Abstract

We employ the velocity map imaging technique to measure kinetic energy and angular distributions of state selected CH₃ (v_2 =0,1,2,3) and Br ($^2P_{3/2},^2P_{1/2}$) photofragments produced by methyl bromide photolysis at 215.9 nm. These results show unambiguously that the Br and Br* forming channels result in different vibrational excitation of the umbrella mode of the methyl fragment. Low energy structured features appear on the images which arise from CH₃Br⁺ photodissociation near 330 nm. The excess energy of the probe laser photon is channeled into CH₃⁺ vibrational excitation, most probably in the v_4 degenerate bend.

I INTRODUCTION

As in all methyl halides or alkyl and aryl halides, the $\tilde{A} \leftarrow X$ band of CH₃Br, characterized by excitation to the anti-bonding σ^* orbital localized along the C-Br bond, exhibits a broad photodissociation continuum. This diffuse band in the ultraviolet range, environmentally relevant to atmospheric chemistry, 1,2 is characterized by a prompt dissociation via two dominant photofragmentation pathways:

$$CH_3Br + \hbar\nu \rightarrow CH_3 + Br (^2P_{3/2})$$

 $CH_3 + Br^* (^2P_{1/2})$

The spin-orbit coupling of the halide lifts degeneracy to give rise to three optically allowed electronic transitions to states which are, in order of increasing energy, the ${}^3Q_{\rm l,}\,{}^3Q_0$ and ${}^1Q_{\rm l}$ states. In the C_{3v} geometry, dissociation via the ${}^{X}Q_{1}$ (with X=1 or 3) and ${}^{3}Q_{0}$ states correlates adiabatically to $Br(^2P_{3/2})$ and $Br^*(^2P_{1/2})$, respectively. These transitions can be identified through the orientation of the transition electric dipole moment relative to the C-Br bond: the ${}^{\mathrm{X}}\mathcal{Q}_{\mathrm{l}}$ transitions are perpendicular while the ${}^{\mathrm{3}}\mathcal{Q}_{\mathrm{0}}$ transition is parallel. The dipole moments of $^{\mathrm{X}}Q_{\mathrm{l}}\leftarrow \tilde{X}$ arise from intensity borrowing from Rydberg states lying ~1 eV higher in energy, 3 similarly to CH_3I .⁴ Near the absorption maximum of the $\tilde{A} \leftarrow X$ band, perpendicular and parallel transitions of similar probability are allowed,⁵ in contrast to the $\tilde{A} \leftarrow X$ band in CH₃I. The Franck-Condon region is centered around an equilibrium C-Br bond distance of 1.95±0.1 Å. 6,7 Breaking $C_{3\nu}$ symmetry, induced for instance by the rocking mode ν_6 , leads to coupling between ${}^{1}Q_{1}$ and ${}^{3}Q_{0}$ surfaces opening possible non-adiabatic transitions that strongly influence the product branching ratio between the two spin-orbit channels. This can be quite different for alkyl halides of Cs symmetry for which in some cases no avoided crossing emerges, for example in CH₂ClBr⁸ or in C₃H₇Br. ^{9,10} The curve crossing in CH₃Br has

been calculated to occur at a C-Br internuclear distance around 2.445 Å.⁶ Its probability has been experimentally determined.⁵ In all these systems, the 3Q_1 state seems to be decoupled from the 3Q_0 state.¹¹ Many aspects of this photodissociation system have been summarized before.¹²

A study carried out around the absorption maximum of the $\tilde{A} \leftarrow X$ band at 202 nm and analyzing the kinetic energy distribution of Br fragments suggested that the internal energy of CH₃ is imparted into the v_2 umbrella mode and that the vibrational excitation was different for the two spin-orbit channels.¹³ The $Br(^2P_{3/2})$ -producing channel appears to peak around v_2 =3, while the $Br^*(^2P_{1/2})$ - producing channel peaks around v_2 =1 or 2.¹³ Similar conclusions were reached through use of photofragment imaging of product Br-atoms ($\lambda_{\text{photolysis}} \sim 205 \text{ nm}$).⁴ and of CH₃ by non-resonant multiphoton ionization ($\lambda_{\text{photolysis}} \sim 226 \text{ to}$ 218 nm).⁵ Despite a lack of state specific detection of CH₃, these studies suggest that the umbrella mode vibrational distribution of CH₃ follows the general rules that are $v_2^{\text{max}} > 0$ and $v_2^{\text{max}}(Br) > v_2^{\text{max}}(Br^*)$.

Similar conclusions have been derived from observations in other molecules, such as CH_3I , CF_3Br and $CH_3Cl.^{12,15}$ As a function of the photolysis energy, the vibrational distribution of the umbrella mode is not expected to change drastically. Methyl radical has a planar equilibrium geometry, while CH_3 in the ground electronic state of CH_3Br has a pyramidal geometry with an equilibrium angle around $111.5^{\circ}.^{6.7}$ In the case of dissociation of CH_3I in the $\tilde{A} \leftarrow \tilde{X}$ band, the vibrational distribution is frequently rationalized by an abrupt change from pyramidal to planar geometry at the seam of the ${}^1Q_1 - {}^3Q_0$ curve crossing, so that any trajectory going through the non-adiabatic transition, which leads to Br (${}^2P_{3/2}$), receives extra umbrella mode excitation. In other words, if the Br producing channel is populated significantly by this non-adiabatic transition, its umbrella activity is expected to be more

excited than that of the Br* producing channel for which the pyramidal to planar relaxation occurs more gradually and adiabatically along the 3Q_0 surface.

Another suggested explanation not involving the ${}^{1}Q_{1}$ - ${}^{3}Q_{0}$ curve crossing relies on the difference in slope of the potential energy surface of ${}^{1}Q_{1}$ and ${}^{3}Q_{0}$ states as a function of the distance between C and the center of mass of the three H atoms in the vicinity of the Franck-Condon region. The ${}^{1}Q_{1}$ surface is steeper, therefore the umbrella excitation will have less time to relax from pyramidal to planar geometry compared to trajectories following the ${}^{3}Q_{0}$ state. 14,16,17 In all these studies, with the exception of some methyl substituted bromides, 18 it has been pointed out that the methyl fragment is likely to be rotationally cold due to a weakly bent excited state for both surfaces. This is confirmed by studies of the photodissociation of rotationally state-selected methyl bromide between 213 nm and 235 nm. 19 The rotational distribution of CH₃ photofragments extends up to N=6 for photolysis at 230 nm and slightly higher - N=9 - when photolysis is performed at 212.8nm, with almost no difference between a Br* and Br channels. 19 This experiment has investigated mainly the production of vibrational ground state methyl and the influence of deuteration. Similar work has been performed on the extreme red wing (240-280 nm) of the $\tilde{A} \leftarrow \tilde{X}$ absorption band with an effusive molecular beam. 20

We report here kinetic energy and angular distributions of bromine and methyl fragments recorded by the velocity map imaging technique following photodissociation of CH₃Br at 215.9 nm. The vibrational states of methyl radicals were probed by resonant enhanced multiphoton ionization (2+1 REMPI) via the intermediate Rydberg $3p^{-2}A_2^n$ state. At this photolysis energy the direct absorption ratio of parallel to perpendicular excitation is around $\begin{bmatrix} {}^3Q_0 \end{bmatrix}/{\begin{bmatrix} {}^3Q_1 + {}^1Q_1 \end{bmatrix}} = 1.5.^5$ We have recorded velocity map images of individual vibrational states of CH₃ excited in the v_2 umbrella mode up to v_2 =3, in contrast to previous

experiments in which only the kinetic energy distribution of Br fragments were available 14,20 or where CH₃ was detected only in its ground vibrational state 19 or without vibrational state selection. The images show two features that can be assigned to formation of Br and Br*. We are thus able to unambiguously confirm the prior interpretation of Br atom velocity maps and photofragment images which implicated a greater degree of ν_2 -vibrational excitation in the Br-forming channel.

We also observe for the first time, the photolysis of CH_3Br^+ cation in the near UV. This results in a highly structured velocity map image, which can be assigned to progression of high vibrational states of the CH_3^+ product ion. An indirect photodissociation mechanism involving non-adiabatic coupling is proposed.

II EXPERIMENTAL SET-UP

Methyl bromide with 99% purity containing the natural abundance of bromine isotopes was used without further purification. A 10% CH₃Br/He mixture at 0.5 bar stagnation pressure expanded supersonically through a solenoid pulsed valve (General Valve Series 9, Parker Hannifin Corp.) with a 0.8 mm orifice to produce a 300 μs long pulsed molecular beam. After passing through a skimmer, the molecular beam was collimated to 1 mm and entered the ion optical region of a standard velocity mapping ion source.²¹ The molecular beam was then intersected midway between the repeller and the extractor plates by two counter propagating laser beams both perpendicular to the time-of flight axis, which dissociated CH₃Br and selectively ionized the fragment of choice. The ions produced were accelerated before being mass-selected at the end of a 1-m long time-of-flight tube by gating the gain of a 7.5 cm diameter dual microchannel plate (MCP)/phosphor imaging detector (Burle ElectroOptics). The gating voltage pulse was applied on the front MCP-plate and was typically -500 V over 170 ns. The images were recorded typically over 36000 laser shots by

imaging software (Davis, LaVision) on a (640x480) CCD camera (XC7500, Sony) coupled to a frame grabber (PCimage SG, Matrix Vision). The repeller voltage was fixed at 5kV for the methyl fragments so that the detector surface is 80% filled and at 3kV for the Br fragment to enlarge the images. The optimal velocity mapping condition corresponds to an extractor/repeller voltage ratio of 0.7. In the kinetic energy range explored here, one pixel on the image corresponds roughly to 30 meV shift.

The repetition rate is fixed at 10 Hz by the photodissociation laser. The 215.9 nm photolysis beam was produced by frequency doubling the output of an Nd:YAG (Continuum Powerlite 7010, 3rd harmonic at 355 nm) pumped dye laser (Sirah) operating on Stilbene, through a 7 mm BBO crystal. The 1 mJ/pulse output was focused by a 50 cm focal length lens on the molecular beam. The photofragments were selectively ionized by a REMPI probe laser. $Br(^{2}P_{3/2})$ photofragment was the only species probed by a single laser scheme; namely, photodissociation and detection by (2+1) REMPI via the ${}^4D^0_{5/2}$ state at 215.9 nm. The methyl photofragments were photoionized by (2+1) REMPI via the $3p^2A_2^*$ Rydberg state,^{22,23} using the doubled (circa 340 nm) output of a dye laser (Continuum ND6000) operating on a mixture of DCM/LDS698 and pumped by the second harmonic of an Nd:YAG laser (Continuum Powerlite 8020). About 4 mJ/pulse of this probe laser light was focused by a 60 cm focal length lens onto the molecular beam. Vibrationally excited states of CH₃ were probed via 2^{ν}_{ν} two-photon transition, up to v=3. The REMPI laser for each of those transitions was tuned to the transition maximum, which corresponds to a Q branch. The $Br^*\left({}^2P_{1/2}\right)$ photofragments were photoionized by (2+1) REMPI via the ${}^{2}P_{1/2}^{0}$ state at 238.6 nm. To produce this wavelength, the doubled output of a dye laser (Continuum ND6000) operating with R640 and pumped by the second harmonic of an Nd:YAG laser (Continuum Powerlite 8020) was mixed with the pump laser's fundamental of 1064 nm.

In the case of methyl ion detection, no ion background was observed with the REMPI laser alone but the dissociation laser produces some background ions via a one-photon transition to the \tilde{B} $^2A_1^{'}$ state of CH₃ followed by absorption of a second photon ionizing CH₃. 24 A background is also present on the Br* image as the $\tilde{A} \leftarrow X$ band of CH₃Br is excited not only by the photolysis laser at 215.9 nm but also by the REMPI laser at 238.6 nm. In each case, background contributions were recorded independently and carefully subtracted. Typically these sources of background were around 20% of the signal for methyl detection and 50% of the signal for Br* detection. Table I summarizes the resonant states and the corresponding REMPI wavelengths used for all species detected in this experiment.

The spatial overlap between the laser and molecular beams was optimized using an NO molecular beam and non-resonant multiphoton ionization. To ensure detection of all photofragments, the typical delay introduced between the two lasers did not exceed 5 ns. Both laser polarizations were parallel to the detector plane in order to maintain cylindrical symmetry required for the inverse Abel transformation. Reconstruction of the 3D-velocity map led to fragment kinetic energy and angular distributions. The dissociation energy assumed in this work was reported by Janssen et al. to be $D_0=2.901+/-0.016$ eV. ¹⁹

III RESULTS AND DISCUSSION

Velocity map images are highly structured, reflecting two different photochemical pathways in CH₃Br. The first reflects the photochemistry of the $\tilde{A} \leftarrow X$ band in methyl bromide neutral. The second is due to the photodissociation of CH₃Br⁺ around 330 nm. Both of these appear to exhibit rich electronically non-adiabatic behavior as discussed in part A for the CH₃Br and in part B for its cation.

A- Methyl Bromide

Experimental Images

Figure 1 shows typical images obtained for m/z=15 (CH₃⁺) and m/z= 79 (Br⁺). Image 1-(a) shows a one-color experiment using only the photolysis laser at 215.9 nm and is representative of some of the general observations of this work. Here one sees two sharp concentric rings at the outer edge of the image, which arise when the methyl fragment is unintentionally ionized via the R-branch of the $(\tilde{B}^2A_1^2, 0_0^0)$ transition. The two outer rings correspond to the two Br spin-orbit channels in CH₃Br photolysis at 215.9 nm. For all intents and purposes, this image is background and no attempt was made to analyze its information content. Rather, this background is subtracted from methyl images obtained in two-color experiments. Fig. 1 (b-e) show these results after background subtraction. Here, one also sees two concentric rings at the perimeter of the image, which reflect the velocity and angular distributions of specific vibrational states of CH₃ produced in the 215.9 nm photolysis of CH₃Br. Here CH₃ is detected by 2+1 REMPI via the $3p^{-2}A_2^+$ Rydberg state. One also sees a sequence of features closer to the center of the images, which arise from CH₃⁺ produced in photodissociation of CH₃Br⁺, which is itself produced by 2-photon non-resonant ionization at 215.9 nm. We return to a discussion of this process later in part B.

The images shown in Fig.1 (b-e) have been recorded with the REMPI laser tuned to peak of the sharp Q-branches of the $\left(3p^{-2}A_{2}^{"},2_{v}^{v}\right)$ system. Images recorded with or without scanning over the Q-branch profile were found to be identical, indicating that no CH₃ rotational selectivity is possible under our conditions. Two color images of Br($^{2}P_{3/2}$) and Br($^{2}P_{1/2}$) fragments, ionized by 2+1 REMPI, are also shown in Figure 1-(g) and 1-(h) respectively.

As v_2 umbrella excitation increases in these experiments, the signal intensity decreases due to a faster predissociation of CH₃ in the intermediate $3p^{-2}A_2^*$ state used for REMPI

detection.²⁶ Consequently, the origin band image of CH₃ (Fig. 1-(b)) is an average over 12000 laser shots compared to 36000 for the others. This predissociation combined with the other uncertainties associated with use of a structureless Q branch for REMPI detection make it impossible to derive the CH₃ v₂ vibrational population distribution based on intensities of the images. However, if we assume that the energy distribution of bromine fragments reflects only umbrella mode activity, we can reconstruct the v₂ vibrational distribution. To test this assumption we probed other vibrational states, for example the symmetric CH stretch mode v_1 . Normally, the excitation of symmetric the CH stretching mode, v_1 (372 meV), cannot be probed via the Q branch of the 1_1^1 band (at 333.9 nm) as it overlaps the $P(4)0_0^0$ band. 10,23,27 However, the translational energy released in the simultaneously detected channels is large enough that they can be identified and separated in this imaging experiment. The excess energy for the methyl fragment excited by one quantum of v_1 , following dissociation at 215.9 nm, is 2.01 eV for the Br* channel and 2.47 eV for the Br one. In contrast, the excess energy for the production of CH₃(v=0)+Br* is 2.385 eV. In this region of the image, each pixel corresponds to about 30 meV of translational energy. Images recorded at the peak of the 111 Q-branch (Fig. 1f) show no significant difference compared to those recorded in the 0_0^0 Qbranch. We also tried to probe the v_1 vibration through the 1_1^0 line, without success. Therefore we conclude that the dissociation dynamics do not significantly involve the symmetric stretching mode in CH₃Br, in contrast to the photodissociation of CH₃I in which as much as 10% of the internal energy is channeled into the v_1 mode, albeit only for the ground spin-orbit channel^{23,28,29}

This statement seems consistent with the reported absence of v_1 activity in experiments in the range 212.8 nm to 235 nm detected by slicing at a velocity resolution three times higher than ours.¹⁹ With this high-resolution slicing, Janssen et al.¹⁹ were able to detect fragments

excited in the v_4 rocking mode for CD₃Br. It is, however important to remember that this same slicing experiment shows a strong effect of the *D*-isotope substitution enhancing production of vibrationally excited methyl in contrast to the lighter isotope, CH₃Br.¹⁹

The absence of v_1 activity in CH₃Br dissociation is a somewhat different than CH₃I photodissociation, where the stretching activity observed mainly for the I-channel is associated with impulsive behavior of the photodissociation along the ${}^{1}Q_{1}$ surface at high available energy. This impulsive feature is expected to be stronger in CH₃Br since the ${}^{1}Q_{1}$ surface is steeper than in CH₃I. However none of the investigations on CH₃Br or CH₃Cl photodissociation has reported a v_{1} activity. Trajectory studies involving potential energy surfaces that take into account this coordinate might be helpful in explaining this difference observed in the v_{1} activity of the methyl halides.

Energy Distributions and Correlation of CH₃ v₂ excitation with Br S.O. state

Fig. 2 shows the kinetic energy probability distributions obtained from analysis of the images of Fig. 1. This experiment yields the kinetic energy of the CH₃ fragments as a function of their umbrella excitation as well as the Br and Br* energy distributions. This energy mapping of the fragments allows a more detailed study of the non-adiabatic coupling. In each translational energy distribution for CH₃(v), the lower kinetic energy peak corresponds to production of Br*+CH₃(v,J) while the higher energy one results from Br+CH₃(v,J). We fitted each peak with a Lorentzian function. From the derived width parameters (shown in Table I) one can see the CH₃ fragments' translational energy distribution is at least ~30 % wider when formed with Br atoms in comparison to those formed with Br*. This broadening can be explained by a higher degree of rotational excitation of the methyl fragment in the more energetic Br-forming channel, similar to the results of Ref. 19.

We calculated the [Br*]/[Br] branching ratio for each vibrationally state specific channel and found that it decreases as the excitation of the CH₃ umbrella mode increases. The

decreasing [Br*]/[Br] ratio seen here is in agreement with the propensity previously inferred from Br-atom images by Gougousi et al.⁵ and Underwood et al.²⁰

Under the apparently valid assumption that only CH₃ umbrella motion is excited, the sum of individual methyl distributions should reflect closely the bromine fragment distributions. Consequently, we independently fitted the translational energy distributions of the $Br(^2P_{3/2})$ and $Br^*(^2P_{1/2})$ fragments, using the component vibrational state specific translational energy distributions of the CH₃ fragments and varying the relative contribution of each CH₃ vibrational state.

The vibrational distributions obtained in this way are listed in the last two columns of table I and the fits to the Br and Br* distributions are displayed on Fig. 3. Here, the vibrational distribution of the Br* channel peaks at v_2 =1 and contributions from vibrational state v_2 =2 and lower are enough to fully reconstruct the distribution. For the Br channel, it is evident that contributions from the first three quanta in the umbrella mode (observed directly in this work) are not enough to reproduce the translational energy distribution; larger CH₃ internal energy is clearly required. We were able to fit the Br translational distribution with reasonable assumptions about the vibrational state specific CH₃ translational energy distributions for higher values of v_2 . For contributions from v_2 = 4, 5 and 6, we assume the same rotational energy distribution as that implied by the translational energy distribution for v_2 =3 and used the known vibrational energies of these states.³⁰ It remained then only to vary the contributions from each vibrational state to arrive at the good fit shown in Fig. 3b.

The vibrational excitation is obviously substantially hotter for the Br channel than for the Br* channel with a maximum near $3v_2$. This confirms the "inverted" distribution previously suggested by Gougousi et al.⁵ and Van Veen et al.¹³ obtained by less direct means. The combination of direct detection of individual quantum states of CH₃ as well as Br and Br*

in this work provides the most reliable and accurate information on the CH₃ excitation in CH₃Br photodissociation and how it varies between the two spin orbit states.

The Br/Br* branching ratio

The Br and Br* photofragment quantum yields are related to the [Br*]/[Br] branching ratio by the following equations:

$$\Phi_{Br} = \frac{[Br]}{[Br] + [Br^*]} = \frac{1}{1 + \frac{[Br^*]}{[Br]}} \quad \text{and } \Phi_{Br^*} = 1 - \Phi_{Br}$$
 Eq. 1

Since the two-photon transition strength is not known for the Br and Br* REMPI detection scheme we used, it is not possible to evaluate the overall branching ratio [Br*]/[Br] simply by dividing the areas under the Br and Br* fragment translational energy distributions in Fig. 2. However Φ_{Br} has been measured by Gougousi et al.⁵ down to 218 nm. Extrapolating those results, we find Φ_{Br} = 0.58±0.05 at 215.9 nm. This leads to a branching ratio of $\frac{[Br^*]}{[Br]}$ =1.38±0.15 and to Φ_{Br} =0.42±0.05.

The [Br*]/[Br] ratio could depend on the CH₃ rotation and vibration. We measured images probing through the 0_0^0 Q-branch, which show an increase in the [Br*]/[Br] ratio as one tunes from the blue to the red. This effect has been previously observed²⁶ and studied in CH₃I.³¹ The bending mode of the parent molecule is not only the promoting mode for the non-adiabatic coupling between 1Q_1 and 3Q_0 , but also correlated with rotation of CH₃ fragments. For example, for trajectories that explore bent geometries near the ${}^1Q_1 - {}^3Q_0$ curve crossing, larger rotational excitation of the methyl fragment is expected for the 1Q_1 than for the 3Q_0 state. Note that from the ratio $\frac{[Br^*]}{[Br]}$ in the detection of CH₃ produced in the origin band (see Table II), we can compare the yield $\Phi_{Br} = 0.82 \pm 0.04$ measured at 215.9 nm in our case

on a supersonic molecular beam to $\Phi_{Br^*} = 0.72$ measured at 213 nm by selecting the initial parent molecule (K=J=1) Lipciuc and Janssen.¹⁹ These two ratios are in good agreement.

Angular distributions and alignment in CH₃

The angular distributions, $I(\theta)$, of the photofragments were obtained by integrating the Abel-inverted images over the radial full-width half maximum of each of the peaks shown in Fig. 2. The angular distributions were fitted to the expression:

$$I(\theta) \propto 1 + \frac{\beta}{2} (3\cos^2 \theta - 1)$$
 Eq. 2

where β is the photofragment recoil anisotropy parameter for a given dissociation channel. The distributions and fits are presented in Figure 4 and the values for the anisotropy parameters shown in the first two rows of Table II. Looking at the symmetry of the states involved, one would expect, in the limit of a prompt dissociation, that Br and CH₃ produced by excitation to 1Q_1 and 3Q_1 states to have a perpendicular transition character and $\beta=-1$, while Br* and CH₃ produced by excitation to the 3Q_0 state to exhibit a parallel transition character and $\beta=+2$.

The β parameters derived from bromine fragment angular distributions are 1.88 for the Br* producing channel and -0.11 for the Br channel, in good agreement with previous results. The Br* channel's anisotropy agrees approximately with the parallel transition picture of 3Q_0 excitation of CH₃Br. The Br channel's almost isotropic angular distribution is, however, inconsistent with a perpendicular transition for CH₃Br excitation to ${}^3Q_1/{}^1Q_1$ states. This can be explained by the non-adiabatic coupling between the 3Q_0 to the 1Q_1 state which gives parallel character to the otherwise perpendicular transitions. The observed β parameters can be rewritten as a combination of direct and indirect contributions as follows:

$$\beta(Br) = a_{indirect}\beta({}^{3}Q_{0}) + a_{direct}\beta({}^{X}Q_{1})$$

$$a_{indirect} + a_{direct} = 1$$

$$\beta(Br^{*}) = b_{direct}\beta({}^{3}Q_{0}) + b_{indirect}\beta({}^{X}Q_{1})$$

$$b_{indirect} + b_{direct} = 1$$
Eq. 3

Here the coefficient a_{direct} is the quantum yield for direct excitation to the ${}^{X}Q_{1}$ states and dissociation yielding $\operatorname{Br}({}^{2}\operatorname{P}_{3/2})$ atoms. The $a_{indirect}$ coefficient is the probability for excitation to the ${}^{3}Q_{0}$ state followed by non-adiabatic transition and dissociation along the ${}^{X}Q_{1}$ state(s) to form $\operatorname{Br}({}^{2}\operatorname{P}_{3/2})$ atoms. b's are defined in an analogous fashion. The four coefficients of Eq. 3 can be calculated taking the approximation of a pseudo-diatomic system with a dissociation time occurring on a faster timescale than the rotational period of the parent molecule, so that $\beta({}^{3}\operatorname{Q}_{0})$ and $\beta({}^{X}\operatorname{Q}_{1})$ have the values of a perfect parallel and perpendicular transition respectively, namely $\beta({}^{3}\operatorname{Q}_{0})=2$ and $\beta({}^{X}\operatorname{Q}_{1})=-1$. The coefficients for Br fragments (Table 2) show that $a_{indirect}=0.3$ of the Br fragments come from ${}^{3}Q_{0} \to {}^{X}Q_{1}$ non-adiabatic coupling in agreement with results published by Gougousi et al. 5 If the same procedure is applied to the Br* channel, we find that almost all $(b_{direct}=0.96)$ Br* is produced by a direct pathway. The excitation probability to different surfaces $(P_{3_{Q_{0}}}$ and $P_{X_{Q_{1}}})$ and the coupling between these surfaces $(P_{10}$ and $P_{01})$ can be calculated from the quantum yields $\Phi_{Br}=0.58\pm0.05$ and $\Phi_{Br}=0.42\pm0.05$ 5 and a and b coefficients as follows and the results are summarized in Table II:

$$\begin{split} P_{01} &= P_{^{3}Q_{0} \rightarrow ^{X}Q_{1}} = \frac{a_{ind}.\Phi_{Br}}{a_{ind}\Phi_{Br} + b_{D}\Phi_{Br^{*}}} \\ P_{^{3}Q_{0}} &= a_{ind}\Phi_{Br} + b_{D}\Phi_{Br^{*}} \\ \text{and} \\ P_{10} &= P_{^{X}Q_{1} \rightarrow ^{3}Q_{0}} = \frac{b_{ind}.\Phi_{Br^{*}}}{b_{ind}.\Phi_{Br^{*}} + a_{D}\Phi_{Br}} \\ P_{^{X}Q_{1}} &= b_{ind}.\Phi_{Br^{*}} + a_{D}\Phi_{Br} \end{split}$$

Conservation of momentum dictates that the state specific angular distributions of the CH₃ fragments, weighted by the CH₃ quantum state population distribution, match those of the Br fragments. It is evident from the values in table II that this is not the case. We attribute these differences to alignment of the methyl fragment, which appears to be particularly

important for vibrationally excited CH₃, as well as the influence of vibrationally enhanced predissociation in the REMPI detection used here.

Rotational alignment has been observed before for methyl following photodissociation of CH₃I. Powis and Black^{28,32} found that CD₃ produced by dissociation of CD₃I at 266nm is strongly aligned, rotating mainly around its C₃ axis with K=±N, where N is the total angular momentum excluding spin and K its projection along its three-fold symmetry axis. However this alignment probably originates from rotationally hot parent molecules present in the 300K effusive molecular beam used in that work. Houston and coworkers²⁶ used a supersonic molecular beam and their experimental results on both CD₃I and CH₃I conclude that CD₃ and CH₃ fragments are also aligned; however, here K=0 dominates reflecting rotation around an axis perpendicular to the three-fold symmetry axis. These results were confirmed by Janssen et al.³³ who, following the treatment of Kummel and Zare,³⁴ measured the alignment parameters from O, P, R and S branch methyl spectra in CD₃I. In the current case we do not have enough polarization geometries and wavelengths to address this problem quantitatively.

Still we can take an approach which is at least sufficient to demonstrate that alignment effects are present. In an approximate fashion, we fitted our experimental angular distribution to a series expansion of even Legendre polynomials³⁵ terminated at the sixth order polynomial:

$$I(\theta) = 1 + \beta_2 P_2(\cos \theta) + \beta_4 P_4(\cos \theta) + \beta_6 P_6(\cos \theta)$$
 Eq. 6

In this expansion, alignment will manifest itself with nonzero values for β_4 and/or β_6 .

The results of this fitting procedure are presented in Table 3 and the fits to the data are presented in Fig. 4. Values of β_6 are -within our experimental error- zero. However, β_4 clearly exhibits non-zero values for most vibrational quanta and are generally higher in CH_3+Br^* than in CH_3+Br channel. This result shows the presence of CH_3 alignment in both channels and that CH_3 alignment is more important in the CH_3+Br^* channel, although the rotational

temperature seems to be lower in that channel. It is likely that the stronger alignment in the CH₃+Br* channel are related to its direct dissociation mechanism.

Fitting Br and Br* angular distributions in the same fashion does not indicate significant alignment of Br. Note also that $Br(^2P_{1/2})$ with J=1/2 cannot have alignment.

The presence of alignment as well as the predissociation of the CH₃ 3p intermediate Rydberg state^{28,32} prevent us from using methyl angular distributions to extract curve crossing probabilities as a function of methyl fragment excitation. However, it is noteworthy that the methyl angular distributions vary only weakly with vibrational excitation (See table III) indicating that the curve crossing probability will not change significantly. This is consistent with the analysis of Underwood et al..²⁰

B- Methyl bromide cation

Identification of Ion Dissociation

In order to determine the origin of the low velocity rings in the CH_3^+ images we have also obtained ion images at m/z = 94-96 (CH_3Br^+). These images (not shown) appear as tiny dots at the velocity origin, as expected for ionized CH_3Br travelling with the velocity of the molecular beam. When the laser light used for CH_3 REMPI detection (hereafter referred to as "the ion-dissociation laser") is introduced at wavelengths near 330 nm, we observe that the CH_3Br^+ peak is reduced by as much as ~75% without any significant change in the intensity of $^{79,81}Br^+$. This clearly shows the occurrence of the following channel:³⁶

$$CH_3Br + 2 hv_{\lambda=215.9nm} \rightarrow CH_3Br^+ + e^-$$

$$CH_3Br^+ + hv_{\lambda=322-334 \text{ nm}}$$
 ("ion-dissociation laser") $\rightarrow CH_3^+ + Br/Br^*$

See Fig. 5 for an energy diagram. The additional smaller-radius rings in the CH_3^+ images (Fig.s 1 c-f) correspond to this second source of CH_3^+ .

The ground electronic state $(^2E_{3/2})$ of CH_3Br^+ is formed by the removal of a nonbonding (2e) electron from one of the halogen lone pairs. This state's geometry is similar to the neutral ground state but with a slight elongation of the C-Br bond³⁷ as well as a Jahn-Teller distortion from C_{3v} geometry.² The ionization energy to form $CH_3Br^+(X^2E_{3/2})$ is 10.54 ${\rm eV}^{38,39}$ and the spin orbit excited $X^2E_{1/2}$ state lies at 10.86 eV.⁴⁰ Two photons at 215.9 nm (11.48 eV) are sufficient to reach the ionization continuum but not enough to reach dissociative ionization threshold (12.74 eV) leading to $CH_3^+(^1A_1) + Br(^2P_{3/2})$. ^{39,41} Although it has never been observed, 42 the appearance potential of $CH_3^+(^1A_1) + Br(^2P_{1/2})$ is expected at 13.2 eV. One photon from the ion-dissociation laser is required to dissociate CH₃Br⁺. Photoelectron spectroscopy of CH₃Br shows that the first electronically excited state of CH₃Br⁺ lies 13 eV above CH₃Br with a vertical excitation energy of 13.5 eV. ^{2,44,45} See Fig. 5. This state is formed by removing an electron from the (3a₁) outer-valence molecular orbital associated with the C-Br bond and labeled A²A₁. Excitation to this state yields, with 100% efficiency, the CH₃⁺ fragment. 44 Some vibrational bands have been observed around 12.8 eV revealing a bound character of the A²A₁ state at energies lower than those relevant to this work.³⁹

The observation of highly vibrationally excited CH₃⁺

The inner ring structure observed in Fig.'s 1c-f depends only weakly on the wavelength of the ion-dissociation laser. Fig. 6 shows the translational energy distributions for CH_3Br^+ photodissociation derived from each image. In order to compare results at different photolysis wavelengths, the translational energy scale has been shifted relative to the available energy for the experiment carried out with the ion-dissociation laser at $hv_{ref}=3.84~eV$ (322.8 nm), corresponding to the image shown in Fig. 1e. The energy scale shift was imposed according to the following formulas:

$$E_{T}(v) = E_{kin}^{CH_{3}}(measured) \times \frac{m_{CH_{3}Br}}{m_{Br}} + \Delta$$
$$\Delta = h(v_{ref} - v)$$

where v is the frequency of the ion-dissociation laser. This approach to the analysis allows us to identify vibrational progressions of the CH₃⁺ product that appear in different experiments. Using this analysis, we discover a progression of states at center-of-mass translational energies: 33, 190, 376, 528 and 686 meV. Observation of this progression is additional evidence demonstrating the multiphoton scheme of Fig. 5.

To assign these quantized features requires additional consideration as one cannot *a priori* determine which states of the CH_3Br^+ are formed by the two-photon ionization at 215.9 nm. Inspection of Fig. 6 shows that nearly all of the ion signal appears below 1.5 eV. With an ion-dissociation laser photon of $h\nu_{ref}$ =3.84 eV, one gets an appearance energy for CH_3^+ +Br at 12.88 which is in good agreement with the appearance energy of 12.74 eV expected for the A state:

$$CH_3Br^+(^2E_{3/2}) + h\nu_{\lambda=322.8nm} \rightarrow (CH_3^+ + Br) (E_T=10.54 + 3.84 - 12.74 \text{ eV} = 1.64 \text{ eV})$$

We are able to reproduce the progression of Fig. 6 using a vibrational harmonic frequency of $CH_3^+ \nu_4$ =170 meV (in-plane bend) or ν_2 =168 cm⁻¹ (umbrella mode).⁴³ Table 4 shows this analysis more completely. More generally, it is clear that there is a propensity for channeling available energy into CH_3^+ vibration and not into translation.

Two-photon threshold photoelectron spectra shows that photoionization onto X ${}^{2}E_{3/2}$ dominates. 40 If $A^{2}A_{1}$ was the dissociating state accessed directly by $CH_{3}Br^{+}$ absorption of a 330 nm photon, the angular distribution would be expected to be perpendicular, yet we observe a parallel process. Thus an indirect dissociation process must be important. For example, the 2^{nd} excited electronic state seen in $CH_{3}Br$ photoelectron spectroscopy around 14.5 eV possesses E symmetry (B state on Fig. 5). 42 This state correlates adiabatically

to $CH_3(X^2A_2)+Br^+(^3P)$. It has been shown in the case of CH_3Cl that a favorable overlap of the orbitals makes the oscillator strength to the B state $(\pi^*\leftarrow\pi)$ much larger than to the A state $(\sigma\leftarrow\pi)$. In the same work, a parallel electronic transition has been observed in an energy range similar to that of the A state absorption. In addition, the coupling between the B and A states of the cation has been proposed to rationalize experimental observations in multiphoton ionization of CH_3I .

It is interesting to compare the kinetic energy release distributions of CH_3^+ observed in Fig. 6 with the ones recorded by one-photon dissociative ionization⁴²: The average translational energy observed in a one photon experiment at hv=14.3 eV (close to the present energy), is ~0.4 eV, ⁴² which is remarkably similar to the observations of this work.

Thus, internal conversion to the A^2A_1 state would involve electron transfer from CH_3 to Br, possibly explaining the large vibrational excitation seen in the CH_3^+ product.

IV Conclusion

We have measured angular and kinetic energy distributions of state selected methyl and bromine fragments using velocity map imaging of single and multiphoton excitation of CH₃Br at 215.9 nm. Our single photon data confirm previous results on differences between Br and Br* channels for methyl production with v_2 umbrella mode excitation and show that [Br*]/[Br] branching ratio decreases with umbrella mode excitation. The v_2 -state specific imaging measurements of CH₃ photofragments show that CH₃Br photolysis produces vibrationally hot methyl peaking at v_2 =1 for the Br channel and at v_2 =3 for the Br* channel. Although absorption to the Br* producing 3Q_0 state dominates the $\tilde{A} \leftarrow X$ band at this wavelength, significant amount of Br product is observed, 18% of which comes from $^3Q_0 \rightarrow ^xQ_1$ avoided crossing. Alignment effects observed in methyl fragments and predissociation of the intermediate states used for REMPI detection prevented the extraction

of non-adiabatic probabilities from methyl data as a function of v_2 . Qualitatively, based on the overall angular distribution behavior with v_2 excitation there seems to be no significant dependence on the methyl umbrella mode excitation on the curve crossing probability.

In addition to single photon data, a 2+1 excitation scheme of CH_3Br is detected in methyl images, where two photons of 215.9 nm light produce CH_3Br^+ which subsequently absorbs a photon of 320-330 nm and is excited via a parallel transition to E-symmetry excited ionic state. Coupling of those states to the A excited state of CH_3Br^+ leads to production of vibrationally hot CH_3^+ (possible in the ν_4 degenerate bending mode excited by the nonadiabatic state mixing) and Br^* .

Figure Captions

Fig 1: Images of methyl radicals (a-f) produced from the 215.9 nm photolysis laser with background (a) subtracted. The images were respectively acquired over 12000 (b) and 36000 (a,c-f) laser shots. Images of bromine fragments produced in (g) Br and (h) Br* states. The images are presented in 0-255 grey scale with the darkest shade corresponding to the maximum of the signal.

Fig 2: Kinetic energy release distributions. The top panel is obtained from bromine fragment images. The others are obtained from specific vibrational states of the methyl fragment detected via the $(3p^{-2}A_2^r, 2_v^v)$ state. The vertical dotted lines indicate the expected maximum kinetic energy release in the methyl fragments if no methyl rotation were excited. $Br(^2P_{3/2})$ results have been derived from images recorded at two repeller voltages: 3kV (diamonds) and 5 kV (circles).

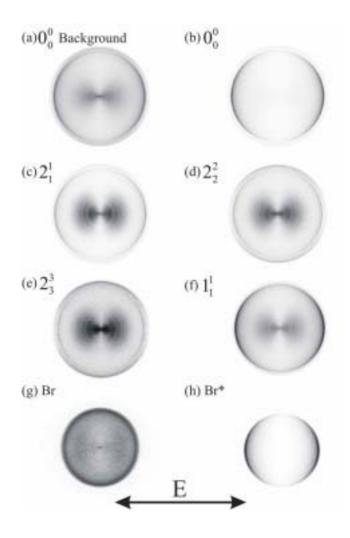

Fig 3: Reconstruction of Br translational energy distributions from vibrationally state specific translational energy distributions of CH₃. (a) $Br^*(^2P_{1/2})$ channel and (b) $Br(^2P_{3/2})$ channel. See text. Diamonds correspond to images recorded at 3 kV for the repeller plate and crossed circle at 5 kV.

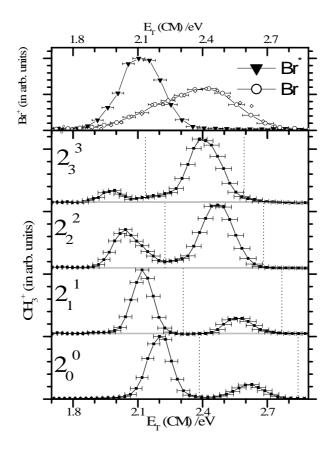

Fig 4: Angular distributions of bromine atom and methyl fragment calculated from the images shown in Fig. 1. In each panel the circles correspond to the distribution for the Br channel and the squares correspond to the Br* channel. The solid lines corresponds to the fit using Eq. 2 with the anisotropy parameters listed in the Table II.

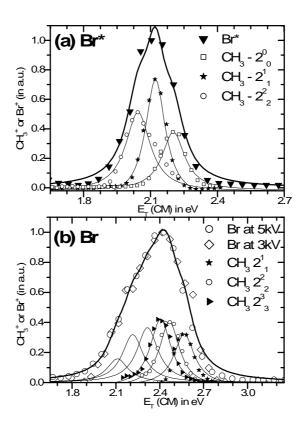

Fig 5: Energy diagram of the photodissociation of methyl bromide cation in C_{3v} geometry with adiabatic correlation to products shown by dotted lines.

Fig 6: Vibrational Progression of CH_3^+ obtained from central rings in the images of Fig. 1. An energy shift, Δ , relative to the photodissociation of CH_3Br^+ taking place at 322.8 nm (2_3^3 REMPI wavelength) is introduced to account for the change in photolysis wavelength in each image. The maximum available energy for translation is indicated by vertical lines, for photodissociation of CH_3Br^+ to CH_3^++Br or $CH_3^++Br^*$ with a cation initial state $X^2E_{3/2}$ (solid lines) or $X^2E_{1/2}$ (dashed lines).
