Abstract—One of the most important collective communication patterns used in scientific applications is the complete exchange, also called All-to-All. Although efficient algorithms have been studied for specific networks, general solutions like those available in well-known MPI distributions (e.g. the MPI_Alltoall operation) are strongly influenced by the congestion of network resources. In this paper we present an integrated approach to model the performance of the All-to-All collective operation, which consists in identifying a contention signature that characterizes a given network environment, using it to augment a contention-free communication model. This approach, assessed by experimental results, allows an accurate prediction of the performance of the All-to-All collective operation over different network architectures with a small overhead. We also discuss the problem of network contention in a grid environment, studying some strategies to minimize the impact of contention on the performance of an All-to-All operation.

Index Terms—MPI, all-to-all, total exchange, network contention, performance modeling, computational grid, personalized many-to-many communications

I. Introduction

One of the most important collective communication patterns for scientific applications is the total exchange [4] (also called All-to-All), in which each process holds n different data items that should be distributed among the n processes, including itself. An important example of this communication pattern is the All-to-All operation, where all messages have the same size m.

Although efficient All-to-All algorithms have been studied for specific networks structures like meshes, hypercubes, tori and circuit-switched butterflies, general solutions like those found in well-known MPI distributions rely on direct point-to-point communications among the processes. Because all communications are started simultaneously, architecture independent algorithms are strongly influenced by the saturation of network resources and subsequent loss of packets - the network contention.

In the first part of this paper we present a new approach to model the performance of the All-to-All collective operation. Our strategy consists in identifying a contention signature that characterizes a given network environment. Using such contention signature, we are able to accurately predict the performance of the All-to-All operation, with an arbitrary number of processes and message sizes. To demonstrate our approach, we present experimental results obtained with different network architectures (Fast Ethernet, Gigabit Ethernet and Myrinet). We believe that this model can be extremely helpful on the development of application performance prediction frameworks such as PEMPIs [20] and task schedulers.

Later, we focus on the performance modeling of All-to-All in a grid environment. We observe that contention at the wide-area level not only exists but represents a major component on the communication performance. We propose therefore an algorithm adapted for inter-cluster message exchanges. This algorithm minimizes the impact of network contention and, by extension, allows a better performance modeling. Indeed, we show that this algorithm not only outperforms the traditional All-to-All algorithms on a grid environment but also allows an accurate performance modeling using only elements derived from our local-area models.

This paper is therefore organized as follows: Section II presents a survey of performance modeling under communication contention. Section III presents the network models used in this paper and we formalize the total exchange problem, as well as some performance lower bounds. In Section IV we propose a strategy to characterize the contention signature of a given network and for instance, to predict the performance of the All-to-All operation. Section V validates our model against experimental data obtained on different network architectures (Fast Ether-
II. Related Works

In the All-to-All operation, every process holds $m \times n$ data items that should be equally distributed among the $n$ processes, including itself. Because general implementations of the All-to-All collective communication rely on direct point-to-point communications among the processes the network can easily become saturated, and by consequence, degrades the communication performance. Indeed, Chun and Wang \[5\][6] demonstrated that the overall execution time of intensive exchange collective communications are strongly dominated by the network contention and congestive packet loss, two aspects that are not easy to quantify. As a result, a major challenge on modeling the communication performance of the All-to-All operation is to represent the impact of network contention.

Unfortunately, most communication models like those presented by Christara et al. \[4\] and Pjesivac-Grbovic et al. \[22\] do not take into account the potential impacts of network contention. Indeed, these works usually represent the All-to-All operation as parallel executions of the personalized one-to-many pattern \[15\], as presented by the linear point-to-point model below, where $\alpha$ is the start-up time (the latency between the processes), $\frac{1}{n}$ is the bandwidth of the link, $m$ represents the message size in bytes and $n$ corresponds to the number of processes involved in the operation:

$$T = (n - 1) \times (\alpha + \beta m) \tag{1}$$

The development of contention-aware communication models is relatively recent, as shown by Grove \[11\]. For instance, Adve \[1\] presented one of the first models to take into account the effects of resource contention. This model considers that the total execution time of parallel programs is the sum of four components, namely:

$$T = t_{\text{computation}} + t_{\text{communication}} + t_{\text{resource-contention}} + t_{\text{synchronization}} \tag{2}$$

While conceptually simple, this model was non-trivial in practice because of the non-deterministic nature of resource contention, and because of the difficulty to estimate average synchronization delays.

While the non-deterministic behavior of the network contention is a major obstacle to modeling communication performance, some authors suggested a few techniques to adapt the existing models. As consequence, Bruck \[2\] suggested the use of a slowdown factor to correct the performance predictions. Similarly, Clement et al. \[7\] introduced a technique that suggested a way to account contention in shared networks such as non-switched Ethernet, consisting in a contention factor $\gamma$ that extends the linear communication model $T$:

$$T = \alpha + \beta \times m \times \gamma \tag{3}$$

where $\gamma$ is equal to the number of processes. A restriction on this model is that it assumes that all processes communicate simultaneously, which is only true for a few collective communication patterns. Anyway, in the cases where this assumption holds, they found that this simple contention model enhanced the accuracy of their predictions for essentially zero extra effort.

The use of a contention factor was supported by the work of Labarta et al. \[19\], that intent to approximate the behavior of the network contention by considering that if there are $m$ messages ready to be transmitted, and only $b$ available buses, then the messages are serialized in $\frac{m}{b}$ communication waves. Also, König et al. \[18\] have shown indeed that some All-to-All algorithms that are optimal with unlimited buffers become less efficient when communications depend on restricted buffers sizes.

A similar approach was followed by Jeannot et al. \[14\], who designed scheduling algorithms for data redistribution through a backbone. In their work, they suppose that at most $k$ communications can be performed at the same time without causing network contention (the value of $k$ depending on the characteristics of the platform). Using the knowledge of the application transfer pattern, they proposed two algorithms to schedule the messages transfers, performing an application-level congestion control that in most cases outperforms the TCP contention control mechanism.

Most recently, some works aimed to design contention-aware performance models. For instance, LoGPC \[21\] presents an extension of the LogP model that tries to determine the impact of network contention through the analysis of $k$-ary $n$-cubes. Unfortunately, the complexity of this analysis makes too hard the application of such model in practical situations.

Another approach to include contention-specific parameters in the performance models was introduced by Chun \[5\]. In his work, the contention is considered as a component of the communication latency, and by consequence, the model uses different latency values depending on the message size. Although easier to use than LoGPC, this model does not take into account the number of messages passing in the network nor the link capacity, which are clearly related to the occurrence of network contention.

III. Definitions

A. Network Models

In this work we assume that the network is fully connected, which corresponds to most current parallel machines with distributed memory.

Communication Model: The links between pairs of processes are bidirectional, and each process can transmit data on at most one link and receive data on at most one link at any given time.

Transmission Model: We use Hockney’s notation \[12\] to describe our transmission model. Therefore, the time to send a message of size $w_{i,j}$ from a process $p_i$ to another process $p_j$, is $\alpha + w_{i,j}/\beta$, where $\alpha$ is the start-up time (the
communication latency between the processes) and \( \frac{1}{2} \) is the bandwidth of the link. As in this paper we assume that all links have the same latency and bandwidth, and because we only investigate the regular version of the MPI_Alltoall operation where all messages have the same size \( m \), \( \forall i,j, w_{i,j} = m \), and therefore the time to send a message from a process \( p_i \) to a process \( p_j \) is \( \alpha + m\beta \).

**Synchronization Model:** We assume an asynchronous communication model, where transmissions from different processes do not have to start at the same time. However, all processes start the algorithm simultaneously. This synchronization model corresponds to the execution of the MPI_Alltoall operation, used as reference in this work.

**B. Problem Definitions**

In the total exchange problem, \( n \) different processes hold each one \( n \) data items that should be evenly distributed among the \( n \) processes, including itself. Because each data item has potentially different contents and sizes according to their destinations, all processes engage a total exchange communication pattern. Therefore, a total exchange operation will be complete only after all processes have sent their messages to their counterparts, and received their respective messages.

Formally, the total exchange problem can be described using a weighted digraph \( dG(V, E) \) of order \( n \) with \( V = \{p_0, \ldots, p_{n-1}\} \). This digraph is called a message exchange digraph or MED for short. In a MED, the vertices represent the process nodes, and the arcs represent the messages to be transmitted. An integer \( w(e) \) is associated with each arc \( e = (p_i, p_j) \), representing the size of the message to be sent from process \( p_i \) to process \( p_j \). Note that there is not necessarily any relationship between a MED and the topology of the interconnection network.

The port capacity of a process for transmission is the number of other processes to which it can transmit simultaneously. Similarly, the port capacity for reception is the number of other processes from which it can receive simultaneously. We will concentrate on the performance modeling problem with all port capacities restricted to one for both transmitting and receiving. This restriction is well-known in the literature as 1-port full-duplex.

**C. Notation and lower bounds**

In this section, we present theoretical bounds on the minimum number of communications and on the bandwidth for the general message exchange problem. The number of communications determines the number of start-ups, and the bandwidth depends on the message weights.

Given a MED \( dG(V, E) \), we denote the in-degree of each vertex \( p_i \) in \( V \) by \( \Delta_i(p_i) \), and the out-degree by \( \Delta_i(p_i) \). Let \( \Delta_r = \max_{p_i \in V} \{\Delta_i(p_i)\} \) and \( \Delta_s = \max_{p_i \in V} \{\Delta_i(p_i)\} \). Therefore, we obtain the following straightforward bound on the number of start-ups.

**Claim 1.** The number of start-ups needed to solve a message exchange problem on a digraph \( dG(V, E) \) without message forwarding is at least \( \max(\Delta_s, \Delta_r) \).

Given a MED \( dG(V, E) \), the bandwidth bounds are determined by two obvious bottlenecks for each vertex - the time for it to send its messages and the time for it to receive its messages. Each vertex \( p_i \) has to send messages with sizes \( \{w_{i,j} \mid j = 0 \ldots n-1\} \). The time for all vertices to send their messages is at least \( t_s = \max_{j=0}^{n-1} w_{i,j}/\beta \). Similarly, the time for all vertices to receive their messages is at least \( t_r = \max_{j=0}^{n-1} w_{i,j}/\beta \).

**Claim 2.** The time to complete a personalized exchange is at least \( \max\{t_s, t_r\} \).

We can combine the claims about the number of start-ups and the bandwidth when message forwarding is not allowed.

**Claim 3.** If message forwarding is not allowed, and either the model is synchronous or both maxima are due to the same process, the time to complete a personalized exchange is at least \( \max(\Delta_s, \Delta_r) \times \alpha + \max\{t_s, t_r\} \).

Because in this paper we do not assume messages forwarding, the fan-in and fan-out of a process must be \((n-1)\). Further, as we consider messages to be the same size and the network to be homogeneous, we can simplify Claim 3 so that the following bound holds.

**Proposition 1.** If message forwarding is not allowed, and all messages have size \( m \), and both bandwidth and latency are identical to any connection between two different processes \( p_i \) and \( p_j \), the time to complete a total exchange is at least \((n-1) \times \alpha \times (n-1) \times \beta m \).

**Proof.** The proof is trivial, as the time to complete a total exchange is at least the time a single process needs to send one message to each other process.

**IV. Contention Signature Approach**

To cope with this problem and to model the contention impact on the performance of the All-to-All operation, we adopt an approach similar to Clement et al. [7], which considers the contention sufficiently linear to be modeled. Our approach, however, tries to identify the behavior of the All-to-All operation with regard to the theoretical lower bound (Proposition 1) on the 1-port communication model. In our hypothesis, the network contention depends mostly on the physical characteristics of the network (network cards, links, switches), and consequently, the ratio between the theoretical lower bound and the real performance represents a “contention signature” of the network. Once identified the signature of a network, it can be used in further experiments to predict the communication performance, provided that the network infrastructure does not change.

Initially, we consider communication in a contention-free environment. In this case, a process that sends messages of size \( m \) to \( n-1 \) processes needs at least \((n-1) \times \alpha \times (n-1) \times \beta m \) time units. Further, by the properties of the 1-port communication model, the total communication time of the All-to-All operation must be at least \((n-1) \times \alpha \times (n-1) \times \beta m \) time units if all processes start communicating simultaneously, as stated by Proposition 1.

In the case of the All-to-All operation, however, the intensive communication pattern tends to saturate the
network, causing message delays and packet loss that strongly impact on the communication performance of this collective communication. In this network congestion situation, traditional models such as those presented by Christara [4] do not hold anymore, even if the communication pattern has not changed.

Therefore, our approach to model the performance of the MPI_Alltoall operation despite network contention consists on determining a contention ratio $\gamma$ that express the relationship between the theoretical performance (lower bound) and the real completion time. For simplicity, we consider that this contention ratio $\gamma$ is constant and depends exclusively on the network characteristics. Therefore, the simplest way to integrate this contention ratio $\gamma$ in our performance model would be as follows:

$$T = (n - 1) \times (\alpha + m\beta) \times \gamma$$  

(4)

A. Non-linear aspects

Although the performance model augmented by use of the contention ratio $\gamma$ improves the accuracy of the predictions, we observe nonetheless that some network architectures are still subject to performance variations according to the message size. To illustrate this problem, we present in Fig. 1, a detailed mapping of the communication time of the MPI_Alltoall operation in a Gigabit Ethernet network. We observe that the communication time does not increase linearly with the message size, but instead, present a non-linear behavior that prevents our model to accurately predict the performance when dealing with small messages.

To cope with this non-linearity, we propose an extension of the contention ratio model to better represent this phenomenon when messages are sufficiently large. Hence, we augment the model with a new parameter $\delta$, which depends on the number of processes but also on a given message size $M$. As a consequence, the association of different equations helps to define a more realistic performance model for the MPI_Alltoall operation, as follows:

$$T = \begin{cases} 
(n - 1) \times (\alpha + m\beta) \times \gamma & \text{if } m < M \\
(n - 1) \times (\alpha + m\beta) \times \gamma + \delta & \text{if } m \geq M 
\end{cases}$$  

(5)

V. Validation

To validate the approach proposed in this paper, this section presents our experiments to model the performance of MPI_Alltoall operation using three network architectures, Fast Ethernet, Gigabit Ethernet and Myrinet. As previously explained, our approach compares the expected and real performance of the MPI_Alltoall operation using a sample experiment with $n'$ nodes; the relationship between these two measures allows us to define the $\gamma$ and $\delta$ parameters that characterize the "network contention signature".

To obtain these parameters, we compare the sample data obtained from both theoretical lower bound and experimental measure, while varying the message size. Indeed, the lower bound comes from Proposition 1, with parameters $\alpha$ and $\beta$ obtained from a simple point-to-point measure. The parameters $\gamma$ and $\delta$ are obtained through a linear regression with the Generalized Least Squares method, comparing at least four measurement points in order to better fit the performance curve.

The different experiments presented in this paper represent the average of 100 measures for each set of parameters (message size, number of processes), and were conducted over two clusters of the Grid’5000 network:

The *icluster2* cluster, located at INRIA-Rhone-Alpes, composed of 104 dual Itanium2 nodes at 900 MHz, used for the experiments with the Fast Ethernet network (5 Fast Ethernet switches - 20 nodes per switch - interconnected by 1 Gigabit Ethernet switch) and the Myrinet 2000 network (one 128 ports M3-E128 Myrinet switch). All machines run Red Hat Enterprise Linux AS release 3, with kernel version 2.4.21.

The *GdX* (Grid’Explorer) cluster, operated by INRIA-Futurs. This cluster includes 216 nodes with dual AMD Opteron processors at 2 GHz running Debian Linux kernel 2.6.8 and a Broadcom Gigabit Ethernet network.

A. Fast Ethernet

Taking as basis the measured performance for a 24 machines network, we were able to approximate the performance of the Fast Ethernet network with a contention ratio $\gamma = 1.0195$. Indeed, this relatively small difference must be considered in the light of the retransmission policy: although the communication latency (and therefore the timeouts) is relatively small (around 60 $\mu$s), the reduced bandwidth of the links minimizes the impact of the retransmission of a lost packet. More important, we observe that the experimental measures behave like an affine equation, showing a start-up cost usually not considered by the traditional performance model which corresponds to the $\delta$ parameter proposed in our model. Therefore, we determined $\delta = 8.23$ $ms$ for messages larger than $M = 2$ $kB$, which means that each simultaneous communication induces an overload of 8.23 $ms$ to the completion time of the All-to-All operation. Applying both $\gamma$ and $\delta$ parameters to the performance model we were able to approximate our predictions from the performance of the MPI_Alltoall operation with an arbitrary number of processes, as demonstrate in Fig. 2a. We observe indeed

![Fig. 1. Non-linearity of communication cost with small messages](http://www.grid5000.fr/)
that our error rate is usually smaller than 10% when there are enough processes to saturate the network, as presented in Fig. 2b.

Fig. 2. Performance prediction on a Fast Ethernet network

B. Gigabit Ethernet

To compute the contention ratio $\gamma$ and a start-up cost $\delta$, we use sample data for an arbitrary number of processes. Indeed, we chose in this example the results for an execution of the All-to-All operation with 40 processes (one by machine). Using linear regression on these data we obtain $\gamma = 4.3628$ and $\delta = 4.93\text{ ms}$ (to be used only for messages larger than $M = 8\text{ kB}$). As a result, the performance predictions from our model correspond to the curve presented on Fig. 3a. As in the case of the Fast Ethernet network, the error rate is quite small when the network becomes saturate, even when we consider different message sizes (Fig. 3b).

C. Myrinet

Although the two previous experiments give important proofs on the validity of our modeling method, they share many similarities on both network architecture and transport protocol (TCP/IP). To ensure that our method is not bounded to a specific infrastructure, we chose to validate our performance model also in a Myrinet network, using the gm transport protocol. Because of the Myrinet+gm stack differs considerably from the Ethernet+TCP/IP stack, any systematic behavior introduced into our sampling data by these architectures should be exposed.

Indeed, the Myrinet network differs from Ethernet-based architectures due to a start-up cost almost inexistent (one of the main characteristics of the Myrinet+gm stack). Indeed, we were able to fit the performance of a 24-processes All-to-All operation using only the contention ratio $\gamma = 2,49754$ (as the linear regression pointed a start-up cost $\delta$ smaller than 1 microsecond).

Nevertheless, when applying this factor to an arbitrary number of machines, as presented in Fig. 4a, we observe that our predictions do not follow the experimental data as observed before with Fast Ethernet and Gigabit Ethernet. Actually, a close look at the error rate (Fig. 4b) indicates that network saturation occurs only when there are more then 40 communicating processes (evidenced by the constant error rate from that point). These results demonstrate the limitations of our approach: while a contention ratio may provide precise performance predictions, it depends on the data used to define the network signature. By using reference data from a partially saturated network we are subjected to inaccurate approximations (even if they are better than the contention unaware predictions).

VI. Problem of Total Exchange between Two Clusters

Multicluster and computational grids are popular heterogeneous environments used by the HPC community,
One part of the computation is performed on cluster both clusters (for example, a code coupling application). Communication within a cluster is faster than communication within a cluster. Without loss of generality, let us assume two clusters, one of its nodes or to a node of another cluster. Based on that topology inter-cluster communications are never remote. Without loss of generality, let us assume two clusters, one of its node or to a node of another cluster. Based on that topology inter-cluster communications are never remote.

Fig. 5. Architecture for the redistribution problem

and part of our efforts concentrate on the development of efficient algorithms and performance models for these environments. More specifically, we must deal with communications costs that differ significantly if they are local or remote. Without loss of generality, let us assume two clusters $C_1$ and $C_2$ with respectively $n_1$ nodes and $n_2$ nodes, as represented in Figure 5. A network, called a backbone, interconnects the two clusters. We assume that a cluster use the same network card to communicate to one of its node or to a node of another cluster. Based on that topology inter cluster communications are never faster than communication within a cluster.

Let us suppose that an application is running and using both clusters (for example, a code coupling application). One part of the computation is performed on cluster $C_1$ and the other part on cluster $C_2$. During the application, data must be exchanged from $C_1$ to $C_2$ using the alltoall pattern. Altogether, this means that we will have to transfer $(n_1 + n_2)^2$ messages over different network environments. The data of all these messages are different but the size of the messages are the same and is given and called $m$ (in bytes). Several MPI libraries (OpenMPI, MPICH2, etc.) implement the alltoall routine assuming that all the nodes are on the same clusters, which means that all communications have the same weight. However, in our case, some messages are transferred within a cluster (from a node of $C_1$ to a node of $C_1$ or from $C_2$ to $C_2$) or between the two clusters.

From the homogeneous cluster prediction model presented in the first part of this paper, which allows a quite accurate representation on the performance of local-area networks, we initially proceed our multi-cluster performance modelling by composing local (contention-aware) and remote communications. Estimate completion time corresponds to the sum of the contention-corrected local-area cost ($T_{C_1}$) and the wide-area communication cost (a function of wide-area latency $\alpha_w$ and bandwidth $\beta_w$):

$$T = \max(T_{C_1}, T_{C_2}) + \max(n_1, n_2) \times (\alpha_w + \beta_w \times m) \quad (6)$$

Unfortunately, this simple strategy fails to represent the operation of the MPI_Alltoall in a grid. Figure 6 compares estimate and measured completion time of the MPI_Alltoall implementation from OpenMPI in a grid with two clusters of 30 machines each. From this experience we observe that not only contention affects also wide-area links but also that local area communications play a small role in the overall performance. Of course, one could try to define additional parameters for the wide-area communications, but the final model would be too complex to be useful in real situation. Instead, we decided to address this problem by redefining the All-to-All problem against the challenges that characterize a grid environment.

A. Minimizing the impact of contention on the backbone

When dealing with wide-area networks, the most important factor to be considered is the time a message takes to be delivered. Indeed, in addition to the geographical distance, message are subjected to network protocols heterogeneity, message routing and transient interferences on the backbone.
Actually, popular algorithms for collective communications on grids (such as the ones implemented in PACX MPI [9], GridMPI [10] and MagPie [16]) try to minimize communications over the wide-area network by defining a single coordinator in every cluster, which participates in the inter-cluster data transfers across the wide-area backbone. By minimizing the number of WAN communication steps, we reduce the probability of inducing contention and accumulating transmission delays on the messages.

However, a single communication between each cluster is an approach inappropriate for the MPI_Alltoall operation. First, it induces additional communication steps to/from the cluster coordinator, which becomes a bottleneck. Second, this approach is not optimal concerning the usage of the wide-area bandwidth, as wide-area backbones are designed to support simultaneous transfers [3]. Hence, in order to improve the performance in a WAN, we need to change the MPI_Alltoall algorithm strategy.

B. The Local Group (LG) algorithm

To cope with this problem, we try to minimize wide-area communication steps in a different way. Actually, most of the complexity of the All-to-All problem resides on the need to exchange different messages through different networks (local and distant). The traditional implementation of the MPI_Alltoall operation cannot differentiate these networks, leading to poor performances. However, if we assume that communications between clusters are slower than intra-clusters ones, it might be useful to collect data in the local level before sending it in parallel through the backbone, in a single communication step.

As a consequence, we propose in [13] a grid-aware solution which performs on two phases. In the first phase only local communications are performed. During this phase the total exchange is performed on local nodes on both cluster and extra buffers are prepared for the second (inter-cluster) phase. During the second phase data are exchanged between the clusters. Buffers that have been prepared during the first phase are sent directly to the corresponding nodes in order to complete the total exchange.

More precisely, our algorithm called Local Group or simply LG works as follow. Without loss of generality, let us assume that cluster $C_1$ has less nodes than $C_2$ ($n_1 \leq n_2$).

Nodes are numbered from 0 to $n_1+n_2-1$, with nodes from 0 to $n_1-1$ being on $C_1$ and nodes from $n_1$ to $n_1+n_2-1$ being on cluster $C_2$. We call $M_{i,j}$ the message (data) that has to be sent from node $i$ to node $j$. The phases are summarized in Algorithm 1.

1) First phase: During the first phase, we perform the local exchange: Process $i$ sends $M_{i,j}$ to process $j$, if $i$ and $j$ are on the same cluster. Then it prepares the buffers for the remote communications. On $C_1$ data that have to be send to node $j$ on $C_2$ is first stored to node $j$ mod $n_1$. Data to be sent from node $i$ on $C_2$ to node $j$ on $C_1$ is stored on node $\lceil i/n_1 \rceil \times n_1 + j$.

2) Second phase: During the second phase only $n_2$ inter-cluster communications occurs. This phase is decomposed in $\lceil n_2/n_1 \rceil$ steps with at most $n_1$ communications each. Steps are numbered from 1 to $\lceil n_2/n_1 \rceil$. During step $s$ node $i$ of $C_1$ exchange data stored in its local buffer with node $j = i + n_1 \times s$ on $C_2$ (if $j < n_1 + n_2$). More precisely $i$ sends $M_{k,i}$ to $j$ where $k \in [0,n_1]$ and $j$ sends $M_{k,i}$ to $i$ where $k \in [n_1 \times s, n_1 \times s + n_1 - 1]$.

3) Example: Suppose that $n_1 = 3$ and $n_2 = 7$. What happens to the message $M_{7,2}$ (i.e., the messages that goes from node 7 on cluster $C_2$ to node 2 on $C_1$)? This is illustrated in Figure 7. During the first phase it is stored on node $\lceil 7/3 \rceil \times 3 + 2 = 8$ on $C_2$. Then during the second phase it is sent to node 2 during the step $s = 2$: node 8 sends $M_{6,2}$, $M_{7,2}$ and $M_{8,2}$ to node 2. During this step nodes 1 and 7 and node 0 and 6 exchange data as well, while in the previous step node 0 and 3, 4 and 1 and 5 and 2 exchange data and in the last step only 0 and 9 exchange data.

exchange messages between $i$ and $j = i + s \times n_1$.
C. Comparison with the standard Total Exchange algorithm

As our algorithm tries to minimize the number of inter-cluster communications between the clusters, we need only $2 \times \max(n_1, n_2)$ messages of size $m \times \min(n_1, n_2)$ in both directions against $2 \times n_1 \times n_2$ messages of size $m$ in the traditional algorithm. For instance, the exchange of data between two clusters with the same number of processes will proceed in one single communication step of the second phase. At the other hand, if $n_2 \gg n_1$, the total number of communication steps will be similar to the traditional algorithm.

An important difficulty that arises in the implementation of the algorithm is how to determine if a node belong to the first cluster or to the second cluster. Indeed, this information is the only extra information required to run the algorithm compared to the standard one. We propose several approaches:

- a simple solution is to extend the MPI API by adding a multi-cluster *alltoall* call where the users passes the value of $n_1$ and $n_2$ assuming that the first $n_1$ nodes of the machine file belong to cluster 1 and the $n_2$ nodes to cluster 2. The problem of such an approach is to port old MPI code to the multi-cluster version.
- At the beginning of the execution MPI can run some network benchmark in order to try to guess the topology of the infrastructure. This is what already does OpenMPI in the case of multiple network interfaces.
- GridMPI has an interesting approach that consists in launching a different MPI "client" on each cluster, each client being interconnected to the other through a GridMPI server. Based on that, for each MPI collective communication call GridMPI is able to determine the cluster a node belongs to.
- another solution consists in modifying the MPI machine file by adding keywords that tells to which cluster a node belongs to, such as in MagPie [16].

As our algorithm minimizes the number of inter-cluster communications, it is also wide-area optimal since it ensures that a data segment is transferred only once between two clusters separated by a wide-area link. Additionally, wide-area transmissions pack several messages together, reducing the impact of transient interferences on the backbone. Hence, Figure 8 presents a comparison between the traditional algorithm used by OpenMPI and the $LG$ algorithm. We observe that $LG$ improves the performance of the MPI *Alltoall* operation, reaching over than 50% of performance improvement comparing to the traditional strategy.

D. Modeling approach

As shown above, the algorithm we propose to optimize All-to-All communications in a grid environment rely on the relative performances of both local and remote networks. Indeed, we extend the total exchange among nodes in the same cluster in order to reduce transmissions through the backbone.

This approach has two consequences for performance prediction: first, it prevents contention in the wide-area links, which are hard to model. Second, the transmission of messages packed together is less subjected to network interferences. For instance, we can design a performance model by composing local-area predictions obtained with our contention ratio model and wide-area predictions that can be easily obtained from traditional methods. Hence, an approximate model would consider the following parts, where $T_{C_n}$ corresponds to Equation 5:

$$T = \max(T_{C_1}, T_{C_2}) + \left[\frac{n_2}{n_1}\right] \times (\alpha_w + \beta_w \times m \times n_1) \quad (7)$$

E. Experimental validation

To validate the algorithm we propose in this paper, this section presents our experiments to evaluate the performance of the MPI *Alltoall* operation with two clusters connected through a backbone.

These experiments were conducted over two clusters of the Grid’5000 platform\(^2\), one located in Nancy and one located in Rennes, approximately 1000 Km from each other. Both clusters are composed of identical nodes (dual Opteron 246, 2 GHz) locally connected by a Gigabit Ethernet network and interconnected by a private backbone of 10 Gbps. All nodes run Linux, with kernel 2.6.13 and OpenMPI 1.1.4. The measures were obtained with the *broadcast-barrier* approach [8].

To model the communication performance of both *inter-cluster* and *intra-cluster* communications we use the *parameterised LogP* model (*pLogP*) [16]. The *pLogP* parameters for both local and distant communications were obtained with the method described in [17]. To model the contention at the local level we used $\gamma = 2.6887$ and $\delta = 0.005039$ for $M \gg 1KB$ parameters obtained from the method of the least squares as described in [23].

Therefore, in Figure 9 we compare the performance predictions obtained with Equation 7 against the effective completion time of the $LG$ algorithm. We observe that prediction fit with a good accuracy to the real

\(^2\)http://www.grid5000.fr/
execution times, which is not possible with the traditional MPI_Alltoall algorithm. Indeed, the new algorithm minimizes the impact of distant communications, concentrating the contention problems at the local level. Because we are able to predict the performance of local communications even under contention, we can therefore establish an accurate performance model adapted to grid environments.

VII. CONCLUSIONS AND FUTURE WORKS

In this paper we address the problem of modeling the performance of Total Exchange communication operations, usually subject to important variations caused by network contention. Because traditional performance models are unable to predict the real completion time of an All-to-All operation, we try to cope with this problem by identifying the contention signature of a given network. In our approach, two parameters $\gamma$ and $\delta$ are used to augment a linear performance model in order to fit the performance of the MPI_Alltoall operation. Because these parameters characterize the network contention and are independent of the number of communicating processes, they can be used to accurately predict the communication performance when communications tend to saturate the network. Indeed, we demonstrate our approach through experiments conducted on popular network architectures, Fast Ethernet, Gigabit Ethernet and Myrinet.

We also address the problem of modeling the MPI_Alltoall operation in a grid environment represented by two clusters. We demonstrate that network contention also affects wide-area communications but, instead of developing a new complex performance model, we observed the behaviour of MPI_Alltoall and proposed a grid-aware algorithm that reduces drastically the impact of contention, improving drastically the communication performance. Additionally, we are able to predict the overall performance of this new algorithm by simply extending our local-area contention-aware model, which represents an important advantage when comparing with the traditional MPI_Alltoall implementation.

Our efforts now are concentrating on the development of grid-optimized algorithms for the generalized total exchange problem (represented by the MPI_Alltoally op-
