Abstract

Since the first suggestion of 1500-year cycles in the advance and retreat of glaciers (Denton and Karlen, 1973), many studies have uncovered evidence of repeated climate oscillations of 2500, 1500, and 1000 years. During last glacial period, natural climate cycles of 1500 years appear to be persistent (Bond and Lotti, 1995) and remarkably regular (Mayewski et al., 1997; Rahmstorf, 2003), yet the origin of this pacing during the Holocene remains a mystery (Rahmstorf, 2003), making it one of the outstanding puzzles of climate variability. Solar variability is often considered likely to be responsible for such cyclicities, but the evidence for solar forcing is difficult to evaluate within available data series due to the shortcomings of conventional time-series analyses. However, the wavelets analysis method is appropriate when considering non-stationary variability. Here we show by the use of wavelets analysis that it is possible to distinguish solar forcing of 1000- and 2500- year oscillations from oceanic forcing of 1500-year cycles. Using this method, the relative contribution of solar-related and ocean-related climate influences can be distinguished throughout the 10 000 Holocene intervals since the last ice age. These results reveal that the mysteriously regular 1,500-year climate cycles are linked with the oceanic circulation and not with variations in solar output as previously argued (Bond et al., 2001). In this light, previously studied marine sediment (Bianchi and McCave, 1999; Giraudeau et al., 2000), ice core (O'Brien et al., 1995) and dust records (Jackson et al., 2005) can be seen to contain the evidence of combined forcing mechanisms, whose relative influences varied during the course of the Holocene. Circum-Atlantic climate records cannot be explained by solar forcing, but require changes in ocean circulation, as suggested previously (Broecker et al., 2001; McManus et al., 1999).

Interactive Discussion

1 Introduction

It was suggested, for both the late Glacial and the Holocene, a 1500 yr variability of the climate (Bond et al., 1995, 1997, 2001). Initially associated with the so-called Dansgaard-Oeschger oscillations (Dansgaard et al., 1993), this period seems to occur independently of the general glacial – interglacial climate changes. According to these results, the millennial-scale variability was attributed to the same forcing, ruling out any direct link with the ice-sheet oscillations. In North Atlantic as in other part of the world, many paleo-climatic records of the last 10 000 years show a pattern of rapid climate oscillations with cyclicity around 1–2 kyrs. Since the pioneering studies of Gerard Bond on IRD from the North Atlantic Ocean (Bond et al., 1995; 1997; 2001), the 1500-year cycle during the Holocene was tentatively attributed to solar activity Bond et al., (2001), to ocean current intensity variation Bianchi and McCave (1999), to tidal forcing Berger and von Rad (2002), to atmospheric processes linked to the North Atlantic Oscillation (NAO, Giraudeau et al., 2000) or to modifications of the geomagnetic field (St-Onge et al., 2003).

Up to now, classical Fourier spectral analysis remains the most common tool for studying the frequency pattern of a signal, although many alternative methods clearly improved the efficiency of Fourier analysis for variance density estimation (for instance, multi-taper methods).

Nevertheless, a thorough study of the Bond et al. (2001) time series clearly highlights the limits of Fourier spectral analysis. For instance, a simple Fourier transform (Blackmann-Tuckey, max entropy) provides 2 peaks corresponding to ≈ 1000 -year and 2500-year cyclicities, while Bond et al. (2001) reported a 1500-year oscillation (Fig. 2). The confidence limits shown on the figures were computed by testing the estimated power spectra against a background red noise spectrum AR (1) with a lag-1 autocorrelation of 0.11. The background red noise spectrum was itself calculated by filtering noise from signal using eigenmode decomposition, noise being modelled thereafter using a first-order autoregressive spectrum procedure. As a matter of fact, the application

Interactive Discussion

of a 1000-year filter to the composite series of IRD does not provide very conclusive correlation during 0–5000 years, whereas the 1500-year Gaussian filter matches perfectly (Fig. 2). This provides a perfect example of the effect of instationarity in a signal.

This result demonstrates the limited ability of classical Fourier spectral analysis to detect a 1500-year fluctuation that evolves through time. Such observations are typical of non-stationary processes, in which frequency content and statistical properties change through time. Wavelet analysis (WA) presents the advantage of describing non-stationarities, i.e. discontinuities, changes in frequency or magnitude (Torrence and Compo, 1998). Redundancy of the continuous wavelet transform is used to produce a time/frequency or time/scale mapping of power distribution, called the local wavelet spectrum (or scalogram). As a major advantage with respect to classical Fourier analysis, the local wavelet spectrum allows direct visualization of the changing statistical properties in stochastic processes with time.

WA performed on Bond et al. (2001) time series highlights 2 major cyclicities: 1000 and 2500 years (Fig. 3). The dominant 2500-year cycle is continuous throughout the Holocene whereas the 1000-year cycle is absent during the first part of the Holocene (until 5000 years). This time-slice is characterized by an increase in spectral power at another period around 1500 years, reaching its maximum intensity at 3000 years cal. Bond et al. (2001), had compared their records with the residual $\delta^{14}\text{C}$ (Stuiver et al., 1998) to justify the solar influence. We have processed the residual $\delta^{14}\text{C}$ following rigorously the same protocol as the one used when processing the IRD data. WA reveals the same general feature for $\delta^{14}\text{C}$ and IRD for the dominant periodicities with special emphasis on the attenuation of the 1000-year cycle during 5500-0 years period (Fig. 3). These results confirm the solar origin of the cycles at 1000 and 2500 years recorded in the IRD series. Nevertheless the two series show some discrepancies: a 1600-year cycle is recorded during the Holocene in the residual $\delta^{14}\text{C}$ excepted during 5500-0 years exactly when the 1500-year cycle of Bond' series is well expressed. Thus the occurrence of this 1500-year cycle in the IRD series records a forcing other than solar activity.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[⏪](#)[⏩](#)[◀](#)[▶](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

In this matter, WA were performed on some discriminating published records considered as well-dated data series of North Atlantic climate proxies, such as variations of the sediment grain-size to reconstruct the activity of deep-water masses. Also, we re-processed sortable silt grain-size data published by Bianchi and McCave (1999) on a sediment core situated off Iceland whose sedimentation is directly influenced by the activity of the Iceland Scotland Overflow Water, ISOW, (Fig. 1), one of the main component of the thermohaline circulation. Wavelets analysis confirms the previously published results of FFT analysis (Bianchi and McCave, 1999) which evidenced a cyclicity around 1500 years. Moreover WA also highlights the maximum influence of this cyclicity exactly during 5500–2000 years cal BP at this time the IRD displayed the 1500-year cycle (Fig. 3). This is also confirmed with a 1700-years cycle in the *Emiliana Huxleyi* concentration record, a proxy of surface hydrology, in a core off Iceland (Jackson et al., 2005).

Also, we can postulate that the IRD series, classically used as a reference of the climatic fluctuations during the Holocene, records at last two dominant forcing: solar activity for wavelengths at 1000- and 2500-year and oceanic activity for the cyclicity at 1500 years characterising the late Holocene. According to the actual state of the art, this “double” forcing on the IRD signal can be explained by the respective influence of sun on continental ice-sheets, during 11 500 to 5500 cal BP, and of oceanic currents intensity strength on the geographical distribution of IRD in the North Atlantic Ocean during 5500–0 years cal BP.

In addition to analysis of several marine paleoclimatic proxies, the detailed Holocene variations of both ice-core and continental parameters were studied. The GISP 2 ice core from the summit of Greenland (Fig. 1) provides a precise and accurately-dated record of climatic changes during the Holocene. We looked at the evolution of sodium concentration in the ice because it is thought to represent the direct deposition of sea spray (O’Brien et al., 1995). WA of this signal reveals an unexpected result (Fig. 3): the variations of sodium shows an “oceanic forcing”-like cyclicity at 1600 years (1500–1700) during the late Holocene with maximum of intensity during the 5500–0 years cal

BP. The striking feature of sodium flux in ice likely reflecting the cyclonic activity forced by ocean activity could be explained by considering the ocean-atmosphere coupling. Indeed in the North Atlantic Ocean the meridional overturning circulation obviously have a direct influence on sea-ice repartition subsequently affecting the synoptic atmospheric configuration in the North Atlantic area (O'Brien et al., 1995). As a result, the variations of the oceanic circulation near Iceland during the Holocene as recorded both by grain-size evolution (Bianchi and McCave, 1999) and Calcareous nannofossils abundance (Giraudeau et al., 2000) modify indirectly the atmospheric transfer of oceanic Na toward Greenland. In order to constrain the atmospheric variability during the Holocene, a loess series from Iceland (Fig. 1, Jackson et al., 2005) was analysed using WA. The results display a dominant 1700 years variability (Fig. 3) evidencing the influence of ocean activity on the overlying low-altitude atmospheric configuration. The rather dispersive values obtained for the “so-called 1500-year cycle” through WA on the various data series analysed could result from discrepancies in their respective model-age (isotopic stratigraphy, AMS14C, ice-core tuned). As the chronology of the Greenland ice-core is very well constrained, we propose to use the 1600-year cycle defined in ice-core as the most accurate estimation, close to the 1700-year cyclicity defined in marine and aeolian records.

By re-visiting well-known series from the North Atlantic Ocean, wavelet analysis reveals that the Holocene millennial variability is composed of at least three periodicities. Our results strongly suggest that two wavelengths are directly forced by solar activity (1000 and 2500-year cycles) whereas the third one (1600-year cycle, dominant during 5500-0 years cal) may correspond to oceanic internal forcing. Our results, based on a purely mathematical approach are not able to provide any additional explanation on the origin(s) of this oceanic variability, which may result from atmospheric water transport (Broecker et al., 2001) or a persistent internal salt oscillator (McManus et al., 1999) or perhaps an orbital modulation of the mechanisms driving millennial-and centennial-scale climatic change through the Holocene as suggest by (Turney et al., 2005). They nevertheless rule out the previously favoured strictly external climate forcing due to

variations in solar output through a linear process.

Although cyclicities of 1000 years and 2500 years are apparently broadly distributed over the whole climatic system (Nederbragt and Thurow, 2005) the global extension of the 1600-year cycle is much more controversial. Indeed the 1500-year cycle is often
5 evidenced within various series on the basis of

a simple comparison with the mis-interpreted IRD reference dataseries, thus introducing a systematic bias in their conclusions. When submitted to our WA, these series display in fact cyclicities of 2500 and 1000 years instead of the expected 1500-year one. The circum- North Atlantic climate is particularly sensitive to changes in oceanic
10 forcing due to changes in the strength of the meridional overturning circulation (Manabe and Stouffer, 2000; Alley et al., 1997; McManus et al., 2004). It remains to be seen whether this oceanic forcing extends globally, but the approach presented here provide a means to evaluate the respective influence of solar and oceanic forcing in high-resolution records from appropriate locations throughout the climatic system.

15 2 Methods

The wavelet transform, contrary to the Fourier transform, is used to decompose a signal into a sum of small wave functions of a finite length that are highly localized in time, for different exploratory scales. By difference, Fourier transform aims to separate a signal into infinite-length oscillatory functions (sine waves) like, which results in a complete
20 loss of time information as separated frequencies always apply to the entire length of the signal. Hence, instationary processes can not be described correctly using infinite complex exponentials, because of changes in frequency content across time. Wavelet transform is a band-pass filter which consists of convoluting the signal with scaled and translated forms of a highly time-localized wave function (the filter), the so-called “mother wavelet”. The reference wavelet ψ , referred to as the “mother wavelet”,
25 comprises two parameters for time-frequency exploration, i.e. a scale parameter (a)

Interactive Discussion

and a time-localization parameter (b) so that:

$$\Psi_{a,b}(t) = \frac{1}{\sqrt{a}} \cdot \Psi \left(t - \frac{b}{a} \right) \quad (1)$$

Parameter a produces “daughter wavelets” for investigation at different scale levels, while parameter b allows translation of each daughter wavelet across time to detect changes in frequency content. The continuous wavelet transform of a signal $s(t)$, producing the wavelet spectrum, is defined as:

$$S(a, b) = \int_{-\infty}^{+\infty} s(t) \cdot \frac{1}{\sqrt{a}} \cdot \Psi \left(\frac{t-b}{a} \right) \cdot dt \quad (2)$$

Time-frequency representation actually plots the wavelet power the time series. In practice, since the wavelet transform consists in applying a low-pass filter to a given time series, wavelet power is computed by fast Fourier transform (FFT), which makes easier the convolution of the time series by the wavelet filter (convolution in the time domain corresponds to a simple algebraic product in the frequency domain). Once the Fourier transforms of the time series and the wavelet filter have been computed, the inverse Fourier transform of their product is calculated as follows:

$$W_n(s) = \sum_{k=0}^{N-1} \hat{x}_k \cdot \hat{\psi}^* (s\omega_k) e^{i\omega_k n \delta t} \quad (3)$$

with N : number of points in the time series, s : scale of daughter wavelets, n : time index, k : frequency index, \hat{x}_k : Fourier transform of the initial time series x_n , $\hat{\psi}^*$: complex conjugate of the Fourier transform of ψ (wavelet filter), ω : frequency, δt : time step.

Finally, the wavelet power of the complex function $W_n(s)$ is defined as the square of the amplitude of the wavelet transform, that is, $|W_n(s)|^2$. The resulting plot of the wavelet power spectrum $|W_n(s)|^2$ is a contour map in which frequency, Fourier period or wavelet scale (y-axis), and power (z-axis) are plotted against time (x-axis). Several

types of wavelet are available. In this study the Morlet wavelet (a gaussian-modulated sine wave) was chosen for continuous wavelet transform:

$$\Psi(\eta) = \pi^{-\frac{1}{4}} \cdot e^{im\eta} \cdot e^{-\frac{\eta^2}{2}} \quad (4)$$

where η is a dimensionless time parameter and m is the wavenumber that defines the basic resolution of the mother wavelet. A wavenumber of 10 was used, this choice offering a good trade-off between frequency and temporal resolution for the time series analyzed herein. To avoid edge effects and spectral leakage that are produced by the finite length of the time series, all series were zero-padded to twice the data length. However, zero-padding causes the lowest frequencies near the edges of the spectrum to be underestimated as more zeros enter the series. The area delineating this region is known as the cone of influence and marks those parts of the spectrum where energy bands are likely to be less powerful than they actually are because edge effects are becoming important.

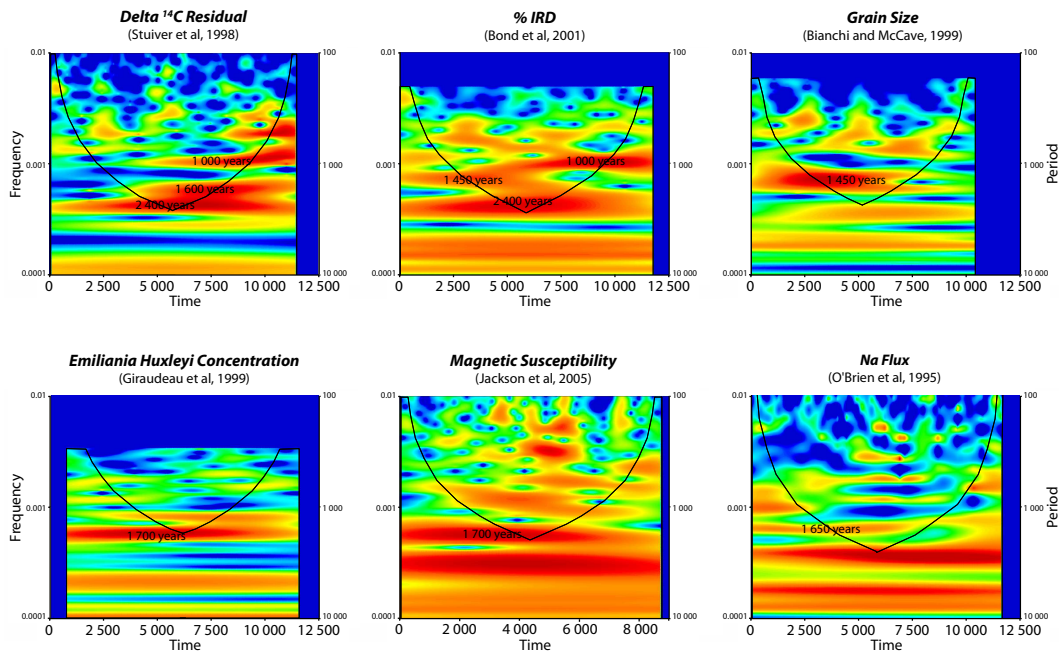

Fig. 3. Wavelet transform analysis of the marine, continental and ice core records of North Atlantic climate proxies over the Holocene period. Occurrence of the periods (labelled) with respect to the time is given by the bright yellow-red colours. Black line corresponds to cone of influence (see Methods paragraph). Horizontal band corresponding to periodicity higher than 3000 years are not meaningful.

1500-year cycles in Holocene North-Atlantic records
