Abstract

The mechanics of the transition from continental subduction toward upper crustal nappe stacking is still poorly understood and is studied here through a 2D thermal and strength numerical modelling of a subducted passive margin. Geological observations in the core of most mountain belts show the piling up of several HP-LT upper crustal units that are most likely related to the detachment of upper crustal units from the subducted continental margin and to the subsequent stacking of the detached units at depths. The Adula unit (Lepontine dome, Central Alps, Switzerland) is a long and thin upper crustal unit and is used here as a natural case-study as it provides a well-documented example of these units. 2D thermal modeling shows that two steps, successive in time, characterized the burial history of the passive margin undergoing continental subduction: 1-an increase in the margin strength due to an increase in the confining pressure during the first million years of the margin subduction and 2-the progressive heating of the subducted margin from the overlying lithosphere leads to a decrease in the margin strength due to thermal weakening, which progressively counter-balances the increase in confining pressure. Two strength gradients develop within the subducted lithosphere: 1-along the slab, the strength decreases with increasing burial depth and 2-perpendicular to the slab, the strength increases with depth due to an inverse temperature distribution. The detachment of HP-LT continental units from the subducted margin could occur when the slab strength becomes lower than the applied net stress. This allows the detachment of ductile weakened thin and long upper-crustal units. The thickness and length of the detached crustal units are controlled by the following parameters, in order of their importance: subduction dip angle, crustal rheology, mantle heat flux and subduction velocity. The comparison of our model results with the geometry and PT conditions of the Adula unit yields an estimate of the Alpine subduction dip angle at the time of deformation and metamorphism.

Figure 1: Schematic drawing of a three-step evolution in a convergence zone at a lithosphere scale. 1-Oceanic subduction, 2-Continental subduction, 3-Collision. This study focused on the continental subduction and subsequent detachment of the HP-LT crustal unit, as indicated by the black box.

1   Introduction

Mountain building is the result of three successive steps ([4, 61] – Figure 1).

The first stage is oceanic subduction, which induces the formation of oceanic accretionary wedges. Second, the subduction of continental margin induces the stacking of long and thin upper crustal units at great depths [10, 24, 43], and leads to the piling-up of high-pressure, low-temperature (HP-LT) units. At this stage, the convergence between the two plates is mostly accommodated within the subduction zone, where the stacking of HP-LT metamorphic units occurs [31, 29, 35]. Third, the ongoing convergence induces a more penetrative shortening, which leads to a pronounced thickening on a lithosphere scale. This induces the widening of the orogen, marked by the migration of orogenic fronts [40, 4] and defines the collision *sensu-stricto* (Figure 1-3). These three stages are well defined in the Alps, and therefore, we have chosen this will area as our field case-study in this paper. Oceanic closure and the beginning of oceanic subduction in the Liguro-Piemontais Ocean started during Cretaceous time (Albo-aptien, 100 Ma [49, 62, 18, 57]). The age of the continental subduction is established by HP-LT and UHP metamorphism ages, which range from the Eocene to the Early Oligocene (50-35 Ma – [62, 14, 6, 19, 27, 57, 61, 44]). Finally, continental collision *sensu-stricto* occurred during the late Oligocene and the Miocene (30-15 Ma) as evidenced by the ages of the successive frontal thrust in the northern ans southern parts of the Alpine collision belt [9, 37, 15, 16].

Most of the numerical models of orogenic processes analyze the evolution from subduction to collision on a lithosphere scale, with an emphasis on exhumation processes and surface-tectonic interactions [4, 21, 22]. The three successive steps of orogenic formation have been modeled with a particular focus on the role of crustal rheology (a weak upper crust versus a strong lower crust) and the crust-mantle coupling in defining the crustal thickening style. In these types of models, the depths at which the upper crustal material is detached from the down going subducted plate is indirectly imposed by a velocity discontinuity (called point S, [4, 21, 54, 8]). This velocity discontinuity is often defined at the crust-mantle boundary and avoids detachment of continental unit at depths greater than 60 km [5, 4, 21, 54]. The aim of the present paper is to analyze the processes that control the detachment of a crustal unit during continental subduction. This topic is crucial to quantify the parameters that control the maximum depth reached by a crustal unit in a continental subduction and subsequently to better understand the parameters that define the peak pressure of metamorphic rocks. This topic is also a first step toward understanding the piling-up of HP-LT units, which is typical of the core of mountain belts.

Van den Beukel [5] was the first to attempt to describe stacking during the subduction of a continental margin. Assuming a relatively hot subduction thermal gradient, Van den Beukel [5] qualitatively discussed the conditions for stacking occurrence by comparing the margin strength, inferred from the 2D thermal states of continental subduction, and the applied net stress. The margin strength is shown to increase during the first 20-40 km of the burial history and then decreases at greater burial depths. The applied net stress along the subduction plate, which was assumed to be the sum of the buoyancy plus the resisting stress, increases with burial depth. At burial depths greater than 30-40 km, the margin strength becomes lower than the applied net stress, leading to a possible thrust sheet detachment. However, the detachment is dictated by a prescribed rheological discontinuity at the

Lower crust	2800	1000	2,1	0,0	30 to 10
Mantle	3300	1000	3,0	0,0	70 to 90

Table 1: Thermal parameters for the 2D thermal models from Turcotte and Schubert [64]. The thickness of the radiogenic crust (upper crust) is set to one-third of the crust thickness.

base of the weak upper crust. The depth at which stacking occurs is seen to decrease with an increasing subduction thermal gradient and increases with increasing convergence velocity. Therefore, thermal heating, and hence strength weakening, during continental subduction seems to control unit stacking at depths. The role of subduction velocity, subduction dip angle and crustal rheology in defining the stacking depth need to be more systematically investigated. Moreover, the relationship between continental unit thickness/length and stacking processes remains poorly constrained. These are the two main objectives of the present paper.

Using a 2D thermal and strength model of the continental subduction, we will show that thin crustal units could detach from the subducted lithosphere due to a thermal weakening of the continental margin during burial and without prescribed rheological heterogeneities. The comparison of the applied net stress along the subduction plane and the 2D margin strength allows us to quantitatively predict stacking areas (e.g. unit length and thickness) within the margin crust. The role of subduction dip angle, subduction velocity, rheological and thermal parameters are investigated. Finally, our model predictions are tentatively compared with the Adula unit (Lepontine dome, Swiss Alps).

2 Model

Following Van den Beukel [5], this study is based on a 2D comparison of the applied net stress along the subduction plane and of the margin strength that evolves with burial history. The applied net stress is estimated by a simple force balance analysis, that is slightly different to that proposed by Van den Beukel. The margin strength is calculated from the 2D temperature distribution within the subducted lithosphere, which evolves with burial history (Figure 2).

2.1 2D thermal modeling

The 2D transient heat conduction is solved using the finite element method and the numerical code SARPP (see detailed description in Gueydan et al. [28] and Leroy et al. [38]):

$$\rho.C.\frac{\partial T}{\partial t} - k.\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) = r \tag{1}$$

where ρ, C, k and r are the density, capacity, thermal conductivity and radiogenic heat production, respectively. The values of these parameters for the crust and the lithosphere mantle are given in Table 1. The heat equation is solved only in the subducted lithosphere and in the thin low-conductive overlying layer (Figure 2-ab). The 2D temperature distribution within the overlying lithosphere is assumed to be a steady-state continental geotherm defined by the mantle heat flux, crustal thickness and radiogenic heat production within a 10 km thick radiogenic crust. The value of the heat flux will be changed in this study. The presence of a thin and low conductive overlying layer on the top of the subducted lithosphere accounts for the heat transport between the subducted lithosphere and the overlying lithosphere (Figure 2-b). The thickness of that layer has been set to 3 km and its conductivity varies between 1.0 to 2.0 $W.m^{-1}.K^{-1}$ and has been adjusted so that our 2D modeled temperature distribution within the subducted lithosphere is comparable to that of previous 2D models. At a conductivity k_s of 1.75$W.m^{-1}.K^{-1}$, Appendix A provides a detailed comparison between our modelling and previous studies and shows no major differences in terms of temperature estimates for varying subduction dip angle and velocity.

The temperature boundary conditions for the subducted lithosphere are as follows. A mantle heat flux is applied at the base of the structure while a temperature that evolves with time (e.g. during burial) is applied at the top of the overlying layer. At a given time and for a given horizontal position in the subducted plate, the top temperature is that given by the steady-state geotherm of the overlying lithosphere plate (Figure 2a and 2c). The top temperature therefore increases with time (e.g. with burial) and that increase is faster for both larger
Figure 2: Model set-up. a-2D thermal model and the three forces acting on the subducted continental margin: buoyancy $\vec{B}$, tectonic $\vec{T}$ and overlying weight $\vec{F}$ forces. At equilibrium, the acting force i.e. the sum of the three previous forces, is equal to the opposite of the reaction material force: $\vec{A} = -\vec{R}$. See Appendix B for a detailed description of the forces and related stresses. Continental subduction is described by a dip angle α and velocity V. Thermal boundary conditions are a steady-state continental geotherm in the overlying lithosphere and a mantle heat flux q_m at the base of the subducted lithosphere. The 2D model will resolve heat conduction only in the subducted lithosphere and a thin low-conductive overlying layer, which accounts for heat transport between the subducted lithosphere and the overlying lithosphere. The subducted lithosphere strength will be also calculated from the 2D temperature distribution, which evolves with the burial history. b-The geometry of the passive margin that will enter subduction is composed by three successive 100 km long domains: a thinned lithosphere with a 10 km thick crust, a transition zone where the crustal thickness progressively increases and finally, a non-thinned lithosphere with a 30 km thick continental crust. c-The applied top temperature calcuated from the steady continental geotherm of the overlying lithosphere increases with burial depths, and thus time, as a function of the subduction dip angle (α) and the velocity (V). See text for further details.

subduction velocities and subduction dip angles (Figure 2c). We systematically investigated the role of these two parameters in defining the 2D temperature and strength distribution within the subducted margin.

The initial condition includes the 2D temperature distribution of a passive margin with an age of 120 My after break-up, defined by the previous modeling done by Leroy et al. [38]. At that age, the thermal equilibrium is almost reached and thus, the lithosphere-asthenosphere boundary is nearly flat [38]. Following (author?) [38], the geometry of the passive-margin that will enter subduction is composed of three successive 100 km long domains: a thinned lithosphere with a 10 km thick crust, a transition zone where the crustal thickness progressively increases and finally, a non-thinned lithosphere with a 30 km thick continental crust (Figure 2b). The studied structure has been divided into 60×30 lagrangian elements. This geometry is typical of a non-volcanic passive margin [48, 25, 3, 38]. In the present paper, we will not discuss the role of that geometry in the stacking process; instead we prefer to study the role of thermal and rheological parameters in details.

Shear heating and advection have been neglected in the present study. England and Wilkins [20] have recently exemplified the role of frictional heating and heat dissipation on the thermal state of the oceanic slab during oceanic subduction. In a continental subduction environment, the physics of such frictional heating is however less constrained and even undefined, for varying subduction dip angles and subduction velocities [51, 11]. A fully coupled thermo-mechanical analysis would permit to have a 2D strain rate pattern within the subducted plate and subsequently, an accurate modeling of either the shear or frictional heating [51, 32, 33, 11]. In the present paper, we prefer to use a simple numerical model in order to focus on the role of thermal and rheological parameters in the stacking process at deep burial depths. Therefore, the thermo-mechanical analysis and thus, the role of either shear or frictional heating, is beyond the scope of this paper and will be post-poned to future works.

2.2 Strength estimate

The strength of the subducted margin is calculated from the 2D temperature distribution as follows. The material strength is defined as the minimum brittle strength (τ_b) and ductile strength (τ_d). The brittle strength (τ_b) is the Mohr-Coulomb shear stress, which increases with lithostatic pressure and therefore, with burial depth:

$$\tau_b = \sigma_1 - \sigma_3 = 2.\mu^\star.P = \frac{2.\mu.\rho.g.z}{\sqrt{\mu^2 + 1} \pm \mu} \tag{2}$$

Rheology	$A\ (MPa.s^{-1})$	$Q\ (kJ.mol^{-1})$	n	Reference
Dry Plagioclase (crust)	$3,2.10^{-4}$	$238,0$	$3,2$	Ranalli 2003 [56]
Wet Quartz (crust)	$4.0.10^{-4}$	$152,0$	$2,5$	Paterson 1990 [50]
Mafic Granulite (crust)	$1,4.10^{+4}$	445	$4,2$	Wilks 1990 [65]
Dry Olivine (mantle)	$2,4.10^{-5}$	$540,0$	$3,5$	Karato 1993 [36]

Table 2: Ductile rheological parameters used to compute the ductile strength from the 2D temperature distribution within the subducted continental lithosphere.

where μ is the friction coefficient, ρ is the density of rocks above depth z, and g is the acceleration of gravity. The depth z is the burial depth increasing with time plus the vertical position within the subducted margin. The sign $(\pm\mu)$ before the coefficient of friction depends on the tectonic regime: it is positive in a compression mode and negative in an extension mode. Therefore, the parameter $\mu^{\star}$ is an apparent friction coefficient that accounts for the tectonic setting and for pore fluid pressure effect [55]. For our study, $\mu^{\star}$ is equal to 2.12 in compression, with a friction coefficient of 0.7 [13]. The ductile strength (τ_d) is calculated from the dislocation creep flow law at a given average strain rate over the subducted lithosphere ($\dot{\varepsilon} = 10^{-15}s^{-1}$), and thus depends on the temperature:

$$\tau_d = \sigma_1 - \sigma_3 = \left[\frac{\dot{\varepsilon}}{A}\right]^{1/n}.\exp\left(\frac{Q}{n.R.T}\right) \tag{3}$$

where A, Q, n the pre-exponential constant, the activation energy and the stress exponent, respectively; and are given in Table 2 for both the crust and the mantle. In contrast to Van den Beukel, we do not assume any rheological differences between the upper and lower crust, so that the conditions for stacking can be studied in the absence of crustal heterogeneities (e.g. weak upper crust versus strong lower crust). Three sets of ductile rheological parameters for the crust (Table 2) will be used in this study: Dry Plagioclase (strong felsic crust), Mafic Granulite (strong mafic crust) and Wet Quartz (weak crust).

2.3 Stacking prediction

The detachment of a crustal unit from the subducted lithosphere is modeled here by comparing the applied net stress, hereafter denoted as σ_A, and the margin strength τ. Stacking occurs when the strength becomes lower than the applied stress:

$$\text{Stacking if:} \quad \tau \leq \sigma_A \tag{4}$$

Numerical results will quantify the time evolution of the margin strength τ in 2D. The applied net stress σ_A has been calculated analytically and is the sum of tectonic stress σ_T, friction stress σ_F and buoyancy stress σ_B:

$$\sigma_A = \sigma_B + \sigma_T + \sigma_F \tag{5}$$

Note that the buoyancy force is commonly the only force accounted for in subduction analyses [52, 30, 31, 35, 1, 22]. This assumption should be relevant in the study of lithosphere plates sinking into the mantle at great depths (200-400 km), where the mantle is supposed to behave like a fluid. In the present analysis, we account for two other forces since most of the evolution of the subducted margin occurs within the overlying lithosphere. Appendix B gives a full description of the three stresses used to define the applied net stress that are shown in Figure 3 as a function of the burial depth for a given subduction velocity and subduction dip angle. The tectonic stress σ_T is assumed to be at its maximum during the burial in the overlying crust, which is the elastic part of the overlying lithosphere. At greater burial depths, the tectonic stress progressively decreases to zero at the lithosphere-asthenosphere boundary (figure 3). The maximum value of σ_T is defined by the integral of the strength of a margin prior to subduction divided by the lithosphere thickness. Thus, this value corresponds to the necessary stress to deform the passive margin that enters subduction [13, 64, 63]. The friction stress σ_F is defined as the Mohr-Coulomb shear stress along the subduction fault plane. This stress is therefore a function of the overlying weight, which increases with burial, and of the friction coefficient of the subduction plane denoted μ_s. This friction coefficient is constant and at its maximum in the first 30 km of the subduction plane and then progressively decreases to zero at the lithosphere-asthenosphere boundary of the overlying plate. In the parametric study that follows, we will investigate the role of that friction coefficient μ_s in the stacking process. During burial in the overlying crust, σ_F increases with an increase in the overlying weight. During burial in the overlying mantle, the increase in σ_F is less pronounced because the increase in the overlying weight is counter-balanced by a decrease in the friction coefficient. This competing effect leads to a decrease in σ_F at burial depths greater than approximately 50 km. Finally, σ_F becomes zero in the overlying asthenosphere. The buoyancy stress σ_B is equal to zero during the burial in the
Figure 3: Evolution of the applied stresses on the subduction zone for a subduction dip angle and velocity ($\alpha = 30^o$ and $V = 1cm.y^{-1}$) as a function of the burial depth. σ_T σ_F and σ_B are the tectonic stress, the friction stress and the buoyancy stress, respectively, which are defined from the three forces presented in Figure 2. The full definition of these three stresses is provided in Appendix B. At an increasing burial depth, the applied net stress that is the sum of these three stresses ($\sigma_A = \sigma_F + \sigma_T + \sigma_B$) first decreases due to the dominance of both the friction stress σ_F and the tectonic stress σ_T and then increases due to the dominance of the buoyancy stress σ_B. See text for further details.
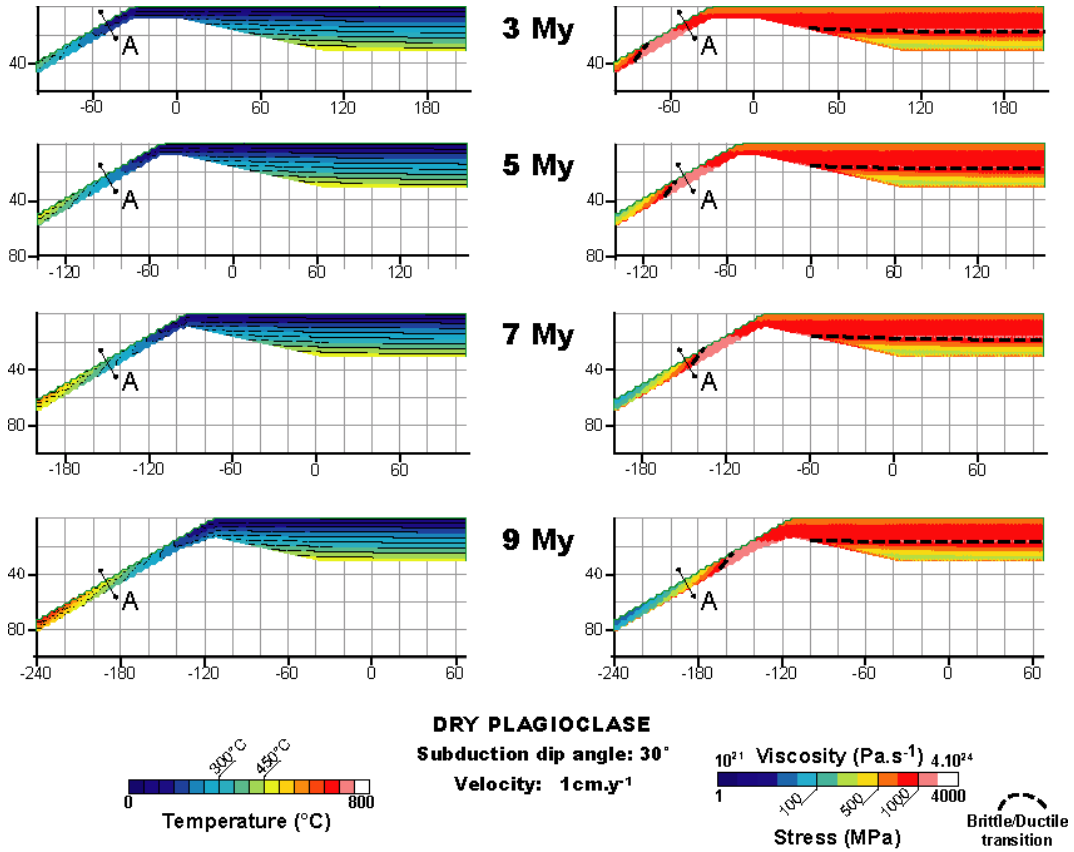

6

Figure 4: Evolution of temperature (left) and strength (right) in the subducted crust for burial times of 3 Ma, 5 Ma, 7 Ma and 9 Ma. Dry plagioclase is used to compute the crustal strength (Table 2) and the subduction dip angle and velocity are $\alpha = 30^o$ and $V = 1cm.y^{-1}$, respectively. The cross-section A will be used to calculate the mean strength τ_A at 50 km from the edge of the margin in Figure 5. The Brittle - Ductile transition is overprinted on the strength with dashed lines.

overlying crust because there is no density contrast between the subducted crust and the overlying crust. Then, the buoyancy stress increases linearly with the burial depth because the length of the crustal material entering the overlying mantle is increasing linearly [56].

The competing effects of these three stresses imply that during the burial history, the applied net stress σ_A along the subducted margin first decreases at burial depths lower than 80-90 km, because the tectonic stress dominates at these depths (Figure 3), and then, increases with larger burial depths when buoyancy stress is dominant. The numerical modeling will now allow us to quantify the strength evolution of the subducted margin and therefore, to predict stacking (e.g. when the material strength becomes lower than the applied net stress).

3   2D Thermal and Material Strength Evolution

Figure 4 presents the temperature and strength of the crustal part of the passive margin undergoing continental subduction for the reference model at four different ages after continental subduction has begun: 3 Ma, 5 Ma, 7 Ma and 9 Ma. The geometrical, thermal and rheological parameters for the reference model are: subduction dip angle $\alpha = 30^o$, subduction velocity $V = 1cm.y^{-1}$, diffusive layer conductivity $k_s = 1.75W.m^{-1}.K^{-1}$, crustal conductivity $k_c = 2.1W.m^{-1}.K^{-1}$, Dry Plagioclase for the ductile rheology and the brittle crust rheology $\mu = 0.7$. For the applied net stress, the only parameter that can vary is the friction coefficient of the subduction plane that is for the reference model $\mu_s = 0.7$. The role of these parameters in the stacking processes will be discussed later in the parametric study and is summarized in Table 3. In the reference model, at 3 Ma, most of the margin has not been subducted. In the non-subducted continental crust, the temperature distribution has not changed from the initial state and thus, temperature increases with depth. As a consequence, the rheological layering of the non-subducted margin crust yields a brittle-ductile transition at a depth of 20 km, which is typical for Dry

Plagioclase [56]. Only approximately an 80 km-long part of the margin is subducted where the temperature distribution drastically changes from the initial conditions. Due to of the heating from the overlying lithosphere, the temperature decreases with depth within the subducted crust, defining a classical reverse temperature profile. Along the margin, the heating is greater at greater burial depths. The margin strength is calculated from the 2D temperature distribution as the minimum between the brittle and ductile stresses (equations 2 and 3). The progressive heating from the overlying lithosphere will induce a decrease in the ductile stress, while the burial induces an increase in the brittle stress. As a consequence, an originally brittle crustal material can become ductile during the burial history. This feature is observed at 3 Ma only in the deeper part of the subducted passive margin where the upper part of the crust has become weak and ductile, as imaged by the brittle-ductile transition that almost occurs at 300^oC (Figure 4). Continental subduction is thus marked by two strength gradients (Figure 4): first, along the subduction zone, the strength decreases with increasing burial depths, and second, perpendicular to the subduction zone, the strength increases with depth due to a temperature inversion. For larger times (e.g. 5 Ma, 7 Ma and 9 Ma - Figure 4), there is an increase in the length of the crust that has been subducted. Because the brittle-ductile transition remains at the same depth (isotherm 300^oC - Figure 4), the length of the ductile material increases with time, as already discussed by Hacker [31]. A material point initially located near the surface, and that is ongoing subduction, will therefore become ductile at a depth of around 20-30 km. In contrast, a material point initially located at a depth of 10 km will become ductile at a larger burial depth of 40 km.

In summary, the subducted continental margin is progressively heated by the overlying lithosphere during continental subduction. This induces the reverse temperatures and strength profiles in the subducted crust and thereby, a strong thermal weakening in the upper part of the subducted continental crust. On the lithosphere scale, the two strength gradients, along the subduction zone and perpendicular to the subduction zone, are progressively enhanced with time during the burial history. For the reference model, only 3 Ma were needed to significantly reduce the strength so that the material became ductile. This evolution of material strength strongly depends on slab velocity, as it will be discussed below. In any case, the material strength never reaches values lower than 10 MPa. The viscosity of the subducted crust is therefore always greater than $10^{22} - 10^{23} Pa.s$, using an overall strain rate of $\dot{\varepsilon} = 10^{-15} s^{-1}$. However, as already discussed, a fully coupled 2D thermo-mechanical modeling would provide a large variation in the strain rate within the deforming slab and hence, in the viscosity. Such models could therefore predict values of slab viscosity that can be much lower than those obtained with the present thermal and strength modeling, which only accounts for a bulk and homogeneous strain rate [23]

4   Mechanical Analysis of the Stacking of HP-LT Crustal Units

Stacking conditions could be estimated by comparing the margin strength with the applied net stress along the subduction plane. A 1D analysis is presented first, in order to explain the approach used to predict stacking. Second, a 2D analysis, based on the 2D thermal and strength modeling, is presented in order to discuss the geometry of the stacked areas.

4.1   1D analysis

Based on the 2D strength evolution of the margin through time, we calculated the mean value of the crustal strength in the middle of the stretched part of the margin (local cross-section A, Figure 4), which is denoted τ_A. The values of τ_A and the applied net stress σ_A for the reference model are plotted as a function of the burial depth in Figure 5. Stacking would occur within the local cross section A when τ_A becomes lower than σ_A (equation 4). In the first stage of the burial history, the material remains brittle and its strength increases with burial depth, because of the pressure sensitivity of the brittle rheology (equation 2). At 5 Ma, τ_A is at its maximum at around 2000 MPa. Then, the heating is sufficient to weaken the material, which then becomes ductile. Between 5 Ma and 7 Ma, the mean material strength drastically decreases from 2000 MPa to 300 MPa (Figure 5). Stacking could occur here at around 7My and at a depth of 40 km, when the material strength τ_A is lower than the applied net stress σ_A. This depth is the minimum depth at which stacking could occur, and defines the minimum stacking depth (MSD) in the following. Stacking was not possible before because the material was entirely brittle and therefore, its strength increased with burial depth. Thus, stacking is only allowed when the material becomes ductile and thereby weakens with ongoing heating. These results pointed out the necessity to account for the three stresses in order to define the applied net stress (Figure 3). If buoyancy stress was the only stress, then σ_A would have been too low to trigger stacking at depths lower than 55-60 km (Figures 2, 3 and 5). It is therefore necessary to account for tectonic stress, which increases the value of the applied net stress at low burial depths, in order to explain the stacking of crustal pieces at depths lower than 55-60 km (i.e. 1.5-1.7 GPa), as may occur in natural cases.
Figure 5: 1D evolution of the applied net stress σ_A and the material strength τ_A, calculated on the local section A of the 2D models of Figure 4, as a function of the burial depth. Dry plagioclase is used to calculate the crustal strength (Table 2); the subduction dip angle and velocity are $\alpha = 30^o$ and $V = 1 cm.y^{-1}$, respectively. Stacking is possible when the material strength becomes lower than the applied net stress (grey shaded areas).

Thus, this 1D analysis reveals that the progressive heating of the slab crust during continental subduction leads to a thermal weakening and a subsequent drastic decrease in the material strength. This thermal weakening is sufficient to allow for the detachment of a crustal unit from the subducted margin at a critical depth hereafter called the minimum stacking depth (MSD). This detachment is not modeled here, but would correspond to ductile shearing at base of the base of the crustal unit, as will be discussed in the 2D analysis.

4.2   2D stacking analysis

4.2.1   Potential stacking area

Assuming that the applied net stress (σ_A) is constant over a vertical section in the subducted crust, we can plot, in 2D, the ratio of the applied net stress along the subduction plane σ_A over the margin strength τ, which is inferred from the 2D numerical results (Figure 6). Stacking is not possible if this ratio is lower than 1 ($\log \sigma_A/\tau < 0$ dark domain in Figure 6). In 2D, the minimum stacking depth (MSD) is the base of the colored areas in Figure 6 and is at a burial depth of 30 km at the top of the subducted crust and at approximately 40 km in the deep crust. This difference is explained by a reverse strength profile (e.g. lower strength in the top of the subducted crust with respect to the deep crust, Figure 4). The position of the MSD does not change with time because the overall 2D thermal state of the subduction does not evolve with time. The progressive heating of the subducted margin with the burial history induces an increase in the length of the stacking area ($\log \sigma_A/\tau > 0$). In 1D, stacking was predicted to occur only after 7 Ma, while in 2D, stacking could occur at 3 Ma. This is because in the 1D analysis, we used a mean value of the margin strength at a given position (point A plotted in Figure 6), which is compared to σ_A, while in 2D, the difference between the applied net stress σ_A and the strength τ was calculated for each material point.

4.2.2   Length and thickness of detached crustal units

Based on the definition of the potential stacking area, it is possible to define the shape (i.e. length and thickness) of the detached continental unit as follows. Within the subducted crust, a sharp strength gradient is observed above the MSD (Figures 6 and 4). The top of the potential stacking area is significantly weaker than its base, which will therefore be less deformed during the stacking processes. Again, the detachment process, e.g. deformation, is not modeled here. However, the 2D thermal and strength models provided important information on the strength gradients both within and along the subduction zone that would have a major impact on the deformation pattern. The detachment of a crustal unit would correspond to a strong ductile shearing of the weakened crustal potential stacking area within the subduction zone. The strength gradients within the continental slab would induce a heterogeneous deformation, and the relatively strong base of the potential stacking area would be little deformed. As a consequence, it is unlikely that the entire potential stacking area will form a future detached unit, and thus,
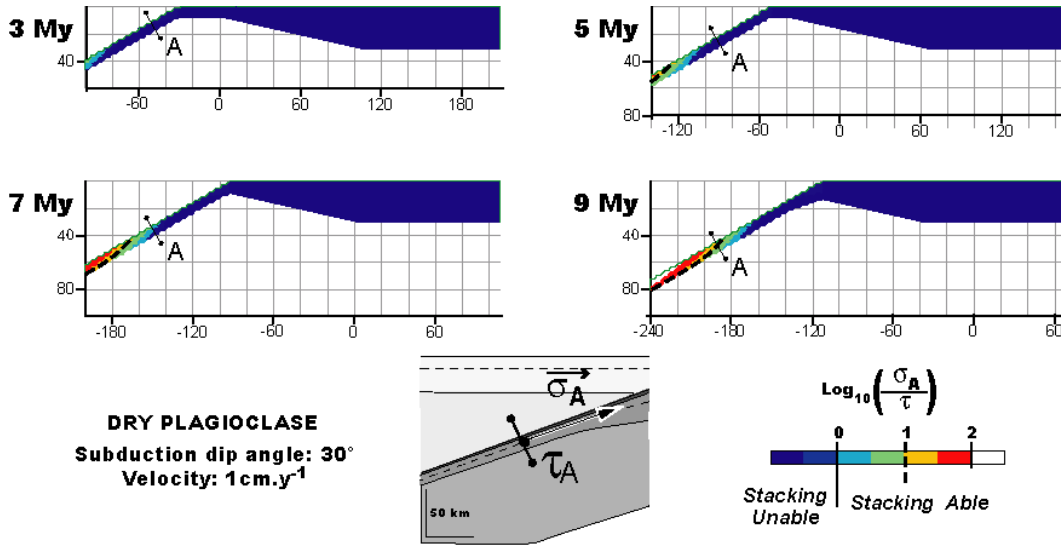

9

Figure 6: 2D evolution of the ratio, in log scale, of the applied net stress (σ_A) over the material strength (τ), providing the evolution of the 2D potential stacking area (light blue to white domains). Dry plagioclase is used to calculate the crustal strength (Table 2); the subduction dip angle and velocity are $\alpha = 30^o$ and $V = 1cm.y^{-1}$, respectively. The dashed line marks the area taken into account for the length and thickness estimation ($\log(\sigma_A/\tau) \geq 1$). See text for further details.

we have proposed that the base of the future detached crustal unit is the region where the ratio σ_A/τ is equal to 10 (i.e. dashed line in Figure 6). On these bases, we can measure the length and thickness of the future detached unit directly from the 2D results. The upper limit of the unit has a dip angle that is higher than the subduction dip angle. This implies that the length of the detached unit is larger in the top of the subducted crust than in the deep subducted crust. Similarly, the thickness of the unit is smaller at shallower levels than at deeper levels. To avoid these variations and to have a single value for the thickness and length, we have chosen to use the mean value for the thickness and length.

For the reference model, the lengths and thicknesses of the future stacked units are shown in Figure 7 as a function of the burial depth (straight line, $\alpha = 30^o$ and V=$1cm.y^{-1}$). The length increases with burial depth. Because the minimum stacking depth (MSD) does not change with time, the length of the potential stacking area, and thereby the length of the future detached unit, increases with burial depth. Similarly, the thickness of the stacked unit increases between burial depths of 30 km (MSD) and 60-70 km, and then, is almost constant at its maximum value (e.g. crustal thickness of 10 km for the thinned part of the margin).

In summary, this 2D thermal and strength modeling predicts the possible detachment of the ductile weakened thin and long upper-crustal units without evoking a vertical crustal heterogeneity. This is the first novelty of this modeling, compared to Van den Beukel's model [5], which explains stacking with lower crustal rheological heterogeneities. The second novelty of this study is that the decoupling of the HP-LT crustal units could only occur in the ductile regime due to a thermal evolution with burial. The detachment should occur along a major shear zone at the base of the unit due to large strength gradients both along and perpendicular to the subduction plane.

5 Parametric Study

Following the analyses made for the reference model (i.e. the straight lines in Figure 7), we have performed a series of 2D models in order to quantify the role of the geometrical, rheological and thermal parameters in defining the HP-LT crustal unit length and thickness (Table 3).

5.1 Role of subduction dip angle (α) and velocity (V)

Figure 7 presents unit length and thickness as a function of burial depth for V=$1cm.y^{-1}$ for four values of the subduction dip angle α (10°, 20°, 30°, 40°) and for $\alpha = 30^o$, for four values of V ($1cm.y^{-1}$, $2cm.y^{-1}$, $3cm.y^{-1}$, $4cm.y^{-1}$). The burial depths at which the unit lengths and thicknesses become non-zero are the minimum stacking depths (MSD). The MSD value is relatively similar for the different subduction velocity (V) and subduction dip angle
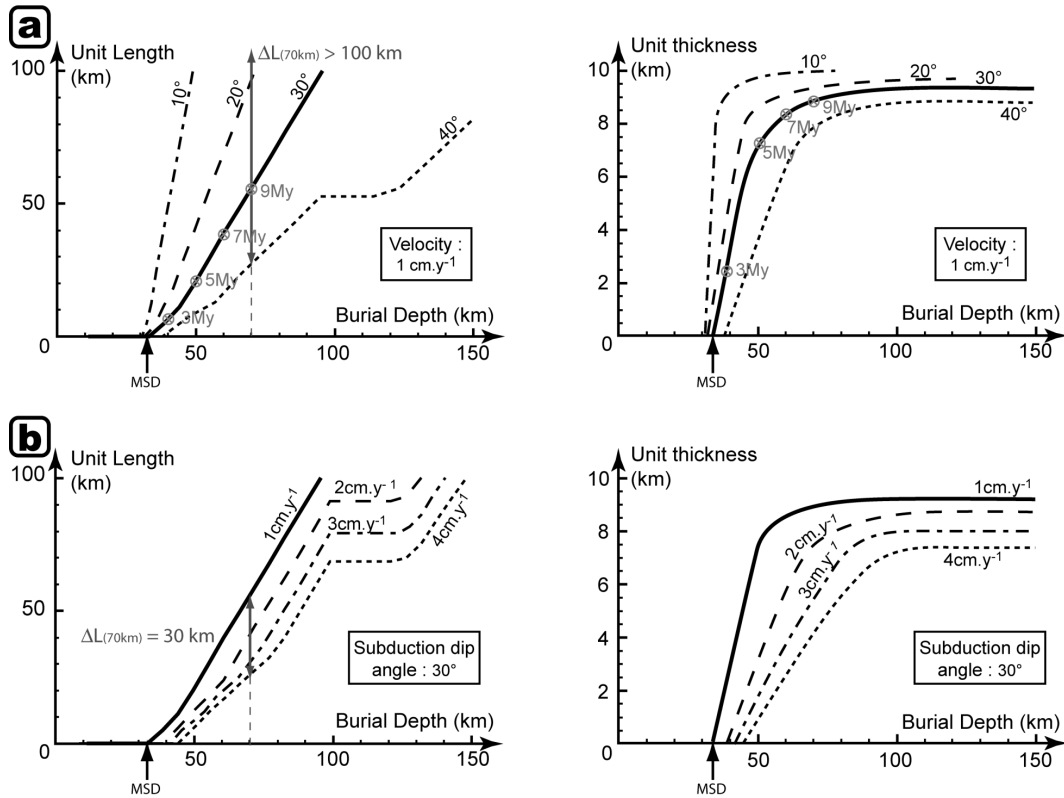

Figure 7: Unit length (left) and thickness (right) inferred from the 2D thermal and strength models in Figure 4, as a function of burial depth. a-for a velocity equal to $1cm.y^{-1}$ and for four subduction dip angle values (10°, 20°, 30°, 40° – top part); and b-for a subduction dip angle equal to 30° and for four velocity values ($1cm.y^{-1}$, $2cm.y^{-1}$, $3cm.y^{-1}$ and $4cm.y^{-1}$ – bottom part). MSD: Minimum Stacking Depth for the reference model. The vertical arrows ($\Delta L(70km)$) represent the variation of the unit length at a burial depth of 70 km induced by the variation in the subduction dip angle (top) and the subduction velocity (bottom) The ($\Delta L(70km)$) values are reported in Table 3 for the entire set of parameters studied.

11

(α) values and ranges between 30 and 40 km. The MSD increases weakly at a higher subduction velocity and/or subduction dip angle. At low burial rates (low dip angle/low subduction velocity), the thermal evolution of the subducted margin is slow enough to allow an almost thermal equilibrium within the subduction zone; and hence, the subducted margin will be heated early in its burial evolution, permitting stacking at lower burial depths. In contrast, an increase in the burial rate will favour an adiabatic evolution of the subducted margin and thus, stacking will occur at larger burial depths.

At the same burial depth, the unit lengths and thicknesses are smaller for larger burial rates (either a larger V or a larger α). As explained above, a low burial rate favours margin heating and a subsequent strength decrease, leading to a rapid increase in the unit length and thickness with burial depth. In contrast, the length and thickness of the stacked unit are reduced for larger burial rates due to more adiabatic evolution of the subducted margin. The variation in the length of the units (ΔL), calculated at a 70 km burial depth (e.g. 2.0 GPa) is defined as a criteria to quantify the impact of the considered parameters on the stacking process. In the reference model at 2.0 GPa, the unit length is $L(70km) = 55km$ (Figure 7, straight line). The variation of the length of the units with the subduction dip angle (10° to 40°), denoted as $\Delta L_\alpha(70km)$ is greater than 100 km. The variation of the length of the units with the subduction velocity $\Delta L_V(70km)$ is only $30km$.

5.2 Role of rheological and thermal parameters

5.2.1 The role of ductile crust rheology

Three crustal rheologies are used for the 2D models (Figure 8a): Dry Plagioclase (reference model, [56]), Wet Quartz [50] and Mafic Granulite [65]. The increase in unit length with burial depth is rather similar for the three crustal rheologies (Figure 8a), but the minimum stacking depth is strongly controlled by the crustal rheology. The stronger the rheology, the deeper the minimum stacking depth. With the same thermal evolution of the margin, a strong rheology will delay the time at which the subducted material will become ductile and thus, will increase the depth at which the margin strength drastically decreases. As a consequence, the minimum stacking depth will be larger for a stronger crustal rheology.
The variation of the length of the units with the crustal rheology at 2.0 GPa (wet quartz, dry plagioclase or mafic granulite) is large: $\Delta L_{rheo}(70km) = 90km$.
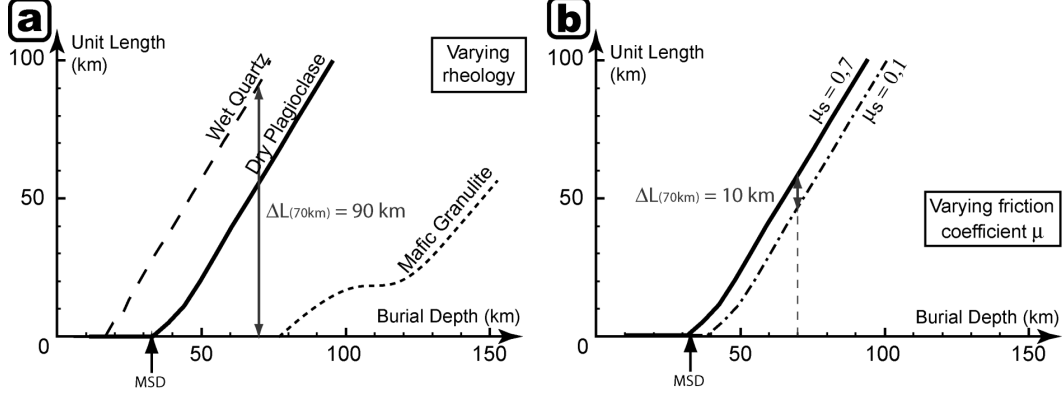

5.2.2 The role of the coefficient of friction (μ_s)

Figure 8b presents unit length as a function of burial depth for two subduction zone friction coefficient values, which define the friction stress for the applied net stress (equation 5): $\mu_s = 0.7$, which is a common value for crustal material at surface [56], and $\mu_s = 0.1$ which corresponds to soft and wet material, such as hydrated sediments in depths [13]. A decrease in μ_s will therefore decrease the absolute value of the applied friction stress along the subduction plane and hence, will increase the applied net stress σ_A because the friction stress has a negative contribution to the applied net stress σ_A (Appendix A). As a consequence, a decrease in the friction coefficient μ_s will inhibit stacking and will therefore increase the Minimum Stacking Depth (MSD). However, changes in the MSD are not significant; compared to the role of ductile crust rheology (Figure 8). At a burial depth larger than the MSD, an increase in the crustal unit length is moreover very similar for the two friction coefficient values (μ_s). The variation in the length of the units with the friction coefficient (0.1 to 0.7) is rather small: $\Delta L_{\mu_s}(70km) = 10km$. The friction coefficient of the subduction plane does not have a significant influence on the stacking process.

5.2.3 Role of thermal parameters

The role of mantle heat flux ($20 < q_m < 40mW.m^{-2}$), radiogenic heat production ($0.0 < r < 2.0\mu W.m^{-3}$), thermal conductivity of the crust ($2.1 < k_c < 2.5W.m^{-1}.K^{-1}$) and of the diffusion layer ($1.0 < k_s < 2.0W.m^{-1}.K^{-1}$) on the evolution of unit length with burial depth are summarized in Figure 8. At a given burial depth, an increase in the mantle heat flux (q_m), or an increase in the radiogenic heat production (r) induces an increase in temperature within the subducted crust and thus, enhance stacking process, leading to a decrease in the MSD and an increase in the crustal unit length (Figure 8c,d). In contrast, an increase in the thermal conductivity of the crust (k_c) or of the thermal conductivity of the diffusion layer (k_s) will decrease the temperature within the subducted crust and thereby, inhibits stacking, leading to an increase in the MSD and a decrease in the crustal unit length (Figure 8e,f). Variations in mantle heat flux (q_m - Figure 8c) have major impact on the upper crustal unit geometry, leading to variation in the unit length $\Delta L_{q_m}(70km) = 35km$ for a variation in heat flux (q_m) from $20mW.m^{-2}$ to $40mW.m^{-2}$. Variations in the radiogenic heat (r - Figure 8d), thermal conductivity of the crust (k_c - figure 8e) and thermal conductivity of the diffusion layer (k_s - Figure 8f) do not significantly influence the increase in unit length and thickness with burial depth: $\Delta L_r(70km) = 5km$, $\Delta L_{k_c}(70km) = 10km$, $\Delta L_{k_s}(70km) = 5km$.
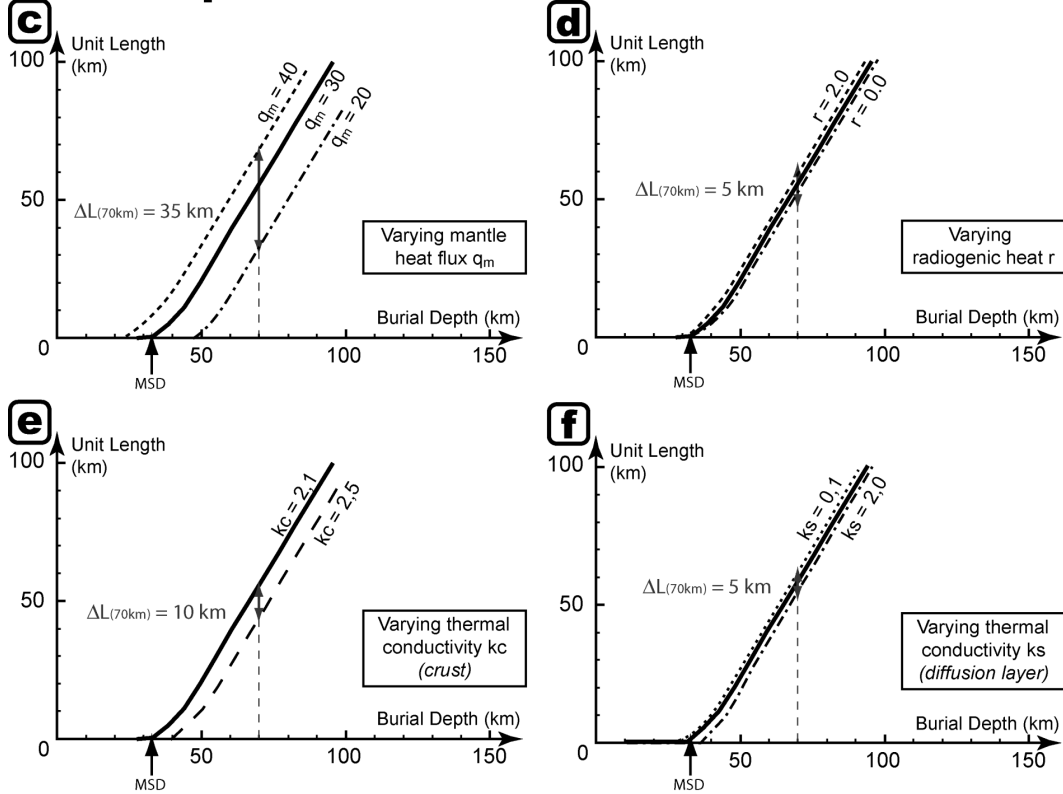

Rheology

Thermal parameters

Figure 8: Unit length inferred from the 2D thermal and strength models as a function of the burial depth for: a-three different ductile crust rheologies (Wet quartz, Dry plagioclase and Mafic granulite, Table 2), b-two subduction zone friction coefficient μ_s values, c-three mantle heat flux q_m values, d-two radiogenic heat production r values, e-two thermal conductivity values for the crust k_c and f-two thermal conductivity values for the diffusive layer k_s. MSD: Minimum Stacking Depth for the reference model. The vertical arrows ($\Delta L(70km)$) show the variation in the unit length implied by the variation in the six parameters studied here. These variations are reported in Table 3.

Parameters	Subduction parameters		Mechanical parameters		Thermal parameters			
	Dip angle (α)	Velocity (V)	Rheology	Friction coeff. (μ_s)	Mantle Heat Flux (q_m)	radiogenic heat (r)	Crustal thermal conductivity (k_c)	D.L. thermal conductivity (k_s)

Controlling role	++	+	++	−	+	−	−	−

Table 3: Respective effect of parameters on the variation of unit length at a 70 km burial depth. The unit length at a depth of 70 kms is $L_{ref}(70km) = 55km$ for the reference model. The rheology abbreviations are as follows: wq: wet quartz, dp: dry plagioclase, mg: mafic granulite

5.3 Respective effect of the subduction, thermal and mechanical parameters

Table 3 presents the reference value, the range of variation used for the numerical models presented in this study and the induce variation in the length of the units at a burial depth of 70 km ($\Delta L(70km)$) for the entire set of parameters studied: subduction dip angle (α) and velocity (V), rheology, coefficient of friction (μ_s), mantle heat flux (q_m), the radiogenic heat production (r), and thermal conductivity of the crust (k_c) and of the diffusive layer (k_s). This compilation allows us to classify the controlling role of the parameters in order of their importance: 1-dip angle α, 2-ductile crust rheology, 3-velocity V and mantle heat flux q_m and 4-all the other thermal parameters. Therefore, stacking is primarily controlled by the dip angle of the slab and the ductile rheology. These findings imply that the length or thickness of the HP-LT continental units found in the core of mountain belts may be tentatively used to infer a subduction dip angle at the time of deformation and metamorphism, as will be discussed below.

6 Comparison with the HP-LT Adula unit

The Lepontine Dome is part of the central Alps where the stacking of thin and long basement units constituted of upper crustal rocks is found. Contacts between these units consist of major kilometer scale ductile shear zone [2, 42, 44], suggesting that these nappe pile occurred at peak pressure within the ductile regime. These field observations are consistent with our modeling results, which suggest that stacking can only occur when the crustal rocks become ductile. The rocks of those units recorded low-to-high pressure and low temperature metamorphism conditions during the Alpine continental subduction phase [61, 44, 57]. The Alpine subduction velocity at the time of peak metamorphism is estimated at $1.0cm.y^{-1}$ [60, 26, 6, 35]. The Adula unit belongs to the Lepontine nappe pile (Figure 9a) and represents the paleo-geographically southernmost part of the European passive margin before the subduction of the Valais trough [58, 60, 47]. The Adula unit consists of a pre-alpine basement constituted of granitoid gneisses and metapelitic schists (Figure 9b), with minor amounts of metasedimentary rocks from the postulated Mesozoic age [34, 39, 45, 46]. Metabasic eclogites and amphibolites occur as boudins between 10 cm to 100 m long within basement rocks (Figure 9b). Ultramafic rocks are generally only present at the base and at the top of the nappe [53, 46, 17]. The peak pressure calculated along the Adula unit presents a gradient from the front (North) to the root (South) of the unit [34, 39, 46, 17]. P_{max} values estimated in different locations [17] are listed in table 4. This precise study allows us to quantify the geometry and depth of the Adula unit stacking. For a given point in Figure 9b, the distance from the front of the nappe is a function of the nappe length and the peak pressure gives the burial depth (Table 4).

The length and thickness of Adula unit are used for comparison with our models. The schistosity of Adula unit is almost horizontal, or slightly east-dipping, except near the Insubric line [12, 44] and it is therefore possible to evaluate the length of this unit on a geological map ass follows (Figure 9b). The thickness is estimated from geological cross-sections, which are constrained by seismic lines and geological surveys [59, 61]. Due to large deformations after stacking, the present day length and thickness of these Penninic units does not represent the length and thickness of the units at the time of the stacking. We have assumed a post-stacking deformation that mostly corresponds to a vertical thinning during stacking and exhumation [41]. The thinning is marked by a foliation parallel to the base and the top of the unit. At the time of stacking, the length was L_m/β_2 and the thickness larger $T_m.\beta_1$. β_1 representing the vertical thinning factor and β_2 the horizontal stretching factor, respectively (Figure 9c). The assumption of a post-stacking deformation with no volume change yields $(T_m\beta_1).(L_m/\beta_2).(l_m/\beta_2) = T_m.L_m.l_m$, and thus, $\beta_1 = \beta_2^2$. Based on [41, 17], we used a value between 2.0 and 2.2 for β_1 and between 1.4 and 1.5 for β_2 in this study.
Figure 9: The comparison between the results from our model results and the geometry of the Adula unit inferred from geological and geophysical data allows us to estimate the subduction dip angle at around 45° for a subduction velocity of $1cm.y^{-1}$. a-Map, modified after Schmid [61], showing the Lepontine units and the location of the Adula unit. This map was used to estimate the length of the Adula unit. However, the length of the Adula unit at the time of stacking has been modified from the map measurement in order to take in account post-stacking deformation (see c- and text for further details). b-Map, modified after Jenny and Dale [34, 17], showing the location list in Table 4. This map allows us to estimate the distance from the front of the unit for each location. c-Schematic 3D diagram showing the deformation of a unit with no change in volume, which mostly corresponds to a vertical thinning. L_m and T_m are the present-day measured length and thickness of the unit, respectively. d,e- The unit length (left) and thickness (right) as a function of burial depth is calculated with a Dry plagioclase for a ductile crust rheology, a subduction velocity of $1.0cm.y^{-1}$ and six subduction dip angles (α: 10°, 20°, 30°, 40°, 45°, 50°). Data (i.e. distance from the front and maximal pressure) from Table 4 are also plotted.

N	Location	Distance from the front (km)	Max pressure (GPa)
1	Funt	2,88	1,25
2	Vals	3,85	1,75
3	Chichalp	9,23	1,70
4	Confin	18,85	2,20
5	Passit	21,15	2,25
6	d'Arbeola	23,85	2,15
7	Trescolmen	26,73	2,25
8	Caurit	46,92	2,40
	Adula unit	28 - 33	2,25 - 2,40

Table 4: Location, distance to the front and peak pressure (in GPa) of the eight selected points within the Adula unit from Dale and Holland [17].

Table 5: Measured temperature in a subducted crust at a depth of 100 km from previous numerical models and natural data for different subduction dip angles and velocities. Our numerical estimates are also provided.

We compared the natural Adula example with a set of six models with a varying subduction dip angle at $V = 1 cm.y^{-1}$, i.e. the estimated convergence velocity at the time of the peak metamorphism. A Dry Plagioclase rheology was selected for the ductile crust rheology since most rock types from the Adula unit are granitoid. The burial depth, deduced from PT conditions, and both the unit length and thickness are plotted in Figure 9d and Figure 9-e, respectively. They were compared to the results from our model. In terms of the unit length, the different natural data are consistent with our modeling and yields a subduction dip angle of $\alpha = 45^o$ (Figure 9d). However, the Caurit location (point 8) is an exception. This can be explained by its position within the root zone, which had been strongly deformed by post-stacking deformation. In terms of the unit thickness, a mean value for the Adula unit also yields a subduction dip angle of $\alpha = 45^o$ (Figure 9e). Based on the north-south PT conditions, Dale and Holland [17] have independently quantified the dip angle of the Adula unit during subduction to be approximately 45°, which is consistent with our estimate. Because the Adula is a single HP-LT continental unit, this high level of consistancy between natural data and our model results validate our modelling of continental stacking and allows us to use the HP-LT continental unit geometry and PT conditions as a proxy to infer a subduction velocity at the time of the peak metamorphism. As already discussed, crustal rheology, subduction velocity and mantle heat flux may also have an impact in defining the HP-LT continental unit geometry.

7   Conclusion

A 2D conductive model of a continental margin undergoing subduction; has been used to argue that two strength gradients develop within the subducted lithosphere: 1-along the slab, the ductile strength decreases with increasing burial depths and 2- perpendicular to the slab, the ductile strength increases with depth, due to an inverse temperature distribution. The detachment of HP-LT continental units from the subducted margin could occur when the slab strength becomes lower than the applied net stress. This allows the detachment of ductile weakened thin and long upper-crustal units. Due to the strength gradients; both along and normal to the subduction zone, the detachments should localize along the ductile shear zones parallel to the base of the crustal units. These models provide a first step toward a broader study of the piling up of the metamorphic units that are observed in the core of most mountain belts. The thickness and length of the detached crustal units are mainly controlled by the following parameters, in order of their importance: subduction dip angle (α), crustal rheology, mantle heat flux (q_m) and subduction velocity (V). As seen in the results above, geological data such as the geometry and the PT path of HP-LT units could be used to infer either the subduction dip angle, crustal rheology, mantle heat flux or subduction velocity at the time of the deformation and metamorphism. However, additional geological and geophysical constraints relative to the subduction dip angle and velocity, crustal rheology or slab thermal state are required to fully describe the mechanics of continental subduction.

APPENDIX A: Model comparison

Table 5 presents the estimated temperature at the top of the subducted crust at a 100 km burial depth based on various numerical models and natural observations for different subduction velocities and dip angles. Our numerical results are consistent with previous models as well as with natural data. This validates the assumption made in this paper to build a simple 2D modeling of the thermal and strength state of continental subduction.

APPENDIX B: Force and stress calculation

The forces applied to a subducted margin crust are as follows (Figure 2): the Tectonic force ($\vec{T}$) induced by the motion of the overlying lithosphere with respect to the subducted lithosphere, the Buoyancy force ($\vec{B}$) due to the

burial of the light subducted crust in a heavier mantle, and the Overlying Weight force ($\vec{F}$), which is related to the weight of the overlying lithosphere situated above the subducted crust.

The mechanical equilibrium yields a classical force balance: the sum of all forces must be null and thus, the Acting force ($\vec{A}$), which is the sum of the three applied forces, has to be the opposite of the reaction material force ($\vec{R}$) :

$$\vec{A} = \vec{T} + \vec{B} + \vec{F} = -\vec{R}$$

From the acting force ($\vec{A}$), we define the applied net stress (σ_A) along the subduction plane as the sum of the following three stresses: tectonic stress σ_T, frictional stress σ_F and buoyancy stress σ_B.

- The tectonic stress is defined by the projection of the tectonic force ($\vec{T}$) along the subduction plane. The magnitude of the tectonic force ($\|\vec{T}\|$) is taken as the overall strength of the margin.

$$\sigma_T = \delta(z).\cos(\alpha).\int_{0km}^{100km} \tau(z)dz \tag{6}$$

with $\int_{0km}^{100km} \tau(z)dz$ the integral of lithosphere strength and α the dip angle of the subduction (Figure 2). Using Dry Plagioclase and Dry Olivine for the crust and mantle rheology, respectively (Table 2), the integral of the lithosphere strength is equal to $800 MPa$. The δ coefficient is used to linearly decrease the tectonic stress along the subduction plane below the overlying crust so that the tectonic stress is at its maximum for subduction within the overlying crust and then decreases linearly to zero at the lithosphere-asthenosphere boundary. To account for that, we assume that:

$$\delta(z) : \begin{cases} \delta(z) = 1 & \forall z \leq z_{moho} \\ \delta(z) = 1 + \frac{z - z_{moho}}{z_{moho} - z_{litho}} & \forall z > z_{moho} \end{cases} \tag{7}$$

with z equaling the burial depth, $z_{moho} = 30km$ for the Moho depth in the overlying lithosphere, and $z_{litho} = 100km$ for the overlying lithosphere thickness.

- The friction stress $\vec{\sigma_F}$ is define as the product of the friction coefficient of the subduction plane μ_s and the overlying weight force $\vec{F}$, resolved along the subduction fault plane : $\vec{\sigma_F} = \mu_s.\vec{F}.\sin(\alpha)$. The overlying weight increases with burial depth and depends on the density of the rocks ($\rho_{(z)}$): $F = \rho_{(z)}.g.z$. The Mohr-Coulomb friction coefficient of the subduction plane (μ_s) is at its maximum during the burial in the overlying crust ($z \leq z_{moho}$). The subduction plane in the overlying crust is considered as a fault plane with a high friction coefficient (μ_s). In the overlying mantle, this friction coefficient (μ_s) decreases linearly with depth.

$$\begin{cases} \sigma_F = -\mu_s.\rho_c.g.z.\sin(\alpha) & \forall z \leq z_{moho} \\ \sigma_F = -\mu_s.\left[\rho_c.g.z_{moho} + \rho_m.g.(z - z_{moho})\right].\sin(\alpha).\delta(z) & \forall z > z_{moho} \end{cases} \tag{8}$$

with z equaling the burial depth, $z_{moho} = 30km$ for the Moho depth in the overlying lithosphere, $\rho_c = 2800 kg.m^{-3}$ for the crustal density, $\rho_m = 3000 kg.m^{-3}$ for the mantle density, $g = 9,81$ for the constant of gravity, α for the subduction dip angle and μ_s for the Mohr-Coulomb friction coefficient of the subduction plane. The friction coefficient μ_s is left to vary in order to investigate its role in the stacking process. The $\delta(z)$ function is defined in equation 7.

- The Buoyancy stress is directly calculated from the Buoyancy force ($\vec{\sigma_B} = \vec{B}.\sin(\alpha)$).

$$\begin{cases} \sigma_B = 0 & \forall z \leq z_{moho} \\ \sigma_B = \left[\rho_m - \rho_c\right].g.(z - z_{moho}).\sin(\alpha) & \forall z > z_{moho} \end{cases} \tag{9}$$

with z equaling the burial depth, $z_{moho} = 30km$ for the Moho depth in the overlying lithosphere, $\rho_c = 2800 kg.m^{-3}$ for the crustal density, $\rho_m = 3000 kg.m^{-3}$ for the mantle density, and α for the subduction dip angle. The buoyancy is null if the burial depth is less than the Moho depth because there is not a difference of density between the subducted crust and the overlying rocks. Below the Moho, buoyancy increases linearly with burial depth.
