23 **Abstract**

24 The concentrations of 9 elements (Ag, As, Cd, Co, Cr, Cu, Mn, Ni and Zn) were measured
25 in the oyster *Isognomon isognomon* and the edible clam *Gafrarium tumidum* from different
26 sites along the SW New Caledonian coast which is subjected to important chemical inputs due
27 to intense land-based mining activities (New Caledonia is the third world producer of nickel).
28 Results indicate that concentrations in the two organisms mirrored the geographical
29 differences in contamination levels as established through element analyses in sediment. On
30 the basis of organism analyses, two out of the seven investigated stations can be considered as
31 relative “reference” sites, except for As, for which very high levels were detected in clam and
32 oyster tissues (up to 441 $\mu\text{g g}^{-1}$ dry wt for clams). Overall, our results indicate that both
33 tropical organisms investigated could be used as valuable bioindicator species for surveying
34 metal contamination in the coastal waters of New Caledonia with reasonable perspectives of
35 wider application to other coral reef environments.

36

37 **Keywords:** Tropical Environment, Metals, Bioindicators, Mining activities

39 **1. Introduction**

40 Surrounded by a barrier reef of 1600 km, the New Caledonia lagoon is one of the largest
41 in the world (Labrosse et al., 2000). However, the lagoon of New Caledonia is subjected to
42 important anthropogenic inputs of metals mainly due to intense land-based Ni mining
43 activities but also to urban development and lack of efficient wastewater treatment. Open-cast
44 mining exploitation presently constitutes the major economical resource of the Territory and
45 results in important coastal discharges of metals, which constitute a threat to coral reef
46 ecosystems (Labrosse et al., 2000). Recently, more efficient extraction processes based on
47 acidic extraction (viz lixiviation) have been developed (Mihaylov et al., 2000; Goro-Nickel,
48 2001), making the extraction from low Ni grade ores (limonite) possible. The acidic
49 extraction of metals is not Ni-selective and makes also soluble all other ore-contained by-
50 product metals. Therefore, the lixiviation process will obviously lead to an increased multi-
51 elemental contamination of the coastal marine environment.

52 Although mining activities are rising up in the island, studies reporting concentrations or
53 behaviour of metals in marine organisms from New Caledonia are scarce (Monniot et al.,
54 1994; Bustamante et al., 2000; Labrosse et al., 2000; Hédouin et al., 2007). In this context,
55 acquisition of reliable and relevant data in the New Caledonian lagoon is a strong priority and
56 the development and implementation of risk assessment studies and metal monitoring
57 programme is expected by the local authorities.

58 Among the approaches used to assess environmental contamination, the usefulness of
59 bioindicator species is now well established. Marine organisms provide valuable information
60 on the geographical and temporal variations of the bioavailable metal concentrations in their
61 environment (eg, Rainbow, 1995; Warnau et al., 1998). Ideally, selected bioindicators should
62 display a simple relationship between metals accumulated in their tissues and the ambient

63 metal concentrations. This should be true regardless of location and environmental conditions
64 considered.

65 Molluscs have been extensively used in temperate regions (eg, Goldberg et al., 1983;
66 Rainbow, 1995), whereas little attention has been paid to the identification of bioindicators
67 specifically adapted to tropical and sub-tropical regions (Phillips, 1991) despite the constant
68 increase in industrial and human activities. Some efforts were devoted to the extension of the
69 Mussel Watch to the Asia/Pacific and Latin America regions (see eg, UNU, 1994; IMWC,
70 1995), using bivalves such as *Saccostrea* spp., *Crassostrea* spp. and *Perna* spp. as
71 bioindicators. However, none of the above-cited species is present in sufficient abundance
72 along the New Caledonia coasts to be considered as a useful candidate to monitor local
73 contamination. Hence, other tropical organisms have to be selected. In this context, recent
74 studies screened metal concentrations in a variety of local marine organisms from different
75 areas of the New Caledonian lagoon with contrasting contamination status (Breau, 2003;
76 Hédouin, 2006; Hédouin et al., 2006; 2007). The latter studies showed that two bivalves,
77 namely the oyster *Isognomon isognomon* and the edible clam *Gafrarium tumidum*, are
78 satisfying the basic ecological and ecotoxicological requirements to be met by a bioindicator
79 species *sensu* Moore (1966) and Phillips (1990b). Among others, metal bioaccumulation and
80 retention capacity of *G. tumidum* and *I. isognomon* exposed via different pathways
81 (seawater, food, and sediment) were characterized in controlled conditions, including the
82 relationships between metals concentrated in the bivalve tissues and the ambient metal
83 concentrations (Hédouin 2006; Hédouin et al., 2006; 2007; submitted). Results indicate that
84 both species are promising bioindicator candidates for tropical environments.

85 The aim of the present study was to further assess, in the field, the reliability of these two
86 species as sentinel organisms and to provide information on the degree of contamination of
87 selected elements of local concern (Ag, As, Cd, Co, Cr, Cu, Mn, Ni, Zn) in different locations

88 along the SW coast of New Caledonia. Results presented in this paper also provide baseline
89 data for future monitoring programmes.

90 **2. Materials and methods**

91 **2.1. Sampling sites**

92 The sampling stations were selected according to supposedly contrasting contamination
93 status (Fig. 1). Oysters were collected in the subtidal zone of Maa Bay, Koutio Bay, Boulari
94 Bay and Grande Rade (GR_S). Maa Bay is subjected to low anthropogenic and terrigenous
95 inputs and was considered as the relative “reference” station for oysters. Koutio Bay is
96 influenced by inputs of domestic wastes from Noumea City and by the occurrence of an
97 important rubbish dump. Boulari Bay is under the influence of La Coulée River that delivers
98 important inputs of lateritic materials to the lagoon due to soil erosion of closed mine sites.
99 Grande Rade (GR_S) is subjected to anthropogenic inputs from the Ducos industrial zone and
100 the metallurgic factory “Société Le Nickel” (SLN).

101 For clams, three intertidal sampling stations were selected: Ouano Beach, Dumbéa Bay
102 and Grande Rade (GR_I). Ouano Beach is situated 100 km northward from Noumea, and is not
103 influenced by industrial activities; it was considered as the “reference” station for clams.
104 Grande Rade (GR_I) is subject to anthropogenic inputs from the SLN factory (scoria and
105 waters), from the Shell Pacific factory (effluents) and from domestic discharges. Dumbéa Bay
106 is an estuarine bay, influenced by waters from La Dumbéa River and subjected to terrigenous
107 inputs.

108 **2.2. Organisms**

109 The clam *Gafrarium tumidum* was collected by handpicking in the intertidal stations. The
110 oyster *Isognomon isognomon* is associated with rocky substrata at depth ranging from 2 to 25
111 m and were collected by SCUBA diving. All the organisms (n = 6 per species per station)

112 were collected from October to November 2004 (mean water temperature: $25.6 \pm 0.8^\circ\text{C}$) to
113 reduce as much as possible the variability of element concentrations due to season or sexual
114 cycle. Body size is well-known to affect metal concentrations in organisms (eg, Boyden,
115 1977; Warnau et al., 1995); therefore only samples with shell width longer than 35 mm for *G.*
116 *tumidum* (Hédouin et al., 2006) and shell length longer than 70 mm for *I. isognomon* (Metian,
117 2003) were selected for analysis. Collected clams (mean \pm SD, n = 18) measured 38.1 ± 2.8
118 mm (width) and weighed 22.7 ± 4.9 g; oysters (mean \pm SD, n = 24) measured 98 ± 13 mm
119 (length) and weighed 36.9 ± 13.2 g. Back to the laboratory, the bivalves were kept for 24 hrs
120 in 30 l of seawater from the same sampling station to allow for depurating gut contents and
121 particulate material present in the mantle cavity. Three body compartments for the clams
122 (digestive gland, gills and remaining soft parts) and four body compartments for the oysters
123 (visceral mass, gills, adductor muscle and remaining soft parts) were removed from the shells.
124 The separated body compartments were weighed (wet wt), dried at 60°C until constant
125 weight, and weighed again (dry wt). They were then stored in acid-washed, hermetically
126 sealed PET containers until analysis for their metal contents.

127 **2.3. Sediments**

128 In parallel to organisms, superficial sediments (top 3-cm layer) were analysed in all the
129 sampling stations (Fig. 1), except in Dumbéa Bay and in Grande Rade (GR_S) (samples lost
130 during diving). Sediments were stored in acid-washed PET bags until return to the laboratory;
131 they were then dried at 60°C until constant weight (5 days). In order to eliminate
132 heterogeneous materials (stones, fragment of corals), sediments were sieved (1-mm mesh
133 size) prior to analysis for their metal contents.

134 **2.4. Sample preparation and analysis**

135 Aliquots of the biological samples (0.1 to 0.5 g) and of the dried sediment samples (0.5 g)
136 were digested using a 3:1 (v:v) 65 % HNO₃ - 30 % HCl mixture (Merck, suprapur quality).
137 Acidic digestion of the samples was carried out overnight at room temperature, then using a
138 MARS[®] V microwave (30 min with constantly increasing temperature up to 100°C for
139 sediment and up to 115°C for biota, then 15 min at this maximal temperature). These
140 conditions allowed for a complete digestion of the biological matrices and a strong although
141 not total (highly refractory humic acids may resist) leaching of the sediment (eg, Coteur et al.,
142 2003; Dalto et al., 2006). Each sample was eventually diluted to 30 to 50 ml with milli-Q
143 water according to the amount of sample digested.

144 Elements were analysed using a Varian[®] Vista-Pro ICP-OES (As, Cr, Cu, Mn, Ni, and Zn)
145 or a Varian[®] ICP-MS Ultra Mass 700 (Ag, Cd and Co). Three control samples (two Certified
146 Reference Materials -CRMs- and one blank) treated and analysed in the same way as the
147 samples were included in each analytical batch. CRMs were dogfish liver DOLT-3 (NRCC)
148 and lobster hepatopancreas TORT-2 (NRCC). The results were in good agreement with the
149 certified values given for the CRMs and indicated the following recoveries (in %): 103 (Ag),
150 98 (As), 103 (Cd), 112 (Co), 79 (Cr), 95 (Cu), 84 (Mn), 113 (Ni), and 106 (Zn). The
151 detection limits ($\mu\text{g g}^{-1}$ dry wt) were 10.1 (As), 0.8 (Cr), 0.5 (Cu), 0.04 (Mn), 1.1 (Ni) and 0.7
152 (Zn) for ICP-OES and 0.1 (Ag), 0.3 (Cd) and 0.03 (Co) for ICP-MS. Mean element
153 concentrations are given on a dry weight basis ($\mu\text{g g}^{-1}$ dry wt).

154 **2.5. Statistical analysis**

155 Comparisons of the data were performed using 1- or 2-way analysis of variance
156 (ANOVA) followed by the multiple comparison test of Tukey (Zar, 1996). Two-way
157 ANOVA was used with sampling location and body compartment as fixed factors. The
158 variability explained by each factor and their interaction was derived from the sum of squares

159 (Warnau et al., 1998). The level of significance for statistical analyses was always set at $\alpha =$
160 0.05.

161 **3. Results**

162 **3.1. *Sediments***

163 Table 1 shows the element concentrations measured in the sediment collected in the
164 different stations. Except for Ag, for which comparison among stations was not possible due
165 to concentrations always under the detection limit, statistical analyses indicated contrasting
166 element concentrations among stations. Boulari Bay and Grande Rade (GR_I) displayed the
167 highest concentrations for all elements. Concentrations in all elements were always
168 significantly higher in Grande Rade (GR_I) than in Ouano Beach ($p_{\text{Tukey}} < 0.0001$).
169 Concentrations in sediment from Boulari Bay were significantly higher (up to 1 order of
170 magnitude) than those measured in the other stations where oysters were also sampled.

171 **3.2. *The oyster *Isognomon isognomon****

172 Among the two factors considered (body compartment and sampling location) and their
173 interaction, the sampling location explained the major part of the variability observed for As,
174 Cd, Cr and Ni (accounting for 16 to 70 % of the global variance) (Tables 2 and 3, Fig. 2A)
175 whereas the body compartment was the predominant factor explaining the variability
176 observed for Cu (29 %), Mn (49 %) and Zn (36 %). Significant interaction between body
177 compartment and sampling location factors was detected for all elements except Mn, and
178 accounted for 14 to 44 % of the global variance, indicating that geographical variation of
179 measured concentrations was dependent upon the body compartment considered. For all
180 elements, an important part of the variation was associated to the residual term, ranging from
181 12 to 58 %, indicating that other, non-investigated factors (biological and/or environmental

182 factors) were also influencing metal concentrations in the oyster soft tissues (see also section
183 3.3).

184 **3.2.1. Geographical variation**

185 The sampling location significantly affected the concentrations of all studied elements in
186 the body compartments of *I. isognomon* (2-way ANOVA, $p_{\text{sampling locations}} < 0.0001$), except for
187 Mn for which calculated probability was borderline ($p = 0.054$) (Table 3, Fig. 2A). Multiple
188 comparison tests on the mean concentrations indicated that one sampling location displayed
189 generally the highest concentrations for one or several elements, whereas the three other
190 locations did not show significant difference in element concentrations, except for Mn (no
191 significant difference among none of the sampling stations) and As (all stations significantly
192 different from each others).

193 Concentrations of Co and Ni in the oysters were significantly higher in Boulari Bay than
194 in Maa Bay ($p_{\text{Tukey}} \leq 0.001$; Table 2, Fig. 2A). Oysters from Grande Rade (GR_S) displayed
195 significantly higher Ag and Cu concentrations than those measured in Maa Bay ($p_{\text{Tukey}} \leq 0.01$)
196 whereas the highest Cr concentrations were measured in oysters from Koutio Bay ($p_{\text{Tukey}} \leq$
197 0.05). In contrast to all other elements, As and Zn concentrations were higher in oysters from
198 Maa Bay.

199 Geographical variation of the element concentrations in the whole-soft parts of the oysters
200 (reconstructed data) were tested using 1-way ANOVA and Tukey test. Results were similar to
201 those from the 2-way ANOVA performed on body-compartment specific concentrations,
202 except for Cd and Zn. For these two latter elements, no significant difference was observed
203 among whole soft parts in the four sites for Cd and between Maa Bay and Grande Rade (GR_S)
204 for Zn (Table 2). The particular opposite pattern of As and Zn displaying highest
205 concentrations in Maa Bay (up to $77 \mu\text{g As g}^{-1}$ dry wt and $13,817 \mu\text{g Zn g}^{-1}$ dry wt) was
206 confirmed in whole soft parts data treatment.

207 **3.2.2. Body distribution**

208 Multiple comparison tests performed after 2-way ANOVA on the mean concentrations in
209 each body compartment (all sampling locations together) indicated that the concentrations of
210 all elements were lower in the adductor muscle than in the other body compartments (Fig.
211 2A). Generally, concentrations in gills and visceral mass were not significantly different, but
212 significantly higher than in the other body compartments.

213 In terms of distribution of total element load among body compartments, visceral mass
214 and remaining soft parts contained the highest proportion of the elements. Body distribution
215 did not differ among sampling locations, except for Ag which occurred in higher proportion
216 (43 %) in the gills of oysters from Grande Rade (GR_S) compared to those from the other
217 stations (5 - 24 %).

218 **3.3. *The clam Gafrarium tumidum***

219 The two-way ANOVA performed on the whole set of data indicated that, with the
220 exception of Mn and Zn, the sampling location was the predominant factor affecting element
221 concentrations, accounting for 23 to 84 % of the global variance (Tables 3 and 4, Fig. 2B).
222 The ranking of sampling stations by order of decreasing concentration depended on the
223 considered clam body compartment. In the case of Ag, Cd, Co, Cr, Mn, Ni and Zn, 35 to 61 %
224 of the element concentration variability was due to undetermined factor(s) (residual term).

225 It is noteworthy that the elements for which the residual terms are the highest (Cd, Co, Cr,
226 Mn) both in clams and oysters are those that are co-occurring in Ni-ores. Therefore, it is most
227 plausible that the undetermined factor(s) are related to mining activities, either directly (eg,
228 nature of exploited soils in different areas) or indirectly (eg, climatic factors such as rains
229 temporarily enhancing soil-erosion and riverine inputs).

230 **3.3.1. Geographical variation**

231 The mean concentrations of all elements measured in clams varied significantly according
232 to the sampling locations (2-way ANOVA, $p_{\text{sampling locations}} \text{ always } \leq 0.002$) (Tables 3 and 4,
233 Fig. 2B). Results showed significant differences between Ouano Beach and Grande Rade
234 (GR_I) for Ag, Cd, Cr, Cu, Mn, Ni and Zn, with the highest concentrations always found in
235 Grande Rade (GR_I). In contrast the concentrations of As were significantly higher in Ouano
236 Beach compared to all the other locations ($p_{\text{Tukey}} \leq 0.001$; Table 4 and Fig. 2B).

237 Geographical variations were tested using 1-way ANOVA and Tukey test for the
238 reconstructed element concentrations in the whole-soft parts of the clams (Table 4). Results
239 were similar to those previously obtained with 2-way ANOVA performed on body-
240 compartment specific concentrations, except for Co which showed significant differences
241 among whole soft parts in the three sampling locations ($p_{\text{Tukey}} < 0.05$). Similarly to oysters, As
242 levels in clams were highest in the “reference” station (Ouano Beach), reaching mean values
243 up to 441 $\mu\text{g g}^{-1}$ dry wt.

244 **3.3.2. Body distribution**

245 The mean concentrations of all elements investigated differed according to the body
246 compartments (2-way ANOVA, $p_{\text{body compartment}} \text{ always } \leq 0.003$). Multiple comparison tests of
247 Tukey indicated that the concentrations of Cd, Cu, Cr, Mn and Zn were significantly higher in
248 the digestive gland than in the other tissues ($p < 0.05$; Fig. 2B). Ag, As, Co and Ni
249 concentrations were similar in the digestive gland and the gills. No major difference was
250 found when considering body distribution in clams collected from Ouano Beach and Dumbéa
251 Bay. In these two stations, the remaining soft parts contained the main fraction (55 to 77 %)
252 of the total body burden for all elements. In contrast, in Grande Rade (GR_I), the elements
253 were similarly distributed between the remaining soft parts and the digestive gland.

254 **4. Discussion**

255 Sediments are a sink for marine contaminants (eg, Salomons et al., 1987) and their
256 element concentrations are often used to assess and monitor the contamination status of the
257 marine environment. According to this concept, Boulari Bay and Grande Rade (GR_I) may be
258 considered as highly contaminated stations compared to Ouano Beach and Maa Bay. In turn,
259 the two latter ones may be defined as relatively non-contaminated stations (see Table 1).
260 However, it is now well known that sediment-associated concentrations are not necessarily
261 representative of the contaminant fraction that is bioavailable, viz the fraction of “direct
262 ecotoxicological relevance” for marine organisms (Phillips and Rainbow, 1993). Therefore,
263 the present study was carried out to assess the usefulness of the oyster *Isognomon isognomon*
264 and the clam *Gafrarium tumidum* as sentinel species over sediment for Ag, As, Cd, Co, Cr,
265 Cu, Mn, Ni and Zn contamination in the SW lagoon of New Caledonia.

266 In agreement with sediment analyses, Maa Bay can also be considered as a relative
267 reference site when considering element measurements in the oyster *I. isognomon* for all
268 elements, except As and Zn. The low element concentrations reported in the oysters from this
269 bay are in the same range as those reported in the literature for *Isognomon* spp. as well as in
270 other oyster genera from clean areas (see Table 5).

271 The elevated concentrations of Co and Ni measured in oysters from Boulari Bay strongly
272 suggest that a high degree of mining-related contamination occurs in this area, most probably
273 due to releases from surrounding mines and mining-enhanced erosion of the soils. This was
274 further confirmed by the high concentrations of Co, Cr, Mn and Ni measured in the sediment
275 from Boulari Bay. However, element analysis in oyster tissues showed that other stations, not
276 identified through sediment analysis, are also highly contaminated for some elements,
277 especially Maa Bay for As and Zn and Grande Rade (GR_S) for Ag. The elevated
278 concentrations recorded in oysters suggest that Maa Bay would be subjected to agrochemical

279 inputs (eg, Francesconi et al., 1999; Warnau et al., 2007) and Grande Rade (GR_S) to important
280 domestic wastewater discharges (eg, Martin et al., 1988; Sañudo-Willhelmy and Flegal,
281 1992).

282 With the exception of As, element concentrations in the clams *G. tumidum* collected from
283 Ouano Beach were always lower than in those from Grande Rade (GR_I). This is in agreement
284 with the results obtained from sediment analysis. Concentrations measured in the clams from
285 Ouano Beach were in the same range as those reported for clean areas from other tropical
286 zones (see Table 5). Ouano Beach may thus be considered as a relatively clean station for all
287 elements considered, except for As. In contrast, Grande Rade (GR_I) can be defined as a highly
288 contaminated station for Ag, Cr, Cu, Mn, Ni and Zn.

289 In this work, the distribution of the considered elements in bivalve tissues was also
290 investigated in order to possibly identify some organs that could be more sensitive than the
291 use of the whole soft parts and able to respond more rapidly to changes in element
292 contamination in the environment (eg, Warnau et al., 1996b; 1998; 1999). Among the body
293 compartments of the clam *G. tumidum*, the digestive gland displayed the highest
294 bioconcentration capacity. In addition, the concentrations measured in this organ easily
295 allowed discriminating the stations according to their contamination levels. Hence, this organ
296 could be proposed as a target for future biomonitoring programmes. In the oyster *I.*
297 *isognomon*, no clear trends could be observed in bioaccumulation and geographical
298 discrimination ability among the different body compartments. Consequently, in a future
299 biomonitoring programme, consideration of the whole soft parts of oysters could be
300 recommended.

301 The two investigated species accumulated some elements up to very high concentrations
302 compared to the concentrations generally reported in the literature (Table 5). These
303 particularities are discussed below.

304 Ni concentrations measured in clams bear out the capacities of this species to accumulate
305 this metal. Indeed, Ni concentrations in clams from Grande Rade (GR_I) were higher (52 ± 12
306 $\mu\text{g g}^{-1}$ dry wt) by one order of magnitude than those usually reported in the literature for other
307 tropical clams (see Table 5). The high levels that we measured for Cr and Ni in sediment and
308 clams from Grande Rade (GR_I) are obviously due to mining activities (presence of SLN
309 industry, which discharges wastes into the Rade) associated to mining-enhanced erosion of
310 lateritic soils, which are enriched in Cr and Ni (Labrosse et al., 2000).

311 Although scarcely available, As concentrations reported in the literature for tropical and
312 subtropical bivalves are generally lower than $30 \mu\text{g g}^{-1}$ dry wt ($< 10 \mu\text{g g}^{-1}$ dry wt if one
313 considers clams and oysters; see Table 5). However, two studies on sub-tropical areas
314 indicated elevated As concentrations in *Isognomon* spp from Florida ($37.3 \pm 6.9 \mu\text{g g}^{-1}$ dry
315 wt) (Valette-Silver et al., 1999) and in the clam *Circentia callipyga* from the Gulf of Oman
316 ($156 \mu\text{g g}^{-1}$ dry wt) (de Mora et al., 2004). In the present study, As was found to reach
317 extremely high concentrations in the clams from Ouano Beach ($441 \pm 84 \mu\text{g g}^{-1}$ dry wt)
318 compared to those observed in Grande Rade (GR_I) ($55 \pm 15 \mu\text{g g}^{-1}$ dry wt) and in the oysters
319 from Maa Bay ($77 \pm 9 \mu\text{g g}^{-1}$ dry wt). To the best of our knowledge, such high body
320 concentrations of As have never been reported in other clams. The Ouano Beach values were
321 in fact on the same order of magnitude than the highest As concentrations ever reported, such
322 as in the cirratulid polychaete *Tharyx marioni* which displays extremely high body
323 concentrations of total As ($2000 \mu\text{g g}^{-1}$ dry wt; Gibbs et al., 1983), the Mediterranean fan
324 worm *Sabella spallanzanii* which shows As concentrations higher than $1000 \mu\text{g g}^{-1}$ dry wt in
325 its branchial crown (Fattorini and Regoli, 2004) or the very high arsenic concentrations
326 monitored in muscles of edible fish ($500 \mu\text{g g}^{-1}$ dry wt) from the Bay of Cienfuegos, Cuba, a
327 few weeks after an accidental release of arsenate oxides from a local nitrogen fertilizer factory
328 in Dec 2001 (Fattorini et al., 2004; Warnau et al., 2007). However the reason for so high As

329 concentrations in *G. tumidum* tissues is not clear. Some authors have reported that As
330 concentrations in organisms were related to the sediment concentrations (such as in
331 *Scrobicularia plana*; Langston, 1980). However no similar correlation was observed here. In
332 addition, laboratory experiments have shown that bivalves generally displayed a limited
333 capacity in accumulating As from seawater (eg, Ünlü and Fowler, 1979; Hédouin, 2006;
334 Gómez-Batista et al., 2007). Thus, the elevated As concentrations reported in this study would
335 be accumulated most probably from the diet of the organisms (Sanders et al., 1989; Gómez-
336 Batista and Warnau, unpubl. results). Accordingly, transfer along the food chain could be
337 proposed as the main route of uptake for As in bivalves, suggesting that food of both oysters
338 and clams are enriched in As in Maa Bay and Ouano Beach, compared to the other sampling
339 locations. Whereas some agricultural activities are carried out in Maa Bay, Ouano Beach is
340 rather subjected to waste discharges from shrimp aquaculture. Hence the important discharges
341 of N-enriched products (due to terrestrial leaching of fertilisers used for local agriculture or to
342 release of aquaculture food excesses) could locally modify the N:P ratio. In environments
343 with phosphate deficit relative to nitrogen, phytoplankton metabolises As much more easily
344 (Benson and Summons, 1981; Phillips, 1990a). This in turn may lead to enhanced trophic
345 transfer of As to filter-feeders and enhanced As accumulation in the tissues of the bivalves
346 (Warnau et al., 2007). Although further investigations are needed to validate such a
347 hypothesis in Maa Bay and Ouano Beach, the extremely high As levels measured in clam
348 tissues are of considerable interest because (1) *G. tumidum* is a seafood product in New
349 Caledonia and (2) little is known about the speciation of As in the tissues of this species
350 (Francesconi et al., 1999) which determines its potential toxicity to consumers (see eg, Kaise
351 and Fukui, 1992; Warnau et al., 2007).

352 *I. isognomon* displayed also very high Zn concentrations in Maa Bay and in Grande Rade
353 (GRs), viz $13,817 \pm 6,621$ and $7,873 \pm 2,087$ $\mu\text{g g}^{-1}$ dry wt, respectively. Elevated

354 concentrations of Zn have been reported for *I. alatus*, reaching 4,010 $\mu\text{g Zn g}^{-1}$ dry wt in
355 individuals collected in the Dominican Republic and 12,163 $\mu\text{g g}^{-1}$ dry wt in the Guadeloupe
356 (see Table 5). Although, Zn is well known to be essential to organisms, acting for example as
357 a co-factor in numerous metalloenzymes (eg, Vallee and Falchuk, 1993), the amounts
358 accumulated are clearly far above the physiological needs of the bivalve. *I. isognomon* must
359 therefore possess a natural capacity to accumulate Zn up to very high levels while avoiding
360 subsequent toxicity. Such a mechanism could be for example the immobilization of Zn under
361 non-toxic forms in granules which are very slowly excreted (eg, Corrêa Junior et al., 2000).
362 Indeed, in many bivalves and especially in oysters, granules may contain up to 60 % of the
363 total body load of Zn (Eisler, 1981).

364 Ag is well known as a highly toxic metal (eg, Warnau et al, 1996a; Ratte, 1999) and the
365 scarcity of data concerning Ag levels in tropical and subtropical organisms in general, and in
366 particular in clams and oysters, is therefore quite surprising (see Table 5). In this way, the
367 concentrations measured in the two investigated species (see Tables 2 and 4) can be
368 considered as baseline data for the New Caledonia lagoon as well as for other tropical
369 environments. Clams and oysters collected from Grande Rade displayed quite elevated Ag
370 concentrations (33 ± 13 and $33 \pm 7 \mu\text{g g}^{-1}$ dry wt, respectively), which are one to two orders
371 of magnitude higher than those measured in bivalves from the “reference” stations (Ouan
372 Beach or Maa Bay) and to the background concentrations generally considered for tropical
373 areas ($< 1 \mu\text{g g}^{-1}$ dry wt in mussels; Klumpp and Burdon-Jones, 1982) and temperate areas ($<$
374 $6 \mu\text{g g}^{-1}$ dry wt in clams and oysters; Cohen et al., 2001). Various bivalves are able to
375 accumulate Ag up to very high concentrations by trapping it as Ag_2S , a stable and non-toxic
376 compound (eg, Berthet et al., 1992; Bustamante and Miramand, 2005). The occurrence of a
377 similar detoxification mechanism in *G. tumidum* and *I. isognomon* could explain the high Ag
378 concentrations observed in their soft tissues. Natural sources of Ag are quite rare in the

379 environment (Luoma et al., 1995) and Ag is considered as a reliable proxy of anthropogenic
380 inputs in coastal waters, such as sewage sludge and boating activities, (Martin et al., 1988;
381 Sanudo-Willhelmy and Flegal, 1992). Therefore the enrichment of Ag in bivalves from
382 Grande Rade would be most probably related to this kind of domestic inputs.

383 **5. Conclusions**

384 In New Caledonia, contaminants released in the lagoon are clearly a matter of concern, as
385 reflected by the elevated concentrations in some elements found in the marine organisms
386 investigated in the present work. The two bivalve species considered in this study merit
387 consideration as they appear to be bioindicator species of interest for surveying the
388 contamination status of the New Caledonian waters. Indeed, these species (1) are abundant
389 and widely distributed in New Caledonia (as well as in other tropical areas), (2) show elevated
390 bioaccumulation capacity, and (3) are able to reveal the differences in element concentrations
391 among different areas, even in complex environments (the locations examined here were
392 subjected to various contamination sources).

393 In a future biomonitoring programme in the SW lagoon of New Caledonia, element
394 concentrations in organisms from Ouano Beach and Maa Bay could be considered as
395 background concentrations for all elements, except for As and Zn. Furthermore, due to the
396 very high levels of As measured in clams from Ouano Beach, the speciation of As in clam
397 tissues should be determined in detail (particularly their inorganic As content) to assess
398 whether their consumption could represent a potential hazard for local consumers (Warnau et
399 al., 2007; Metian et al., 2008).

605

606 **Figure 2.** Comparisons of element concentrations in bivalves, using multiple comparison test
607 of Tukey performed after 2-way ANOVA in (A) the oyster *Isognomon isognomon* and (B) the
608 clam *Gafrarium tumidum*.

609 Mean concentrations are ranked from the left to the right by decreasing order. Concentrations
610 in underlined body compartments or locations are not significantly different ($\alpha = 0.05$).

611 Body compartments: DG (digestive gland), G (gills), M (adductor muscle), VM (visceral
612 mass) and R (remaining soft parts).

613 Sampling locations: OUA (Ouano beach), GR_S (Grande Rade, subtidal), GR_I (Grande Rade,
614 intertidal), DUM (Dumbéa Bay), and KOU (Koutio Bay).

* Concentrations < detection limit.

^{1,2} stations where clams and oysters were collected, respectively.

Significant differences among the mean concentrations in sediments from the different sampling stations are indicated by superscripts; means sharing the same superscript (^{a, b, c}) are not significantly different among sampling stations ($p_{\text{Tukey}} > 0.05$).

Comparisons among sediment concentrations were carried out separately among the stations where clams or oysters were collected.
