Abstract

Novel magnetic nano-composites are obtained by the self-assembly in water of polypeptide-based di-block copolymers polybutadiene-*b*-poly(glutamic acid) combined with hydrophobically modified γ -Fe₂O₃ nanoparticles. These hybrid supramolecular objects are either filled micelles (3-d) or hollow vesicles with a magnetic membrane (2-d), deformation of which under an applied magnetic field has been evidenced. These nanoparticles are also able to respond to stimuli such as pH and ionic strength due to the presence of the polypeptide block, thus forming what we called multi-responsive nanocapsules. These superparamagnetic hybrid self-assemblies offer attractive potentialities in biomedicine and biotechnology due to their dimensions (0.1–0.5 μ m) small enough to stay for some time in the blood circulation, and due to the properties brought about by the iron oxide nanoparticles: possible manipulation by an external magnetic field gradient, local heating by a radio-frequency field for cancer radio-therapy, labeling of organs to enhance the contrast in Magnetic Resonance Imaging.

1. Introduction

High or low molecular weight synthetic amphiphiles of many types have been studied and are revealed to be interesting building blocks that can lead to highly ordered self-assembled structures in water [1]. In comparison with biological systems, depending on their molecular architecture and on external field such as temperature or pH, numerous morphologies have now been accessed, including micelles, vesicles, tubules and more complicated morphologies [1,2]. The specific vesicular morphology, especially formed by the association of lipids, is one of the most interesting aspects both for material science and biological perspectives [2,3]. Nevertheless, applications involving these so-called liposomes are generally limited by their lack of stability probably due to a too small hydrophobic layer thickness forming the core of the liposome membrane [4,5]. Different groups reported on the vesicle formation from block copolymers (called polymersomes) in water and discussed on the improvement of the mechanical properties of the membranes obtained [6–11]. Recently, vesicles have also been obtained from peptide-based diblock copolymers in our group [12] and are called peptosomes [13,14]. In this context, the introduction of nanoscopic inorganic objects into self-organized structures is still a challenge for physico-chemists, even if Nature produces and uses frequently these hybrids. For example, calcium carbonates or phosphates [15] and iron oxides [16] are colloidal particles commonly observed in organisms that are often confined within vesicles. In addition to the biomimetic aspect of these kinds of systems, the formation of hybrids, constituted with nanoscale inorganic compounds dispersed into a self-assembled organic structure, presents two limits: the inorganic particles can be diluted and are only used as local probe, or they can really participate in the supramolecular structure and modify the resultant properties. Nevertheless, the inclusion of magnetic nanoparticles into supramolecular structures and the study of the resulting structure and its properties are still missing, even if some groups are working on the stabilization of these colloidal particles with low and/or high molecular weight surfactant, or on their introduction into polymeric gels.

A novel type of hybrid colloids is presented in this contribution, based on the association of several polymeric systems and ferrofluids. On one hand, we use inorganic nanoparticles made of magnetic iron oxide, which respond to a magnetic field of low intensity. On the other hand the organic part is made of mesoscopic structures (vesicles and micelles) self-assembled from amphiphile polybutadiene-*b*-poly(glutamic acid) diblock copolymers, conformation of which is pH-sensitive. Those PB-*b*-PGA copolymers bearing a cross-linkable hydrophobic block and a hydrophilic peptidic block have been synthesized recently by combining anionic polymerization and ring-opening polymerization [12]. Their polydispersity indices are small enough to obtain well defined self-assembled aggregates. For example, the PB₄₀-*b*-PGA₁₀₀ copolymer leads in water to closed bilayers that also exhibit the particularity of responding to an external pH change by a significant variation of size: their hydrodynamic diameter d_H varies indeed from 200 nm in an acidic medium to 300 nm in a basic medium [17] (or 250 nm in concentrated brine). This transition with pH is fully reversible and is only moderately sensitive to salinity for it is not based on a simple polyelectrolyte swelling effect but on the peptidic nature of the PGA block, which exhibits a real transition between a compact helix conformation at acidic pH and a stretched coil conformation at basic pH.

As for the magnetic nanoparticles, they come from ionic ferrofluids which are colloidal suspensions of nanometric magnetic grains stabilized either in aqueous media by electrostatic charges or in organic solvents by appropriate tensioactives. Before grafting these dispersant molecules, the precursor ferrofluid [18] is prepared by alkaline co-precipitation of FeCl₂ and

FeCl₃ leading to Fe₃O₄ (magnetite) nanocrystals, followed by surface sign reversal with HNO₃ and complete oxidation using Fe(NO₃)₃, which yields positively charged γ -Fe₂O₃ (maghemite) particles in HNO₃. One of the goals of embedding maghemite nanoparticles into the supra-macromolecular objects formed by diblock copolymers consists in utilizing the particles as probes for neutrons scattering in order to elucidate the strong morphological transformation of the vesicles during the size transition between acidic and basic pH. One expects indeed to detect a transient opening of the bilayer and/or a leak-out of the encapsulated content. For this purpose, we benefit from the very strong contrast of the iron oxide particles compared to polymer and solvent by measuring their structure factor inside the aggregates: this $S_{\text{intra}}(q)$ gives indeed both the mean inter-particle distance [19] (hence their local concentration) and the global form factor of the object that they decorate [20]. Another guiding idea is to bring to the whole object a response to a magnetic field, either an induced shape change (ellipsoidal or not) or to trigger the delivery of an active substance by the application of a field.

2. Results and discussion

This work started by the verification that those organic and inorganic systems can effectively be combined together to generate well defined objects which can be properly dispersed into a solvent. Therefore we examined a series of PB-*b*-PGA copolymers which differ by the length of their polypeptide PGA block, their hydrophobic block PB being chosen to enable an easy way to cross-linking within the frame of a future freezing of the structures. In this paper, we present a few cases representative of the reachable structures:

- PB₄₈-*b*-PGA₁₁₄ and PB₄₈-*b*-PGA₁₄₅ which self-assemble in water as micelles of hydrodynamic diameters $d_{\text{H}} = 60$ nm and $d_{\text{H}} = 70$ nm, respectively, the internal diameter of the hydrophobic core being $d_{\text{int}} = 14$ nm as measured by SANS in both cases [21].
- PB₄₈-*b*-PGA₅₆ which forms closed membranes in water, i.e. vesicles characterized by an outer diameter $d_{\text{H}} = 100$ nm and a bilayer thickness $\delta = 14$ nm [21].

We tested the association of these two copolymers with three either aqueous or organic ferrofluids, in which grain size polydispersity had been reduced in a first step by the method of fractionated phase separations [22] by adding excess HNO₃:

- S1S-HNO₃ acidic ferrofluid is an aqueous acidic ferrofluid (pH = 1.2) with a particle size distribution characterized by a Log-normal law of parameters, $d_0 = 6.6$ nm and $\sigma = 0.21$. Its iron oxide surface is coated simply by H⁺ protons, thereby leaving a free access for a future grafting by the glutamic acid moieties of the copolymers.
- S1S-Na₃Cit citrated ferrofluid comes from the previous acidic ferrofluid after coating by trisodium citrate ligands, thus enabling a dispersion at pH = 7.
- S2-CH₂Cl₂ surfacted ferrofluid is grafted by a phosphoric di-ester type tensioactive (Beycostat NE) for a solubilization in dichloromethane. It also has a slightly broader distribution of particle sizes ($d_0 = 6.8$ nm, $\sigma = 0.24$).

The assembly of each copolymer mixed with either 1 or 2 equivalents of the surfacted ferrofluid S2-CH₂Cl₂ was favored by first eliminating the dichloromethane and then redispersing the objects into water, after deprotonating the acidic groups of the copolymer with NaOH to raise the pH up to ≈ 7 . In the case of the bare acidic particles S1S-HNO₃, the flocculation was

induced almost instantaneously after the addition of PB-*b*-PGA copolymers. The supernatant could then be easily replaced by CH₂Cl₂. Finally with SIS-Na₃Cit ferrofluid, the interaction with all the polymers did not lead to any visible destabilization.

After three weeks, all suspensions were analyzed by dynamic light scattering (DLS) and small angle neutrons scattering [23] (SANS). Thus we could show that some of the (co)polymer–particle aggregates reach an equilibrium shape and a proper dispersion state.

Samples PB₄₈-*b*-PGA₁₁₄ and PB₄₈-*b*-PGA₁₄₅ mixed with the S2-CH₂Cl₂ surfacted ferrofluid (A) leads to a dispersion of magnetic micelles in water, diameters d_H of which are between 430 nm and 225 nm (Tables 1 and 2). The large increase of the outer diameter compared to unloaded micelles ($d_H = 60$ nm and 70 nm for PB₄₈-*b*-PGA₁₁₄ and PB₄₈-*b*-PGA₁₄₅, respectively [21]) suggests that their hydrophobic cores are filled with nanoparticles at a high local concentration. The short inter-particle distance given around 80 Å by the position of the structure peak (Fig. 1) corresponds to a volume fraction of nanoparticles inside the micelles of about 45%, of the order of the dense packing value. This high encapsulation yield together with the global 3-d shape of the aggregates is confirmed by a look at the TEM and AFM images in the case of PB₄₈-*b*-PGA₁₁₄, which shows large and thick baggies of inorganic particles. Please note that the copolymer samples combined with 2 mass equivalents of ferrofluid lead to final volume fractions Φ of nanoparticles (from titration of iron) which are 6–7 times smaller than those with 1 mass equivalent (Fig. 2). This difference originates from the fact that the objects are fully dispersed only in the former case but not in the latter case. Thus with 2 equivalents, we get supernatants which are globally more dilute in copolymer–particles complexes.

Table 1

Short summary of samples and self-assembled hybrid objects that have been prepared

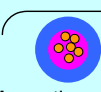

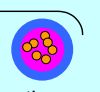

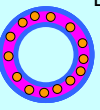

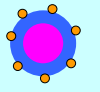

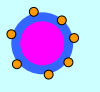

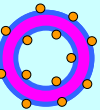

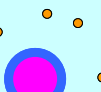

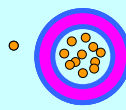

PB_n - <i>b</i> -PGA _p γ-Fe ₂ O ₃ Nanoparticles	PB ₄₈ - <i>b</i> -PGA ₁₄₅ in H ₂ O	PB ₄₈ - <i>b</i> -PGA ₁₁₄ in H ₂ O	PB ₄₈ - <i>b</i> -PGA ₅₆ in H ₂ O	PB ₄₈ - <i>b</i> -PGA ₂₀ in CH ₂ Cl ₂
-surfacted in CH ₂ Cl ₂ $d_0=6.8\text{nm}$ $\sigma=0.24$	 Magnetic Micelles	 Magnetic Micelles	 Magnetic vesicles	
-acidic in HNO ₃ (pH=1.2) $d_0=6.8\text{nm}$ $\sigma=0.24$				
	Objects are not properly dispersed (after 1 month)			
-titrated in Na ₃ Cit (pH=7) $d_0=6.6\text{nm}$ $\sigma=0.21$			 Magnetic vesicles	not properly dispersed
	not properly dispersed

^a Mass equivalent of ferrofluid compared to the copolymer in preparation.^b Code corresponding of the system related to Table 1 and to the text.^c Real concentration of ferrofluid in the final mixture (measured by titration of iron).^d Hydrodynamic diameter as measured by DLS with CONTIN analysis.^e Two populations were observed by DLS.

These peptide-based micellar systems are thus able to encapsulate a large volume of nanoparticles, inducing an over-concentration in these baggies (about 30%), even if the global concentration in the solution is very low ($\Phi_{\text{ferro}} \approx 0.1\%$). More interestingly, these systems are pretty stable compared to ferrofluids alone at the same concentration. Another interesting point comes from the fact that these diblocks are able to be stabilized in micelles with very big sizes when loaded with nanoparticles compared to their equilibrium state in pure water solutions.

Vesicles of PB₄₈-*b*-PGA₅₆ still form in water when in the presence of S2-CH₂Cl₂ (**B**), their outer diameter being significantly increased ($d_{\text{H}} = 620$ nm and 210 nm for 1 and 2 mass equivalents, respectively). Due to their hydrophobicity, the surfacted nanoparticles are confined in 2-d between the two leaflets of the copolymer bilayer, as proved separately by SANS

Fig. 1. Intra-aggregates' structure factor $S_{\text{intra}}(q)$ for hydrophobic nanoparticles associated to PB₄₈-*b*-PGA₁₁₄ and PB₄₈-*b*-PGA₁₄₅, as measured by SANS [24].

Fig. 2. AFM (left) and TEM (right) pictures of hybrid copolymer micelles loaded with magnetic nanoparticles, obtained by combining PB₄₈-*b*-PGA₁₁₄ and 1 mass equivalent of surfacted ferrofluid S2-CH₂Cl₂. The scale bar measures 400 nm in both cases.

measurements, TEM pictures and AFM imaging (which in addition contains a valuable topographical information). Fig. 3 represents the intra-aggregate structure factor $S_{\text{intra}}(q)$ measured by SANS for the hydrophobic nanoparticles associated to PB₄₈-*b*-PGA₅₆ diblock copolymer forming vesicles. In the small q -regime, the form factor of the aggregate follows a power law with a slope approximately -2 typical for flat samples, thus confirming a vesicle-type morphology of the organic–inorganic complex. In this q -region, one can calculate the thickness of the layer forming the vesicle membrane ($\log q^2 S_{\text{intra}}(q) \approx -q^2 \delta^2/12$). From these data, we obtained $\delta = 8.6$ nm and $\delta = 17.7$ nm, respectively, for the system with 1 equivalent and 2 equivalents of the ferrofluid. As the diameter of the ferrofluid itself is 6.8 nm, one can conclude that this membrane is formed by one or two layers of the magnetic colloids depending on the preparation. These results corroborate the fact that the structure peak due to the particles in contact (8 nm) is absent for the preparation obtained with 1 equivalent of ferrofluid that only forms one layer of the inorganic colloid inside the polymeric membrane.

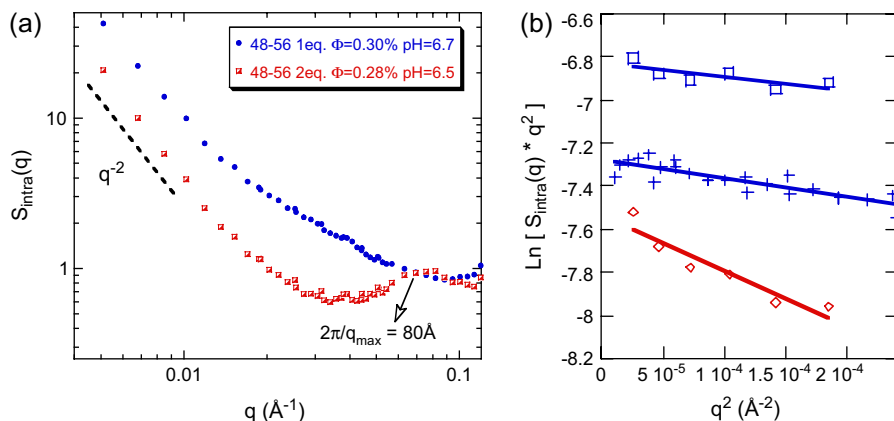

Fig. 3. (a) Intra-aggregates' structure factor $S_{\text{intra}}(q)$ for hydrophobic nanoparticles S2-CH₂Cl₂ associated to PB₄₈-*b*-PGA₅₆, as measured by SANS [24]. (b) Kratky–Porod plots of the same data, slope of which gives the values $\delta_{1\text{eq}}$ and $\delta_{2\text{eq}}$ of membrane thickness.

Fig. 4. (a) TEM picture of a magnetic membrane made of PB₄₈-*b*-PGA₅₆ and 1 equivalent of S2-CH₂Cl₂ (bar length is 333 nm); (b) AFM pictures of the same sample (the bar measures 500 nm on the left and 150 nm on the right).

These data are confirmed by TEM (Fig. 4a) and AFM (Fig. 4b) observations done on the same samples. TEM and AFM measures show only the nanoparticles, respectively, because of the low electron density and low mechanical properties of the polymer compared to the iron oxide. The uniform film visible around the objects by AFM is likely the pure copolymer bilayer spreading onto the mica substrate, with a measured height $\delta_{\text{AFM}} = 4.5$ nm. The vesicles appear holey on the pictures because the strong adhesion of those soft shells on high energy surfaces (freshly cleaved mica for AFM or Formvar coated graphite for TEM) necessitates the ripping of the bilayers (a sort of like peeled orange skins!).

To the authors' knowledge this is the first described case of vesicles with a fluid magnetic membrane [25]. Several magnetic shells were already mentioned in literature [26,27], but none as hollow and floppy as ours. An appropriately designed theory describing their deformation under an applied magnetic field predicts a prolate–oblate transition in that case [28].

Vesicles and micelles of PB₄₈-*b*-PGA₂₀ can also be obtained in CH₂Cl₂ depending on the hydrophilic magnetic particles used (C). When 2 equivalents of the S1S-HNO₃ ferrofluid are added to PB₄₈-*b*-PGA₂₀ the system tends to form a mixture of micelles and vesicles with d_{H} , respectively, of 76 nm and 466 nm, as can be observed by DLS. When the other ferrofluid S2-HNO₃ is added to PB₄₈-*b*-PGA₂₀ the equilibrium structure becomes only spherical micelles with a $d_{\text{H}} = 68$ nm. As the two ferrofluids used are almost identical in terms of size and polydispersity, this difference traduces that the vesicle morphology is probably not thermodynamically stable under these experimental conditions. Moreover, the interaction of the magnetic colloids with the copolymer seems also to be quite different, resulting in a different volume ratio in the solution.

Vesicles self-assembling in water from PB₄₈-*b*-PGA₅₆ can also be filled in their inner aqueous compartment (D) with a neutral ferrofluid just as S1S-Na₃Cit, thereby obtaining magnetic polymersomes analogous to magnetoliposomes [29], which are lipid vesicles loaded with an aqueous ferrofluid at pH 7. In the same way as for magnetic liposomes, after preparing the vesicles one can separate them from nonencapsulated nanoparticles by column chromatography with Sephacryl S1000 as a separating medium [29]. The sorting process is studied by a look at the structure factor $S_{\text{intra}}(q)$.

The low q -region of Fig. 5 is a part of the form factor of large 3-d objects present in both samples. The structure peak in the initial unsorted dispersion gives a local concentration $\Phi_{\text{local}} = 11\%$ inside the vesicles superior to the average concentration $\Phi = 6\%$ (from iron titration). The less pronounced shoulder is still visible in the curve after passage through the column corresponds to $\Phi_{\text{local}} = 0.07\%$, which is 3–4 times higher than the average $\Phi = 0.02\%$. The

Fig. 5. SANS curves for $PB_{48}\text{-}b\text{-}PGA_{56}$ vesicles prepared in the citrated ferrofluid S1S- Na_3Cit before and after column fractionation.

enrichment of loaded vesicles compared to free particles is thus concomitant with a global dilution of all the objects and a partial leak-out of the vesicles, maybe due to a larger size of copolymer vesicles than liposomes described in Ref. [29], compared to the porosity of the separating medium.

3. Conclusions

The main challenge addressed in this paper was to build complexes of maghemite nanoparticles and diblock copolymers into supra-macromolecular objects. The use of these inorganic magnetic particles had two advantages: the first one resides in the fact that they can be model systems for encapsulation of hydrophilic and/or hydrophobic species; the second one consists in utilizing the particles as probes for neutrons scattering in order to elucidate the strong morphological transformation of the vesicles or micelles that were formed by the organic material itself. We demonstrated that spherical micelles in water filled with hydrophobic ferrofluid can be stabilized at a concentration as high as 45% (volume concentration in the micelles). The vesicular morphology is even more interesting than the micelles: these hollow baggies can either encapsulate isolated volumes of hydrophilic ferrofluid or, when the nanoparticles are on the contrary hydrophobic, confine them within the membranes, leading to 2-dimensional “necklace” structure observed by TEM. Finally, inverse systems in organic solvent (dichloromethane) can be obtained by forming spherical micelles or mixtures of micelles and vesicles depending on the hydrophilic ferrofluid used.

Now that we elucidated the self-assembly of those 2-d or 3-d hybrid objects made of magnetic nanoparticles and (co)polymers, the next steps of this study will consist in attempting to modify their shape thanks to the magnetic field. We have started by studying the deformation of the vesicles confining maghemite nanoparticles within their membrane under a constant

magnetic field B [30]: in that case, the anisotropy of the SANS patterns demonstrates a local reorganization of the nanoparticles attributed to an overall ellipsoidal deformation of the vesicles. Then with a time varying field B (for instance a rotating field) we could generate further complex shapes like the starfish-like ones well known for concentrated ferrofluid droplets. Preparing those original shapes with samples at the mesoscopic scale represents a challenge for the physical chemistry community. The aggregates of ferrofluids with diblock rod-coil copolymers open a possible route to reach this goal, also offering the possibility to freeze the structures by cross-linking unsaturated blocks like polybutadiene. The deformation of soft magnetic objects by appropriate DC or AC fields followed by cross-linking seems to us a novel and original way to reach complex mesoscopic shapes. In addition and even more interestingly, these magnetic nanocapsules that can be filled either by hydrophobic and hydrophilic species certainly represent a very promising class of materials for encapsulation of various drugs. By combining a pH change with the application of a magnetic field, we could further enhance the deformation of those vesicles and deliver drugs more efficiently than with a single stimulus. We are currently working in these directions.
