such high-frequency observations at several Western European sites, the inversion suggests higher emissions for Germany (+65%), France (+46%), and UK (+91%) in 2001 compared to UNFCCC values, while results for BENELUX are virtually identical with UNFCCC. The question of whether the derived higher emissions are really significantly different from UNFCCC values comes down to an exact quantification of uncertainties, which is very difficult, both for the bottom-up and the top-down estimates. Only some EU-15 countries specify uncertainties of their  $\text{CH}_4$  estimates, ranging from 1.8% (Sweden) to 48.3% (Austria) (Gugele et al., 2003). No uncertainty estimates are available for the major source countries France and Germany. Furthermore, we note that the RAINS model-based anthropogenic bottom-up emissions are about  $\sim 50\%$  higher than UNFCCC values for UK and Germany.

The tendency to higher emissions for the sum of emissions from Germany, UK, France, and BENELUX has also been observed in some previous studies (Vermeulen et al., 1999; Roemer et al., 2000; Manning et al., 2003), while the recent analysis of Manning (2004) is very close to UNFCCC values, but based on observations of one site (Mace Head) only. Our inversion suggests significantly lower emissions for Finland, for which the bottom-up inventory had predicted high emissions from wetlands ( $\sim 3 \text{ Tg CH}_4/\text{yr}$ ).

Significant anti-correlations are apparent between different European regions. Thus despite some remaining uncertainty about the exact distribution among countries, the top-down estimate for total EU-15 emissions appears relatively robust. Furthermore, the derived EU-15 emissions ( $21.5 \text{ Tg CH}_4/\text{yr}$  total emissions) are very close to the UNFCCC value for year 2001 ( $15.7 \text{ Tg CH}_4/\text{yr}$  anthropogenic emissions), if the natural

net emissions are around 3.9 Tg CH<sub>4</sub>/yr, as assumed in our a priori inventory. However, if the fraction of natural emissions is smaller, as our results suggest, the relative difference between our top-down based anthropogenic emission estimate and the UNFCCC value for EU-15 could be up to 30%.

5 The potential discrepancies between bottom-up and top-down estimates further emphasize the need for independent verification. In a strict sense, however, our top-down approach is not completely independent, as it is using bottom-up inventories as a priori constraints (hence influencing both the model bases functions (emission distribution within one region) and the cost function). Although some other top-down studies based  
10 on Lagrangian models avoid the use of a priori inventories, it is noted that the alternative assumptions required (as constant emissions per grid cell or source area over longer integration times) constitute another form of a priori constraint (in these studies implemented as hard constraint; i.e. they cannot be modified by the inverse system). In general the introduction of some a priori constraints is always required due to the  
15 underdetermined nature of the overall inverse problem.

Concerning potential implications regarding the targets set by the Kyoto protocol, it is noted that the reduction targets are generally defined relative to the base year 1990, and not in terms of absolute emissions. Consequently, higher absolute emissions of individual countries would not constitute a violation of Kyoto obligations, but  
20 only if emissions relative to year 1990 exceed the targets. It is expected that inverse modelling may provide in the future estimates of emission trends with a much smaller uncertainty compared to estimates of absolute emissions as many potential systematic errors remain the same for subsequent years (Dentener et al., 2003b).

Our analysis included a discussion of such potential systematic errors. In particular,  
25 we showed several sensitivity experiments illustrating that a posteriori results are dependent on the exact set of sites used, the data selection procedures and the choice of weighting factors for observations.

However all the scenarios shown here confirm the major conclusions of this study (including scenario S7, which can be considered as most conservative in the sense that

observations are weighted weakly and European sites, with strong regional influence, are not used).

Inverse techniques are a very powerful system analysis tool, allowing to directly link atmospheric observations to emissions. Progress is expected from the further development of inversion techniques including sophisticated data assimilation methods. Furthermore, ensemble inversions applying different models will be particularly useful, in order to increase the confidence in top-down emission estimates. Additional measurements such as  $^{222}\text{Rn}$  and meteorology at all sites would be helpful in order to better assess the ability of the model to simulate the individual sites.

For an operational emission verification system, however, it is particularly important that atmospheric observations are further expanded, especially quasi-continuous high-precision in-situ measurements at well selected sites (Bergamaschi et al., 2004).

Atmospheric  $\text{CH}_4$  can now also be measured from satellite-based sensors such as SCIAMACHY on ENVISAT (Buchwitz et al., 2004), providing a valuable complement to the still rather sparse in-situ measurement network. Use of these satellite data in inverse studies, however, requires a further improvement of their precision, close to the theoretical limit of  $\sim 1\%$ .

*Acknowledgements.* We thank H. Sartorius for provision of  $^{222}\text{Rn}$  measurements at Schauinsland, and K. Uhse and L. Ries for  $\text{CH}_4$  data from the German Umweltbundesamt network. Furthermore, we are grateful to ECMWF for the possibility to use their meteorological analyses and A. Segers for his assistance in preprocessing the ECMWF meteo data as TM5 input. We thank M. Amann for provision of IIASA  $\text{CH}_4$  bottom-up inventories and B. Guegle for discussion on  $\text{CH}_4$  emissions reported to UNFCCC.

Furthermore, we thank T. Alto, F. Raes, A. Leip, J. Wilson, H. Behrend, and I. Levin for helpful comments on the manuscript.

**Table 2.** Global and EU-15 bottom-up emissions per source category in Tg CH<sub>4</sub>/yr.

	a priori [Tg CH <sub>4</sub> /yr]	
	global	EU-15
<b>anthropogenic sources</b>		
coal	30.7	1.2
oil and gas	50.9	2.0
enteric fermentation	86.3	6.1
manure	14.2	2.0
rice	59.7	0.1
biomass burning	32.3	0.5
waste	73.6	5.7
<b>natural sources</b>		
wetlands	174.5	4.4
wild animals	5.0	0.1
termites	19.2	0.1
ocean	17.0	0.0
<b>total sources</b>	<b>563.4</b>	<b>22.2</b>
soil uptake	-37.8	-0.7
<b>total sources + soil</b>	<b>525.7</b>	<b>21.5</b>

## Inverse modelling of national and European CH<sub>4</sub> emissions

P. Bergamaschi et al.

**Table 3.** Atmospheric monitoring sites used in this study. “CM” denotes (quasi) continuous measurements, i.e. with a typical time resolution of 1 h or better, and “FM” denotes flask measurements (typical sampling frequency 1/week). The  $\Delta\text{CH}_4$ <sub>data</sub> column gives the average data uncertainty (according to Eq. 9), evaluated for scenario S1. The last columns specify the sites used in the different inversion scenarios.

## Inverse modelling of national and European CH<sub>4</sub> emissions

P. Bergamaschi et al.

**Table 4.** A posteriori emissions from various scenarios. Scenarios S1–S4 use different sets of sites. In scenarios S5–S7 the weighting factors  $\alpha_{iFM}$  and  $\alpha_{iCM}$  for the observations are varied.  $n_{data}$  denotes the dimension of the observational space (i.e. number of observations), and  $n_{data\,eff}$  is the “effective dimension”, i.e. weighted with the  $\alpha_{iFM}$  and  $\alpha_{iCM}$  of the individual observations. Emissions are given in Tg CH<sub>4</sub>/yr ( $\pm 1\sigma$ ). Chi-square, defined as  $\chi^2 = \frac{1}{n} \sum_{i=1}^n \frac{[\text{CH}_4\,model\,i - \text{CH}_4\,obs\,i]^2}{\Delta\text{CH}_4\,data\,i^2}$ , is given a priori and a posteriori (1st and 2nd iteration) model simulations.

	S1	S2	S3	S4	S5	S6	S7
stations	all	as S1 except DEU, SAC	as S1 except ZGT, KOL, DEU, SAC	as S1 but MHD -2oW and sel. obs.	as S1	as S1	as S3
$\alpha_{iFM}$	1/2	1/2	1/2	1/2	1/4	1/6	1/6
$\alpha_{iCM}$	1/6	1/6	1/6	1/6	1/12	1/18	1/18
$n_{para}$	496	496	496	496	496	496	496
$n_{data}$	6494	5992	5264	6396	6468	6455	5230
$n_{data\,eff}$	1702.3	1619.3	1496	1684.3	845.5	561.7	493.9
$\chi^2$ (a priori)	3.62	3.67	3.70	3.72	3.62	3.62	3.70

**Inverse modelling of  
national and  
European CH<sub>4</sub>  
emissions**

P. Bergamaschi et al.

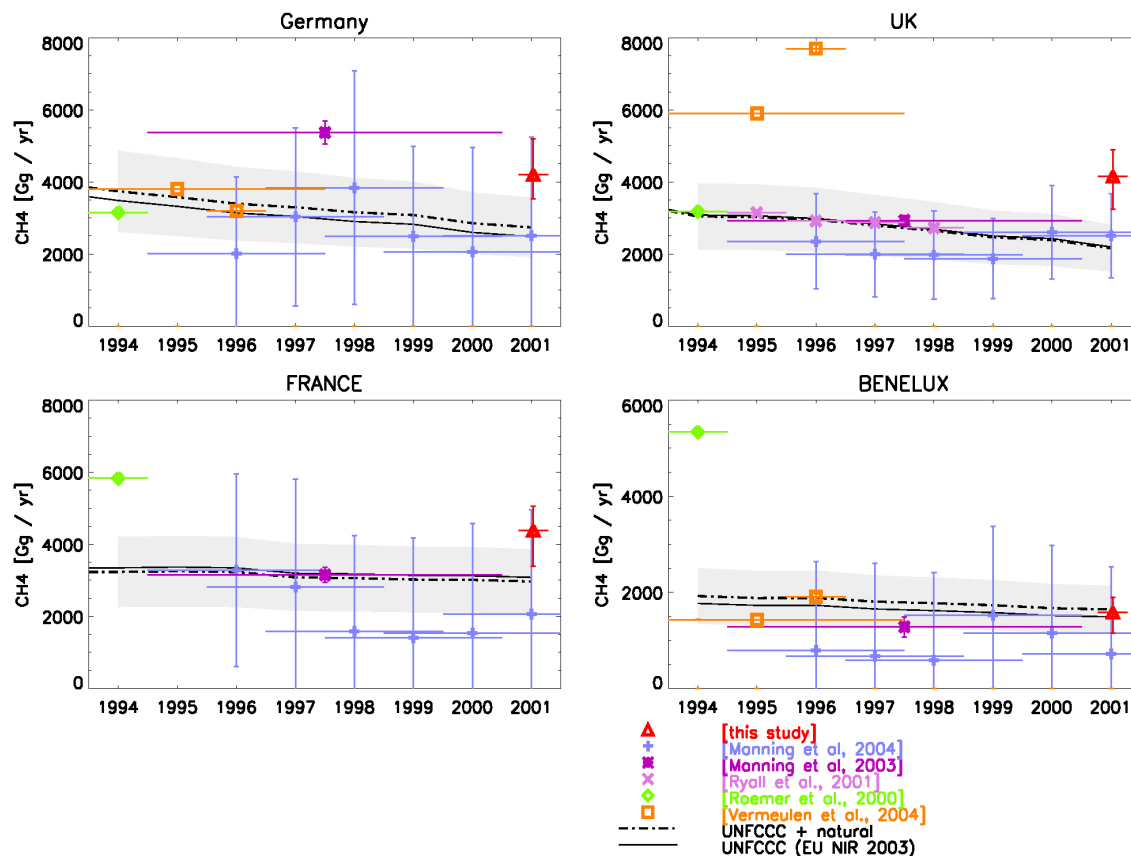

**Fig. 9.** Forward simulation for Pallas (PAL), Finland (year 2002) using the bottom-up inventory compiled in Table 1. The figure illustrates, that the very high modelled CH<sub>4</sub> mixing ratios during summer (mainly due to assumed large emissions from wetlands) are not visible in the observations. This is a further indication that wetland emissions from Finland are distinctly overestimated in the bottom-up inventory.

## Inverse modelling of national and European CH<sub>4</sub> emissions

P. Bergamaschi et al.

**Fig. 10.** Comparison with other inverse modelling studies and UNFCCC values. UNFCCC estimates (black solid curve) are augmented by our bottom-up estimate of net natural sources (including soil sink), displayed by the black dash-dotted line. The grey-shaded area indicates an assumed 30% uncertainty of the total of UNFCCC and natural emissions. Colored symbols represent the various top-down estimates, according to the legend below.
