**HAL** is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

## 26 **Abstract**

27

28 29 30 31 32 33 34 35 Accurate estimations of water balance are needed in semi-arid and sub-humid tropical regions, where water resources are scarce compared to water demand. Evapotranspiration plays a major role in this context, and the difficulty to quantify it precisely leads to major uncertainties in the groundwater recharge assessment, especially in forested catchments. In this paper, we propose a lumped conceptual model (COMFORT), which accounts for the water uptake by deep roots in the unsaturated regolith zone. The model is calibrated using a five year hydrological monitoring of an experimental watershed under dry deciduous forest in South India (Mule Hole watershed).

36

37 38 39 40 41 42 43 The model was able to simulate the stream discharge as well as the contrasted behaviour of groundwater table along the hillslope. Water balance simulated for a 32 year climatic time series displayed a large year-to-year variability, with alternance of dry and wet phases with a time period of approximately 14 years. On an average, input by the rainfall was 1090 mm.year<sup>-1</sup> and the evapotranspiration was about 900 mm.year<sup>-1</sup> out of which 100 mm.year<sup>-1</sup> was uptake from the deep saprolite horizons. The stream flow was 100 mm.vear<sup>-1</sup> while the groundwater underflow was 80 mm.year-1.

44

45 46 47 48 49 The simulation results suggest that i) deciduous trees can uptake a significant amount of water from the deep regolith, ii) this uptake, combined with the spatial variability of regolith depth, can account for the variable lag time between drainage events and groundwater rise observed for the different piezometers, iii) water table response to recharge is buffered due to the long vertical travel time through the deep vadose zone, which constitutes a major water reservoir.

This study stresses the importance of long term observatories for the understanding of hydrological processes in tropical forested ecosystems. 50 51

52

55

#### 56 **Introduction**

57

58 59 60 61 62 Accurate assessment of water balance at the watershed scale is of major importance in a context of a global dramatic increase of human demand for water, either for urban or agricultural requirements. This assessment is complex, since water balance results from the interaction of climate, geology, morphology, soil and vegetation (De Vries and Simmers, 2002).

63 64 65 66 67 68 69 70 71 72 A large suit of rainfall-runoff models are available that are either fully empirical or mechanistic, which make it possible to predict with reasonable accuracy water balance from watersheds in temperate climates (Beven, 2001 ; Wagener et al., 2004). These models are usually evaluated according to their ability to simulate stream discharge. In semi-arid or arid climates, calibration of watershed models is difficult because streams are often ephemeral. Moreover, as potential evapotranspiration equals or surpasses average precipitation, a correct evaluation of actual evapotranspiration becomes crucial (Scanlon et al., 2002, 2006 ; Sekhar et al., 2004 ; Anuraga et al., 2006). Despite the large amount of work dedicated to assess evapotranspiration at the watershed scale, this flux remains the largest source of uncertainity in water budgeting, especially in the case of forested watersheds (Zhang et al., 2001; 2004).

The objective of this paper is to propose a methodology for water balance estimation in a tropical forested watershed, based on the calibration of a conceptual model against stream discharge and groundwater level data. The experimental watershed used in this study was developed as part of the project "Observatoire de Recherche en Environnement – Bassin Versant Expérimentaux Tropicaux" (<http://www.ore.fr/>) (Braun et al., 2005). Our results 74 75 76 77 show that the deep vadose zone plays a major role in buffering the groundwater response to the water percolation. 78 79 80

81

#### 82 **Site description**

83

84 85 The study site is situated in South India (Figure 1), at  $11^{\circ}$  44' N and  $76^{\circ}$  27' E (Karnataka state, Chamrajnagar district).

86

#### 87 *Figure 1: Location map of the experimental site*

88

89 90 91 92 93 94 95 96 97 98 It is located in the transition zone of a steep climatic and geomorphologic gradient at the edge of the rifted continental passive margin of the Karnataka Plateau, which was the focus of extensive geomorphologic studies (Gunnell and Bourgeon, 1997). This plateau, developed on the high-grade metamorphic silicate rocks of the West Dharwar craton (Moyen et al., 2001), is limited westward by the Western Ghâts, a first order mountain range. This mountain forms an orographic barrier, inducing an steep climatic gradient, with annual rainfall decreasing from west to east from about 6000 mm to 500 mm within a distance of about 80 km (Pascal, 1982). These Ghâts are of critical ecological and economical importance and also an important source of all major South Indian rivers, flowing eastward towards the Gulf of Bengal. The climatic transition zone is mainly covered by dry deciduous forests, belonging to

the wildlife sanctuaries of Mudumalai, Waynad, Bandipur and Nagarahole (Prasad and Hedge, 1986). Such a tropical climosequence is comparable, although much steeper (Gunnell, 2000), to the well documented monsoonal West African and the Northeast Brazilian climosequences (Gunnell, 1998). 99 100 101 102

103

104 105 106 107 108 109 110 111 112 113 The Mule Hole experimental watershed  $(4.1 \text{ km}^2)$  is located in the climatic semi-humid transition area and the mean annual rainfall ( $n = 25$  years) is 1120 mm. The mean yearly temperature is 27 °C. On the basis of the aridity index defined as the ratio of mean annual precipitation to potential evapotranspiration, the climate regime can be classified as humid (UNESCO, 1979). Nevertheless, the climate is characterized by the occurrence of a marked dry season (around 5 months from December to April) and by recurrent droughts, depending on the monsoon rainfalls. The rainfall pattern is bimodal, as it is affected by both the South West Monsoon (June to September) and the North East Monsoon (October - December) (Gunnell and Bourgeon, 1997). Streams are ephemeral, and their flow duration ranges from a few hours to a few days after the storm events.

114

115 116 117 118 119 120 121 122 123 The watershed is mostly undulating with gentle slopes and the elevation of the watershed ranges from 820 to 910 m above sea level (Figure 1). The morphology of the watershed is convexo-concave highly incised by the temporary stream network. The lithology, representative of the West Dharwar craton (Naqvi and Rogers, 1987), is dominated by complexly folded, heterogeneous Precambrian peninsular gneiss intermingled with mafic and ultramafic rocks of the volcano-sedimentary Sargur series (Shadakshara Swamy et al., 1995). The Peninsular gneiss represents at least 85% of the watershed basement and the average strike value is N80°, with a dip angle ranging from 75° to the vertical (Descloitres et al., 2008). In such hard-rock context, the aquifer can generally be divided into two parts: one

upper part is the porous clayey to loamy regolith with an apparent density lower than the rock bulk density, the other is in the fractured-fissured protolith with an apparent density close to the bulk density of the rock and a network of fractures of a density decreasing with depth (Sekhar et al., 1994, Maréchal et al., 2004 ; Wyns et al., 2004 ; Dewandel et al., 2006). In the Mule Hole watershed, the average depth of the regolith is 17 m, as estimated through an extensive geophysical and geochemical survey (Braun et al., 2006 ; Braun et al., 2008). The distribution of the regolith depth (Figure 2) shows that the range of variation is 5 to 27 m. No correlation with the position on the hillslope was found. Average total porosity of the regolith is around 12%. Magnetic Resonance Sounding (MRS) performed on the watershed (Legchenko et al., 2006) showed that drainage porosity is around 1% in the regolith and below the detection level  $(\leq 0.5\%)$  in the fractured rock. Finally, timelapse geophysical measurements of both ERT and MRS conducted at the outlet of the watershed indicated a seasonal infiltration of water under the stream (Descloitres et al., 2008). A hydrological investigations allowed estimating the indirect recharge from the stream at around 30 mm.year-<sup>1</sup> at the watershed scale (Maréchal et al., 2009). 124 125 126 127 128 129 130 131 132 133 134 135 136 137 138

139

### 140 141 *Figure 2 : distribution of regolith depth across the Mule Hole watershed (from a geophysical and geochemical survey by Braun et al., 2008)*

142

143 144 145 146 147 148 The soil distribution in the watershed was determined by Barbiéro et al. (2007). The gneissic saprolite, cohesive to loose sandy, crops out both in the streambed and at the mid-slope in approximately 22% of the watershed area. The lower part of the slope and the flat valley bottoms (12% of the area) are covered by black soils (Vertisols and Vertic intergrades), which are 2 m deep on an average. Shallow red soils (Ferralsols and Chromic Luvisols), which are of 1 to 2 m deep, cover 66% of the entire watershed area. The watershed is covered by a dry

deciduous forest with different facies linked to the soil distribution (Barbiéro et al., 2007). Minimal human activity is present as it belongs to the Bandipur National Park, dedicated to wildlife and biodiversity preservation. The predominent tree component of the vegetation consists of *Anogeissus-Terminalia-Tectona* association (ATT facies) forming a relatively open canopy not exceeding 20 m (Prasad and Hedge, 1986 ; Pascal, 1986). Phenology is marked by a strong seasonality, with leaf senescence starting in December and leaf flushing occurring in early April, one or two month before the first significant monsoon rains. This surprising behaviour, leading to a deciduous period of only 2-3 months, much shorter than the dry season, is a general feature of the Asian forests (Singh and Kushawaha, 2005), and was quoted as the "paradox of Asian monsoon forest" by Elliot et al. (2006). 149 150 151 152 153 154 155 156 157 158

159

#### 160 **Model description**

161

162 163 164 165 166 167 168 169 170 The model COMFORT (**CO**nceptual **M**odel for hydrological balance in **FOR**es**T**ed catchments) proposed in this article allows simulating the daily water budget of a forested watershed, through a simple and widely accepted conceptual description of the hydrological processes. It includes a lumped model for the soil moisture and the evapotranspiration in the forest (Granier et al., 1999), a surface runoff model based on the variable source area theory (Moore et al., 1983 ; Beven, 2001) and linear reservoirs for the recharge and groundwater discharge (Beven, 2001 ; Putty and Prasad, 2000). Its originality relies on the introduction of an additional water reservoir located in the weathered vadose zone (saprolite) below the soil, accessible to tree roots but not to understorey vegetation roots.

171

#### 172 *Figure 3 : A schematic representation of the model COMFORT*

The throughfall  $(Rf - E_{In})$  on the saturated area of the watershed  $(SA \text{ in } \%)$  reaches the stream as surface runoff (Os in mm.day<sup>-1</sup>) : 199 200

201

202  $Q_s = (Rf - E_{In}) \times SA / 100$ 

203

204 205 206 207 Saturated area is usually computed as a function of water storage in the soil and the groundwater (see for example Putty and Prasad, 2000). In our context, groundwater level is far below the ground level, thus SA is modelled as an exponential function of the soil moisture deficit:

208

$$
209 \quad SA = SA_{max} \times \exp(-a \times SMD)
$$

210

211 212 213 214 with  $SA_{\text{max}}$  the maximal extension of the saturated area  $(\%)$ , and a being the exponent constant. The proportion  $(\%)$  of the soil surface covered by tree leaves  $(\epsilon)$  is calculated from the forest LAI with the Beer-Lambert function assuming a light coefficient of extinction of 0.5 (Granier et al. 1999).

215

```
216 
     \varepsilon = 1 - e^{-0.5 \times \text{LAI}}
```
217

218 219 The evaporation of rainfall intercepted by the forest canopy, or interception losses,  $E_{In}$  $(mm.day^{-1})$  is computed as:

220

221  $E_{In}$  = minimum (ε × Rf ; ε × PET ; ε × In)

with In (mm) the canopy storage capacity. This equation implies that canopy cannot store water for more than one day, and thus interception losses are nil during non rainy days. This simplification is justified by the fact that In is generally smaller than PET at a daily time step. 223 224 225 226

227 228 229 230 231 As proposed by Granier et al. (1999), to account for the fact that the rate of evaporation of intercepted water is approximately four time greater than transpiration rate (Rutter, 1967), PET is reduced by 20 % of the amount of intercepted water and the total actual evapotranspiration (AET) is limited to  $1.2 \times$  PET. The tree transpiration from the soil layer  $(T_s$  in mm.day<sup>-1</sup>) is then calculated as:

232

233 
$$
T_s
$$
 = minimum (SMD<sub>max</sub> – SMD ; ( $\varepsilon \times$  PET) – (0,2 × E<sub>In</sub>) ; 1.2 × PET - E<sub>In</sub>)

234

235 236 237 238 239 with SMD<sub>max</sub> the maximum soil water deficit (mm), equivalent to the soil water holding capacity. In their model, Granier et al. (1999) propose that T/PET ratio decreases linearly when soil moisture reaches a critical level of 40% of the water holding capacity of the soil. In our model, for the sake of simplicity, transpiration is only limited by the amount of water present in the soil reservoir.

240

241 Evapotranspiration from understorey vegetation is calculated as:

242

243  $E_u$  = minimum (SMD<sub>max</sub> – SMD – T<sub>s</sub>; (1-ε) × PET; 1.2 × PET - T<sub>s</sub> - E<sub>In</sub>)

244

245 Actual evapotranspiration from the soil layer (AETs in mm.day<sup>-1</sup>) is then:

246

247  $AET_s = E_{In} + T_s + E_u$   Eventually, the water in excess in the soil reservoir (when SMD<0) percolates below the soil layer, as "potential recharge" (PR in  $mm.$ day<sup>-1</sup>). This flow is an input to the weathered zone reservoir (module 2).

#### *Module 2: Weathered zone and groundwater*

 This module simulates the daily variations of the moisture deficit in the weathered zone (WZMD in mm) as :

  $\triangle$ WZMD = T<sub>WZ</sub> + R - PR

 where  $T_{WZ}$  is the tree transpiration from the weathered zone below the soil (mm.day<sup>-1</sup>), PR the potential recharge calculated in the module 1 (mm.day<sup>-1</sup>) and R (mm.day<sup>-1</sup>) the recharge. The potential evapotranspiration from the weathered zone  $(mm.day^{-1})$  is the residual of the potential transpiration of trees minus the actual tree transpiration in the soil zone:

```
265 
PET_{WZ} = \varepsilon \times PET - (0.2 \times E_{In}) - T_s
```
 The actual transpiration from the weathered zone  $T_{WZ}$  (mm.day<sup>-1</sup>) is then:

$$
269 \tT_{WZ} = \text{minimum (WZMD}_{\text{max}} - \text{WZMD}; \text{PET}_{\text{WZ}})
$$

 with  $WZMD_{max}$  (mm) the maximum water deficit of the weathered zone.

297

298 with  $L_0$  (masl) the altitude of the base of the aquifer and Sy its specific yield.

299

#### 300 **Data acquisition and model calibration procedure**

301

302 303 304 305 306 307 308 309 310 311 312 313 314 315 316 The climatic data (daily rainfall and PET) necessary to run the model were available for the period 2003-2007 from the automatic weather station (CIMEL, type ENERCO 407 AVKP) installed at the Mulehole forest check post, which is 1.5 km West to the watershed outlet (Figure 1). Daily rainfall data were available at the same location from 1976 to 1995 from Indian Meteorological Department. Daily rainfall data were also available from the Ambalavayal weather station, located 20 km west of the study site, for the years 1979 to 2004. As statistical analysis showed a strong correlation between the two stations, the seven missing years (1996-2002) in the Mule Hole were inferred from the Ambalavayal data. Granier at al. (1999) have shown that soil water content can be equally simulated in forest stands under different climates either with models based on Penmann potential evapotranspiration or with mechanistic approaches tacking into account the canopy structure. Although many studies have shown that evapotranspiration is greater from forest than for the short size vegetation (Zhang et al., 2001) this difference is mainly attributed to better access to soil water at depth. Thus Penmann potential evapotranspiration was used as a forcing variable to the model.

317

318 319 320 321 As year to year variations in PET were little during the years 2003 to 2007, an average daily PET series was calculated and applied to the period 1976-2002. Using an average annual curve of PET does not affect much the rainfall-runoff models (Burnash, 1995 ; Oudin et al., 2005). The simulations were run on the reconstructed time series 1976-2007. Stream

discharge  $(Q_s)$  is measured since August 2003 at a 6 minutes time step using a flume built at the outlet of the watershed. Due to technical problems, level recording was not available from  $15<sup>th</sup>$  April 2007 to  $7<sup>th</sup>$  August 2007. A set of 13 observation wells were drilled in the area in 2003 (P1-P6) and 2004 (P7-P13) (Figure 1). Most of these wells are dedicated to the monitoring of the effects of water seepage from the stream. Wells P2, P3, P5, P6, P9 and P10 are not influenced by the indirect recharge from the stream (Maréchal et al., 2009), and can be used to assess the direct recharge. The water levels are monitored in all the wells either manually at a monthly time step or automatically at an hourly time-step. Due to technical problems (among which elephant attacks), P2 and P9 didn't give reliable records and were not included in the analysis. Additional data from an observation well (OW9) monitored by the Department of Mines and Geology (Karnataka State) since 1975, and located 20 km east of the watershed, which is close to the forest border, was used in the analysis. 322 323 324 325 326 327 328 329 330 331 332 333

334

335 336 337 338 339 340 341 342 343 344 As no measurement of forest leaf surface were carried out in the watershed, the evolution of LAI was hypothesised from qualitative observations from the site and references from literature concerning local tree phenology (Prasad and Hedge, 1986 ; Sundarapandian et al., 2005) and NDVI records for Indian forests (Prasad et al., 2005). Seasonality of leaf flushing and senescence is mostly driven by photoperiod, and therefore can be taken as a constant from one year to the other (Elliot et al., 2006 ; Singh and Kushwaha, 2005). The proposed LAI pattern is presented in the Figure 4a along with ε variations. The comparison with the average monthly rainfall and PET over 32 years period (Figure 4b) shows that maximum PET is reached during the deciduous period and that on average, rainfall exceeds PET during five months.

*Figure 4: a) daily forest LAI and coefficient of extinction ε, b) average monthly rainfall (Rf) (1976-2007) and PET (2003-2007). Vertical bars indicate standard deviation of Rf.*  346 347

348

349 350 351 352 353 354 355 356 357 358 359 360 361 362 363 The two modules were run and calibrated successively, and the model performance was assessed using the Nash & Sutcliffe (1970) efficiency criterion. The module 1 is calibrated against the observed stream discharge values. This module has three forcing variables (Rf, PET and LAI) and four parameters (In, a,  $SA<sub>max</sub>$  and  $SMD<sub>max</sub>$ ). As the sensitivity analysis showed that the model was little sensitive to In value, it was set at 1 mm and calibration was performed on the three remaining parameters. The time series obtained for the potential evapotranspiration from the weathered zone ( $PET_{WZ}$ ) and the potential recharge (PR) are then used as forcing variables for the module 2, which includes five parameters (WZMD<sub>max</sub>,  $\alpha_1$ ,  $\alpha_2$ , Sy and  $L_0$ ). The module 2 is calibrated for each piezometer against observed water table levels. To minimize equivalence possibilities, the following procedure was adopted: because WZMD<sub>max</sub> determines the date of initial water table rise, it is first adjusted by trial and error; then the four remaining parameters are automatically calibrated, with Sy values constrained smaller than 0.01, according to the conclusions of MRS survey (Legchenko et al., 2006). For each calibration, the solver was run with contrasting sets of initial parameter values, which later converged towards the same solution.

364

#### 365 **Results**

366

367 368 369 *Figure 5: observed (black line) and simulated (grey line) daily surface runoff (Qs in mm.day-1) at the Mule Hole watershed outlet for the 5 years of monitoring. Secondary axis is daily rainfall (Rf) in mm.* 

The Figure 5 compares the observed and the simulated surface runoff  $(Q_s)$  at the Mule Hole watershed outlet for the 5 years of monitoring. The Nash-Sutcliffe parameter calculated using the monthly values is 74. Despite this relatively low value, the model was able to reproduce the general trend of observed runoff, in particular the delay between the first monsoon rains and the first observed stream runoff. On the other hand, it was unable to reproduce the runoff observed after summer storm events in 2005, because they are due to Hortonian flow, a mechanism that was not accounted for in the model. However, this kind of event is of marginal importance in this pedoclimatic context. Considering that rainfall is measured in only one weather station located outside the watershed and the high spatial variability of rainfall, especially during strong individual storms, a perfect fit was not expected. In particular in 2005, two events, on  $22<sup>nd</sup>$  of October and  $4<sup>th</sup>$  of November, produced 34 mm.day <sup>1</sup> and 20 mm.day<sup>-1</sup> of runoff for rains of 52 mm.day<sup>-1</sup> and 28 mm.day<sup>-1</sup> respectively. For these events, the actual rainfall in the watershed was probably much higher than the measured one. This is likely to have affected the assessment of water balance for the year 2005, as these two storms represent about one quarter of the total yearly runoff. However, this kind of event remains very rare: during the five monitoring years, only these two events produced more than 20mm of runoff, and only five other individual events produced more than 10 mm of runoff. 371 372 373 374 375 376 377 378 379 380 381 382 383 384 385 386 387 388

389

390 391 392 393 394 The calibrated parameter values are:  $a = 0.1$ ,  $SA_{\text{max}} = 33.3\%$  and  $SMD_{\text{max}} = 173$  mm. The value of maximal saturated area is probably overestimated, considering that the flat valley bottom overlaid by black soil occupies about 12% of the watershed area. The two exceptional storm events mentioned above played an important role in this overestimation. The calibrated value of  $SMD<sub>max</sub>$  is consistent with the soil moisture monitoring carried out in 2004 and 2005

in the site, showing a maximum variation of volumetric water content of 7% in red and black soils (Barbiéro et al., 2007) and an average 2 m depth (Braun et al., 2006). 395 396

397

398 399 400 *Table 1 : Soil water balance (mm.year<sup>-1</sup>) for the monitored year and yearly average for the monitored period and the whole 32 year simulated period. Signification of terms is in the text. \*2003-2006 average* 

401

402 403 404 405 406 407 408 409 410 411 412 413 414 415 Annual soil water balances as well as averages for the monitoring period and the 32 years simulation period are presented in the Table 1. Evapotranspiration is the most important sink for water, accounting for about 70% of rainfall. Interception is about 10% of rainfall, which is in the range of references values given in the literature for broad leaved forests (Ward and Robinson, 2000). Potential recharge is large  $(197 \text{ mm} \cdot \text{year}^{-1})$  on the whole period), and displays an important year to year variability. It is larger than the estimate based on the regression equation proposed by Rangarajan and Athavale (2000) from tritium injection experiments in granitic areas in India, which gives a value of about  $150 \text{ mm}$ , year<sup>-1</sup> for the conditions of Mule Hole. This difference might be due to specificities of the study site, in particular the relatively low PET, mainly due to low temperatures linked with the altitude and to the forested environment which contributes to decrease soil compaction and increase infiltration potential (Bruijnzeel, 2004; Ilstedt et al., 2007). Results also show that the monitoring period is quite representative of the whole 32 years period with respect to the soil water balance.

416

417 418 419 *Figure 6 : relative variation of water table level in hillslope piezometer, compared to simulated potential recharge. Reference values for water table depth are 16.8 m, 27.8 m, 39.1 m and 37.4 m for P10, P3, P5 and P6 respectively.* 

420

421 422 423 424 425 426 427 428 429 430 431 432 433 434 435 The Figure 6 compares the simulated daily potential recharge with observed relative variations in the water table level in hillslope piezometers. Although all piezometers showed a consistent global tendency to water level rise, they displayed significant contrasted behaviour. The relatively shallow piezometer (P10) responded each year to recharge, and the water level rise was almost simultaneous with the first occurrence of the potential recharge. Then the water level variation pattern was smooth, and the yearly maximum level was reached each year about two months after the end of the potential recharge period. For P3, the water table level did not increase in 2004, however showed a steep increase at the end of the 2005 rainy season, followed by a gentle continuous increase. In this well, ephemeral water table variations suggest the occurrence of some preferential flow (from August to October in 2006 and 2007). Finally, the deep piezometers P5 and P6 displayed a declining tendency in 2004 and 2005, a stabilisation or a very gentle rise in 2006, and a marked rise at the end of the rainy season 2007. These contrasted patterns of water table variation among the different hillslope piezometers suggest that they are linked with local processes and not by a regional aquifer dynamics.

436

437 438 *Figure 7: Observed (dots) and simulated (lines) water level (in meter above sea level) in piezometer P3, P5 and P10 for the monitoring period.* 

439

#### 440 *Table 2 : Model parameters for the 3 simulated piezometers.*

441

442 443 444 Comparison of the observed and the simulated water level variations in piezometers for the monitoring period show a very good agreement (Figure 7), with Nash criteria values of 96.7, 94.1 and 95.0 for P10, P3 and P5 respectively. Calibrated parameters (Table 2) are relatively

similar for the three piezometers. The most contrasted parameter is  $WZMD<sub>max</sub>$ , the maximum water deficit of the weathered zone, because it accounts for the observed very long lag-time between water table rise observed in P10 in comparison with P3 (more than one year) and with P5 (more than 3 years). The calibrated value of the specific yield is consistent with the values obtained in similar fractured rock context in the region (Sekhar et al. 2004 ; Sekhar and Ruiz, 2006 ; Maréchal et al., 2006). 445 446 447 448 449 450

451

452 453 454 455 456 457 458 The most surprising result is the small value of the recession coefficient of the recharge reservoir  $(\alpha_1)$ . The recharge flow reaching the groundwater table is then very smooth, and it is mostly compensated by the groundwater discharge. The consequence is that the variations in the water content of the deep vadose zone (regolith and recharge reservoirs) are very large, with a maximum range of variation for the entire 32 year period of 650 mm, 745 mm and 851 mm for P10, P3 and P5 respectively. Although very large, these variations are compatible with the material porosity, considering the depth of this vadose zone (from 15 m to 40 m).

459

460 461 *Figure 8 : Simulated variations of water table level (in masl) in piezometer P3, P5 and P10 for the 32 year simulation period (lines). Dots represent observed values.* 

462

463 464 465 *Table 3: Watershed balance components (in mm.year<sup>-1</sup>) for the piezometers P10, P3 and P5, for the monitoring period and the 32 year simulation and average watershed balance components calculated by weighted average (see text) .* 

466

467 468 469 Average water balances components for each piezometer during the monitoring period and the 32 years simulation period are presented in the Table 3. Unlike the observations for the soil water balance, the monitored period appears dryer than the entire period. This is due to

the fact that the effects of the drought period from 2001 to 2003 persist longer at depth, which is apparent from the late rising of the deepest piezometers. The simulated long term variations of piezometers (Figure 8) reveals an alternance of wet and dry phases, of 12-15 years duration period. Maximum level in P5 is reached 2 to 3 years later than in P10. This simulated pattern was compared to the data recorded by the Department of Mines and Geology (Karnataka State) from 1974 to 2007 in a shallow observation well located outside the forest zone 20 km east of the study site. Although at the annual scale the observation well is much more reactive than P10, they display a very similar long-term trend. This observation suggests that the model was able to describe reasonably the global long-term behaviour of the groundwater. 470 471 472 473 474 475 476 477 478

479

480 481 482 483 *Figure 9 : Simulated variations of water table level (in masl) in piezometer P10 (black line, left Y-axis) and water level (depth to ground level in meters) recorded by Department of Mines and Geology from 1974 to 2007 in a shallow observation well located outside the forest zone 20 km east of the study site (grey line with dots, right Y-axis)* 

484

485 486 487 488 489 490 491 492 493 Figure 10 illustrates the simulated variations of evaporation and transpiration during two years. It shows that transpiration by trees from the soil layer is the dominant flux during most of the year, especially during rainy season. Soil evapotranspiration by the understorey vegetation can be significant during dry season, depending on the occurrence of isolated rainy events. Transpiration of water from the deep weathered zone occurs mainly during dry season, and during dry periods on the course of the monsoon season. Because the model computes transpiration successively from soil and then from the weathered zone, the latter can occur only when soil water is completely depleted, leading to abrupt alternances between the two fluxes (figure 10c), which are probably much smoother in reality.

*Figure 10: Example of simulated daily evapotranspiration fluxes (in mm.day-1) compared to PET during two years a) variations of LAI b) Ein and Eu c) Ts and Twz (see text for signification of abbreviations)*  495 496 497

498

499 500 501 502 503 504 505 506 507 508 509 510 511 512 513 514 With an objective to obtain an assessment of the water balance at the watershed scale, we need to assess the representativity of the monitored piezometers with respect to the entire area. The parameter  $WZMD_{max}$ , which is driving the most important part of the observed piezometer variability, is probably linked with the regolith depth in the vicinity of the piezometer. P10 is located in an area where the regolith depth is around 8m, P3 around 15 m and P6 more than 20m. A resistivity logging performed on P5 suggested a regolith depth of 22m (Braun et al., 2008). As a first approach, we can consider that P10, P3 and P5 are representative of area with regolith depth of 0-12m, 12-18m and more than 18m respectively. According to the regolith depth distribution in the watershed (Figure 2), the proportion is 30%, 27% and 43% for P10, P3 and P5 respectively. With this hypothesis, the watershed balance (Table 3) appears roughly equilibrated during the 32 years simulation period, while the water gain was 125 mm vear<sup>-1</sup> during the monitoring period. The average water uptake by trees from the deep weathered zone is 104 mm, and average groundwater underflow is 78 mm.year<sup>-1</sup>. Groundwater recharge is equivalent to underflow on the long term. This value is close to the recharge that was assessed in this area with Chloride mass balance method (45 mm.year<sup>-1</sup>, Maréchal et al., 2009).

515

#### 516 **Discussion**

517

518 519 The 5 years monitoring allowed us to give a tentative assessment of the water balance of a small experimental watershed using a simple conceptual lumped model. However, the

exercise has proven to be difficult, due to the climatic context and the presence of forest. The plausibility of the model results and the future work needed to validate them are discussed in this section. 520 521 522

523

524 525 526 527 528 529 530 531 532 533 534 535 536 537 538 One uncertainty is linked to the assessment of evapotranspiration in forest stands. This issue continues to generate a great deal of controversy in the litterature (Andreassian, 2004 ; Bruijnzeel, 2004 ; Robinson et al., 2003). The difficulty is also greater for regions with the index of dryness (PET/Rf) close to 1.0 (Zhang et al., 2004), which is the case in our study site. However, despite its limitations, the Penman-Montieth PET approach has proven its ability to simulate soil water moisture in a broad range of climatic conditions and tree species (Granier et al., 1999). The average total evapotranspiration found in our long term simulations (around 900 mm.year<sup>-1</sup>, out of which about 100 mm are linked to extra transpiration by deep tree roots, see Table 3) is in very good agreement with the worldwide evapotranspiration curve proposed for forests and grasslands by Zhang et al. (2001). In our climatic context, water percolation towards the deep vadose zone is mainly concentrated during short rainy periods of the monsoon season, usually few days to two weeks, followed by drier periods. In this configuration, soil water budget is less sensitive to evapotranspiration assessment. However, direct measurements of forest evapotranspiration would allow a better calibration of the model.

539

540 541 542 543 544 According to our model, the spatial variability of the water reservoir located at depth in the weathered zone and accessible to deep roots of trees is a key parameter for water budgeting in semi-arid forested watersheds. Our calibration gave values ranging from 50 to 470 mm (Table 2). Few studies have been dedicated to measure the hydraulic properties of weathered granitic rocks (Jones and Graham, 1993; Katsura et al., 2006). They suggest that weathered rocks have

the capacity to hold appreciable amount of water that is available to plants (Jones and Graham, 1993 ; Williamson et al., 2004). The fact that tree roots are able to uptake water at considerable depth, especially in water limited ecosystems is widely accepted (Nepstad et al., 1994 ; Canadell et al., 1996 ; Collins and Bras, 2007). Importance of water storage in deep weathered rock in forested ecosystems has recently gained recognition, and large scale surveys to quantify deep water reservoirs have been attempted, for example in Cambodia (Ohnuki et al., 2008), leading to estimates as high as 1350 mm. The average total porosity of the saprolite in the Mule Hole watershed was estimated at 12% from geophysical and geochemical studies (Braun et al., 2008). Even assuming that the proportion of the porosity available to plants is only 5%, considering a 16 m deep saprolite would lead to an average water storage capacity of 800 mm, which is compatible with our findings. Considerable spatial variability of water stress and tree mortality during drought period is commonly reported in dry deciduous forests (Nath et al., 2006). A survey dedicated to check whether part of this variability can be explained by the regolith depth would constitute a validation of our hypothesis. 545 546 547 548 549 550 551 552 553 554 555 556 557 558 559

560

561 562 563 564 565 566 567 568 569 The most surprising consequence of the model calibration is the great importance of the recharge reservoir, and its low recession coefficient. In temperate regions, recharge process is usually considered to be very quick, and in most models water percolated below the soil zone is immediately transferred to the groundwater. This is acceptable because groundwater table is generally shallow, and the regolith matric porosity is filled every year by recharge. However, the fact that matric water can drain for a long time is well documented (Healy and Cook, 2002). In a chalk aquifer, Price et al. (2000) demonstrated that the delay between recharge period and the smooth water table rise can be explained by matric water storage in the vadose zone, which is slowly released to groundwater during dry periods. By monitoring water

content variations in a 21m deep sandstone vadose zone, Rimon et al. (2007) found a variation of 660 mm of water content during a rainy season, and a slow decrease in water content during the dry season. In a hydrogologic survey in Australia, in a granitic environment, Ghauri (2004) observes a long delay between rainfall and groundwater response, attributed to matric storage in the deep vadose zone. If this hypothesis is confirmed, it could be of considerable importance for water resource evaluation in hard rock aquifers, because in most cases recharge is assessed through water table level methods (Healy and Cook, 2002). Monitoring of water content variations in the deep vadose zone of our experimental watershed would allow validating this hypothesis. 570 571 572 573 574 575 576 577 578

579

580 581 582 583 584 585 586 587 588 The modelled watershed balance leads to an average water flow of about 180 mm.year<sup>-1</sup>, out of which 80 mm is groundwater underflow. This underflow might reach the streams of higher order rivers, like Nugu Hole or Kabini (Figure 1). Indeed, it is very small compared to the estimates of the flows produced in the humid zone of the climatic gradient that range from 900 to 4700 mm.year<sup>-1</sup> (Putty and Prasad, 2000). However, these high flows are produced during the rainy season, and during the dry season rivers virtually dry up (Putty and Prasad, 2000). Because groundwater underflow from transition area produces a fairly constant load, it might be of significant importance in sustaining the baseflow in large rivers during the dry season. This will be assessed through a regional modelling in a future work.

589

#### 590 **Conclusions**

591

592 593 594 This study is based on a five years monitoring of an experimental forested watershed in the South India, and using a conceptual model of the water balance over a 32 years period allowed us to draw the following conclusions :

i) In tropical forest ecosystems, deciduous trees can uptake a significant amount of water from the deep regolith. This mechanism is particularly important at the end of the dry summer period, because the leaf flushing can precede monsoon rains by several weeks. More investigations are needed to check if variability in regolith depth can be linked to the variability of tree mortality during dry periods in monsoon season. 595 596 597 598 599

600 601 602 ii) This water uptake, combined with the spatial variability of regolith depth, can account for the variable lag time between drainage events and groundwater rise observed for the different piezometers.

603 604 605 606 607 608 609 iii) Water table response to the recharge is buffered due to the long vertical travel time through the deep vadose zone, which constitutes a major water reservoir. The five years monitoring period reveals that the watershed water balance is not equilibrated, mainly due to large variations in water content in the vadose zone. This observation is of great importance for water resource assessment, as water level fluctuation method is often used to estimate yearly groundwater recharge, especially in India (G.E.C., 1997). Our results show that this method can lead to an underestimation of recharge when vadose zone is large.

610

611 612 This study stresses the importance of long term observatories for the understanding of the hydrological processes in tropical forested ecosystems.

613

#### 614 **Acknowledgements**

615 616 617 618 619 The Mule Hole basin is part of the ORE-BVET project (Observatoire de Recherche en Environnement – Bassin Versant Expérimentaux Tropicaux, www.orebvet.fr). Apart from the specific support from the French Institute of Research for Development (IRD), the Embassy of France in India and the Indian Institute of Science, our project benefited of funding from IRD and INSU/CNRS (Institut National des Sciences de l'Univers / Centre National de la

Recherche Scientifique) through the French programmes ECCO-PNRH (Ecosphère Continentale: Processus et Modélisation – Programme National Recherche Hydrologique), EC2CO (Ecosphère Continentale et Côtière) and ACI-Eau. It is also funded by the Indo-French programme IFCPAR (Indo-French Center for the Promotion of Advanced Research W-3000). The multidisciplinary research carried on the Mule Hole watershed began in 2002 under the control of the IFCWS (Indo-French Cell for Water Sciences), joint laboratory IISc/IRD. We thank the Department of Mines and Geology of Karnataka for providing data and the Karnataka Forest Department and the staff of the Bandipur National Park for all the facilities and support they provided. 620 621 622 623 624 625 626 627 628
