# Asymptotic optimal SINR performance bound for space-time beamformers

Marc Oudin and Jean Pierre Delmas

## Abstract

In many detection applications, the main performance criterion is the Signal to Interference plus Noise Ratio (SINR). After linear filtering, the optimal SINR corresponds to the maximum value of a Rayleigh quotient, which can be interpreted as the largest generalized eigenvalue of two covariance matrices. Using an extension of Szegö's theorem for the generalized eigenvalues of Hermitian block Toeplitz matrices, an expression of the theoretical asymptotic optimal SINR w.r.t. the number of taps is derived for arbitrary arrays with a limited but arbitrary number of sensors and arbitrary spectra. This bound is interpreted as an optimal zero-bandwidth spatial SINR in some sense. Finally, the speed of convergence of the optimal wideband SINR for a limited number of taps is analyzed for several interference scenarios.

Space-time beamforming, asymptotic SINR, performance analysis generalized eigenvalues, block Toeplitz matrix, Szegö's theorem.

## I. INTRODUCTION

Beamforming is used in many applications. It consists of spatially filtering signals, thanks to an array of sensors, and allows one to form “nulls” in the direction of interfering sources while maintaining a given gain in a desired direction. Usually, signals are narrowband [1] and spatial processing alone is sufficient (e.g., see [2]). However, in many applications, such as sonar, radar or communications, broadband signals are required to achieve desired performance, for instance in terms of range resolution or channel capacity. The counterpart is that it also leads to a loss in interference rejection performance (e.g., see [1], [3]) and

some sort of frequency compensation is required to keep good nulling performance. Therefore, space-time processing algorithms, which can be based on time or frequency-domain implementations, are used. Most of these algorithms are designed with the constraint that the signal is preserved through optimization criteria such as Linearly Constrained Minimum Variance (LCMV). However, since those algorithms are optimized under constraints, they are not optimal from the Signal to Interference plus Noise Ratio (SINR) point of view, which is the main performance criterion used for detection problems. Indeed, after linear filtering and under the current assumption that observation data are composed of signal of interest and additive Gaussian interference and noise, maximizing the SINR is equivalent to the Neyman-Pearson criterion. In this paper, we consider this context of detection problems. Thus, the objective of this paper is to study the performance of the optimal processing in the sense of SINR maximization.

When a linear filter is applied to observation data, the SINR corresponds to a Rayleigh quotient, associated with the covariance matrices of the signal of interest and interference plus noise components. Therefore, the optimal SINR corresponds to the maximum value of a Rayleigh quotient and can then be interpreted as the largest generalized eigenvalue of the two matrices. Thus, the problem of the optimal SINR computation is closely related to the generalized eigenvalue problem. However, since the interpretation of the generalized eigenvalues of space-time covariance matrices with a finite number of taps is difficult, the analysis of the optimal SINR broadband beamforming does not easily lead to explicit expressions of the optimal SINR. This difficulty to analyse the performance of broadband beamformers with a finite number of taps has also been noted for optimal processing in the sense of other criteria such as Minimum Mean Squared Error (MMSE) or Minimum Variance Distortionless Response (MVDR). Many authors have studied the performance of time domain (e.g., see [5], [6]) or frequency domain implementations (e.g., see [12], [7]) but, to the best of our knowledge, most analyses have been done through numerical simulations (e.g., see [5], [6], [8], [9]) or for particular cases of arrays with temporally white signals (e.g., see [10]). However, we note that in some applications, the number of taps may be much larger than the number of sensors. For instance, in microphone array processing, where acoustic echoes of loudspeakers corrupt the desired signal, acoustic echo cancellers are often used, requiring a great number of taps (about 1000 taps or more), whereas the number of microphones is most of the time moderate (often less than 10 microphones, e.g., see [11]). Furthermore, if technology constraints impose the number of sensors, time filtering may be realized by different means, e.g., by recursive or subband filtering with different complexity/performance tradeoffs. In these conditions, an asymptotic approach in the number of taps seems justified. Moreover, contrary to the previous studies, this approach allows us to consider arrays of arbitrary geometry with a limited but arbitrary number of sensors and arbitrary

interference and signal of interest spectra. Thus, we can compute a theoretical upper bound associated with an infinite number of taps, useful for comparisons with the SINR obtained after different space-time processing algorithms based for instance on FIR (e.g., see [4]), subband decomposition (e.g., see [12], [13]), or IIR filters (e.g., see [14]).

In beamforming problems, if the observation data are modelled by second-order temporally stationary processes, space-time covariance matrices are block-Toeplitz structured. In this paper, we make use of that property to derive a closed-form expression of the asymptotic optimal SINR space-time beamformers. To proceed, we use an extension of the celebrated Szegő's theorem given by Grenander and Szegő in [15] and revisited by Gray [16] which asserts that the eigenvalues of a sequence of Hermitian Toeplitz matrices asymptotically behave like the samples of the Fourier transform of its entries, to the generalized eigenvalues of a pair of Hermitian matrices that has been derived in [17], [18]. This extended theorem allows one to characterize the generalized eigenvalue distribution of Toeplitz matrices and consequently many properties can be derived from it, such as for instance the asymptotic behavior of the minimum and maximum generalized eigenvalues. Using this theorem, we derive in this paper the expression of the asymptotic optimal space-time SINR w.r.t. the number of taps for a fixed number of sensors and give interpretations of the result in particular scenarios. Then, we complement theoretical results by numerical simulations that illustrate the convergence speed of the optimal SINR for a limited number of taps to its asymptotic optimal value in those scenarios.

This paper is organized as follows. In Section II, the data model is presented and the expression and structure of the signal and interference plus noise covariance matrices is derived. Then, in Section III, Szegő's theorem extended to the asymptotic behavior of the generalized eigenvalues of block Toeplitz matrices is recalled and applied to the performance analysis of optimal SINR space-time beamforming. Finally, in Section IV, illustrations by numerical examples are given to illustrate the convergence of the optimal SINR with a finite number of taps to the asymptotic one.

The following notations are used throughout the paper. Matrices and vectors are represented by bold upper case and bold lower case characters, respectively. Vectors are by default in column orientation,  $H$  stands for conjugate transpose.  $\text{Tr}(\cdot)$  and  $\lambda_1(\cdot) \geq \dots \geq \lambda_L(\cdot)$  denote the trace of a matrix and the decreasing ordered eigenvalues of an  $L \times L$  matrix whose eigenvalues are real valued, respectively.

## II. DATA MODEL

### A. Data model

Let us consider an array composed of  $L$  sensors. We denote by  $B$  the bandwidth of the signals around the center frequency  $f_0$ . Then, we consider an environment composed of a signal of interest, a field of interference and thermal noise. These three signals are uncorrelated with each other. The interference and the thermal noise are modelled by non-zero bandwidth second-order stationary processes and furthermore the thermal noise is spatially and temporally white, with power  $\sigma_n^2$ . The baseband, possibly correlated  $J$  interferers<sup>1</sup> have power spectral density (PSD)  $(\mathcal{S}_j(f))_{j=1..J}$  and cross power spectral density  $(\mathcal{S}_{j,j'}(f))_{j \neq j'=1..J}$ . The interference plus noise  $L \times L$  spatial covariance matrix associated with the baseband received signal is equal to (e.g., see [4, chap.6]):

$$\int_{-\frac{B}{2}}^{\frac{B}{2}} \left( \sum_{j=1}^J \mathcal{S}_j(f) \phi(\theta_j, f) \phi(\theta_j, f)^H + \sum_{1 \leq j \neq j' \leq J} \mathcal{S}_{j,j'}(f) \phi(\theta_j, f) \phi(\theta_{j'}, f)^H \right) df + \sigma_n^2 \mathbf{I}$$

with  $\phi(\theta_j, f) = [e^{jpr_1^T \mathbf{i}(\theta_j)}, e^{jpr_2^T \mathbf{i}(\theta_j)}, \dots, e^{jpr_L^T \mathbf{i}(\theta_j)}]^T$  where  $(\mathbf{r}_\ell)_{\ell=1..L}$  denotes a vector pointing from the origin to the  $\ell^{\text{th}}$  sensor,  $\mathbf{i}(\theta_j)$  a unit length arrival vector for an interference  $j$  in the direction  $\theta_j$  and  $p = 2\pi \frac{f_0 + f}{c}$  with  $c$  denoting the propagation speed of the wave. The signal of interest is also modelled by a non-zero bandwidth second-order stationary process with PSD  $\mathcal{S}_s(f)$ . It is assumed to have a known direction of arrival (DOA)  $\theta_s$ . Its  $L \times L$  spatial covariance matrix may be written as

$$\int_{-\frac{B}{2}}^{\frac{B}{2}} \mathcal{S}_s(f) \phi(\theta_s, f) \phi(\theta_s, f)^H df. \quad (1)$$

### B. Expression of the space-time covariance matrices

Let  $K$  denote the number of taps used for temporal processing at each sensor at Shannon sampling rate  $T = \frac{1}{B}$ . The interference plus noise and signal of interest space-time covariance matrices, respectively  $\bar{\mathbf{R}}_{i+n,K}$  and  $\bar{\mathbf{R}}_{s,K}$  are of dimension  $KL \times KL$ . They are respectively Hermitian positive definite (due to the presence of thermal noise) and Hermitian positive semidefinite. Then, due to the second-order stationarity of the processes, these two space-time covariance matrices are block-Toeplitz structured and

<sup>1</sup>Note that this model includes arbitrary second-order stationary field of interference using specular approximations of diffuse interference, e.g., see [4, Section 5.5].

may be written as:

$$\begin{bmatrix} \mathbf{R}_0 & \mathbf{R}_1^H & \cdots & \mathbf{R}_{K-1}^H \\ \mathbf{R}_1 & \ddots & \ddots & \mathbf{R}_{K-2}^H \\ \vdots & \ddots & & \vdots \\ \mathbf{R}_{K-1} & \mathbf{R}_{K-2} & \cdots & \mathbf{R}_0 \end{bmatrix} \quad (2)$$

where matrices  $(\mathbf{R}_k)_{k=0,\dots,K-1}$  are given for  $\bar{\mathbf{R}}_{i+n,K}$  and  $\bar{\mathbf{R}}_{s,K}$  respectively by

$$\int_{-\frac{B}{2}}^{\frac{B}{2}} \left( \sum_{j=1}^J \mathcal{S}_j(f) \phi(\theta_j, f) \phi(\theta_j, f)^H + \sum_{1 \leq j \neq j' \leq J} \mathcal{S}_{j,j'}(f) \phi(\theta_j, f) \phi(\theta_{j'}, f)^H + \frac{\sigma_n^2}{B} \mathbf{I} \right) e^{-i2\pi k f T} df$$

and

$$\int_{-\frac{B}{2}}^{\frac{B}{2}} \mathcal{S}_s(f) \phi(\theta_s, f) \phi(\theta_s, f)^H e^{-i2\pi k f T} df$$

Let us note that the blocks  $\mathbf{R}_k$  are not necessarily Toeplitz, depending on the structure of the array.

To apply the extended Szegő's theorem in the next Section, we remark that the sequences  $\mathbf{R}_k$  associated with the interference plus noise and the signal of interest are generated by the Fourier coefficients of the  $L \times L$  Hermitian matrix valued functions

$$\mathbf{R}_{i+n}(f) = \sum_{j=1}^J \mathcal{S}_j(f) \phi(\theta_j, f) \phi(\theta_j, f)^H + \sum_{1 \leq j \neq j' \leq J} \mathcal{S}_{j,j'}(f) \phi(\theta_j, f) \phi(\theta_{j'}, f)^H + \frac{\sigma_n^2}{B} \mathbf{I} \quad (3)$$

and

$$\mathbf{R}_s(f) = \mathcal{S}_s(f) \phi(\theta_s, f) \phi(\theta_s, f)^H, \quad (4)$$

respectively.

### III. EXPRESSION OF THE ASYMPTOTIC OPTIMAL SPACE-TIME SINR

#### A. Expression of the space-time optimal SINR

Space-time beamforming consists in linearly filtering the  $LK$ -dimensional space-time data by a tap-stacked vector  $\mathbf{w}_K$  when  $K$  taps are used. The optimal space-time processing (in the sense of SINR maximization) maximizes the generalized Rayleigh quotient:

$$\text{SINR}(K) \stackrel{\text{def}}{=} \max_{\mathbf{w}_K} \frac{\mathbf{w}_K^H \bar{\mathbf{R}}_{s,K} \mathbf{w}_K}{\mathbf{w}_K^H \bar{\mathbf{R}}_{i+n,K} \mathbf{w}_K} \quad (5)$$

where  $\bar{\mathbf{R}}_{s,K}$  and  $\bar{\mathbf{R}}_{i+n,K}$  are the space-time covariance matrices for the signal of interest and interference+noise signals, respectively, and given by (2). As noted in the previous Section,  $\bar{\mathbf{R}}_{s,K}$  and  $\bar{\mathbf{R}}_{i+n,K}$

are, respectively, Hermitian positive semidefinite and Hermitian positive definite matrices. Therefore, the solution  $\mathbf{w}_K$  of this optimization problem is given by the generalized eigenvector associated with the largest generalized eigenvalue of the couple  $(\bar{\mathbf{R}}_{s,K}, \bar{\mathbf{R}}_{i+n,K})$ . Then, the optimal space-time SINR is given by the largest generalized eigenvalue of  $(\bar{\mathbf{R}}_{s,K}, \bar{\mathbf{R}}_{i+n,K})$  also corresponding to the largest eigenvalue  $\lambda_1$  of  $\bar{\mathbf{R}}_{i+n,K}^{-1} \bar{\mathbf{R}}_{s,K}$

$$\text{SINR}(K) = \lambda_1(\bar{\mathbf{R}}_{i+n,K}^{-1} \bar{\mathbf{R}}_{s,K}).$$

The value of this optimal SINR is difficult to interpret. Furthermore, closed-form expressions are not attainable, except in the trivial case of narrowband signals. Consequently, it will be insightful to consider the asymptotic (w.r.t. the number of taps) optimal SINR that will be used as an approximation for the upper bound of the SINR in the case of a finite number  $K$  of taps.

### B. Expression of the asymptotic optimal SINR for arbitrary interference

To consider in the following the limit of the SINR w.r.t.  $K$  for arbitrary given interference and signal of interest DOAs, we use the following extension of Szegő's theorem (e.g., see [17, th.3.9] and [18, th.1]) that we recall for the convenience of the reader<sup>2</sup>.

*Theorem 1:* Let  $\mathbf{A}_{K,L}$  and  $\mathbf{B}_{K,L}$  be two  $L$  block Toeplitz  $KL \times KL$  Hermitian matrices with  $L$  fixed, such that  $\mathbf{B}_{K,L}$  is positive definite, generated by absolutely summable sequences  $\{a_n^{u,v}\}_{n=\dots,-1,0,1,\dots}$  and  $\{b_n^{u,v}\}_{n=\dots,-1,0,1,\dots}$  with  $u, v = 1, \dots, L$  of Fourier transform  $a^{u,v}(\omega) = \sum_n a_n^{u,v} e^{-in\omega}$  and  $b^{u,v}(\omega) = \sum_n b_n^{u,v} e^{-in\omega}$ , respectively. Let  $\mathbf{A}(\omega)$  be the  $L \times L$  matrix defined by

$$\mathbf{A}(\omega) = \begin{bmatrix} a^{1,1}(\omega) & a^{1,2}(\omega) & \dots & a^{1,L}(\omega) \\ a^{2,1}(\omega) & a^{2,2}(\omega) & \dots & a^{2,L}(\omega) \\ \vdots & \vdots & & \vdots \\ a^{L,1}(\omega) & a^{L,2}(\omega) & \dots & a^{L,L}(\omega) \end{bmatrix},$$

$\mathbf{B}(\omega)$  is defined in the same way from  $b^{u,v}(\omega)$ , with  $\min_{\omega} \lambda_L \{\mathbf{B}(\omega)\} = m_b > 0$ . Then, for all continuous functions  $F$  on  $I_{\omega} = [m, M]$  with  $m \stackrel{\text{def}}{=} \min_{\omega} \lambda_L(\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega))$  and  $M \stackrel{\text{def}}{=} \max_{\omega} \lambda_1(\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega))$

$$\lim_{K \rightarrow \infty} \frac{1}{K} \sum_{u=1}^{KL} F(\lambda_u(\mathbf{B}_{K,L}^{-1} \mathbf{A}_{K,L})) = \frac{1}{2\pi} \int_{-\pi}^{\pi} \sum_{u=1}^L F(\lambda_u(\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega))) d\omega.$$

<sup>2</sup>We note that the highly sophisticated mathematical tools employed in [17] are sometimes beyond the grasp of the engineering community. Consequently the results obtained in this paper have not received appreciation they deserve in the signal processing literature. Whereas, based on the hypothesis of absolutely summable elements, which relies on an extension of the notion of asymptotic equivalence between matrix sequences established by Gray in [16], the proof given in [18] is within the reach of most of the readers.

From this theorem, we prove the following corollary in Appendix A:

*Corollary 1:* The largest generalized eigenvalue of  $(\mathbf{A}_{K,L}, \mathbf{B}_{K,L})$  is convergent in  $K$  and

$$\lim_{K \rightarrow \infty} \lambda_1(\mathbf{B}_{K,L}^{-1} \mathbf{A}_{K,L}) = \max_{\omega} \lambda_1(\mathbf{B}^{-1}(\omega) \mathbf{A}(\omega)).$$

The assumptions of Theorem 1 and Corollary 1 apply for the sequence of the space-time covariance matrices  $(\bar{\mathbf{R}}_{s,K}, \bar{\mathbf{R}}_{i+n,K})$  w.r.t. the number  $K$  of taps:

$$\lim_{K \rightarrow \infty} \text{SINR}(K) = \max_{f \in [-\frac{B}{2}, \frac{B}{2}]} \{\lambda_1(\mathbf{R}_{i+n}^{-1}(f) \mathbf{R}_s(f))\}.$$

Then, since  $\mathbf{R}_{i+n}^{-1}(f) \mathbf{R}_s(f)$  has rank one, it has the following single non-zero eigenvalue

$$\mathcal{S}_s(f) \phi(\theta_s, f)^H \mathbf{R}_{i+n}^{-1}(f) \phi(\theta_s, f)$$

associated with the eigenvector  $\mathbf{R}_{i+n}^{-1}(f) \phi(\theta_s, f)$  and we obtain the following result:

*Result 1:* For optimal space-time beamforming sampled at the Shannon rate, the SINR tends to the following expression when the number  $K$  of taps increases to infinity

$$\lim_{K \rightarrow \infty} \text{SINR}(K) = \max_{f \in I_f} \{\mathcal{S}_s(f) \phi(\theta_s, f)^H \mathbf{R}_{i+n}^{-1}(f) \phi(\theta_s, f)\} \quad (6)$$

where  $\mathbf{R}_{i+n}(f)$  is defined by (3) and where  $I_f = [-\frac{B}{2}, \frac{B}{2}]$ .

At first glance, this SINR tends to the maximum zero-bandwidth optimal spatial SINR associated with a frequency  $f_m$  in the band  $I_f$ . And consequently, this optimal asymptotic space-time beamformer has the same behavior as an infinitely narrow band-pass filter at  $f_m$  followed by an optimal zero-bandwidth spatial beamformer.

But, we have to elaborate a little bit. Thus, let us compare this optimal asymptotic space-time SINR (6) obtained for  $f = f_m \in I_f$  with the zero-bandwidth optimal spatial SINR corresponding to the demodulation frequency  $f_0 + f_m$  associated with the same signal of interest, interference and noise powers  $\sigma_s^2$ ,  $\sigma_j^2$  and  $\sigma_n^2$ . We see from (3) that this optimal asymptotic space-time SINR (6) is associated with a zero-bandwidth optimal spatial SINR corresponding to signal, interference and noise powers  $B\mathcal{S}_s(f_m)$ ,  $B\mathcal{S}_j(f_m)$  and  $\sigma_n^2$ , respectively. Furthermore, the associated steering vectors  $\phi(\theta_s, f_m)$  and  $\phi(\theta_j, f_m)$  depend on the inter-element spacing of the array which generally is related to  $f_0 + \frac{B}{2}$  (Shannon sampling condition) or sometimes to  $f_0$  for the space-time SINR, whereas this inter-element spacing would have probably been chosen as a function of  $f_0 + f_m$  in the context of narrowband beamforming around frequency  $f_0 + f_m$ . However for temporally white signals of interest, some properties can be proved.

In the case of oversampling with respect to Shannon rate ( $T < \frac{1}{B}$ ), the spectral matrices  $\mathbf{R}_s(f)$  and  $\mathbf{R}_{i+n}(f)$  are both bandlimited to  $[-B/2, B/2] \subset [-1/2T, 1/2T]$ , and consequently  $\min_f \lambda_L(\mathbf{R}_{i+n}(f)) = 0$  and the technical condition on which Theorem 1 is derived is no longer valid. Furthermore, in this case, Theorem 1 has no meaning because the generalized eigenvalues of  $(\mathbf{R}_s(f), \mathbf{R}_{i+n}(f))$  are not defined for  $B/2 < |f| \leq 1/2T$ . In these conditions, proving Result 1 is an open problem which is challenging. However, extensive numerical experiments show that Result 1 extends to that case (see Subsection IV-C).

### C. Expression of the asymptotic SINR for temporally white signals of interest

Suppose now that the signal of interest and the multichannel interferer are temporally white. With  $S_j(f) = \frac{\sigma_j^2}{B}$  and  $S_{j,j'}(f) = \frac{\sigma_{j,j'}}{B}$ , the generating function  $\mathbf{R}_{i+n}(f)$  defined in (3) can be written at frequency  $f = 0$  as:

$$\mathbf{R}_{i+n}(0) = \frac{1}{B} \left( \sum_{j=1}^J \sigma_j^2 \phi(\theta_j, 0) \phi(\theta_j, 0)^H + \sum_{1 \leq j \neq j' \leq J} \sigma_{j,j'} \phi(\theta_j, 0) \phi(\theta_{j'}, 0)^H + \sigma_n^2 \mathbf{I} \right),$$

which is (up to the multiplicative term  $1/B$ ), the interference plus noise spatial covariance matrix  $\mathbf{R}_{i+n}$  associated with zero-bandwidth signals around frequency  $f_0$  with the same powers and correlations. Consequently from (6), we obtain:

$$\lim_{K \rightarrow \infty} \text{SINR}(K) \geq \sigma_s^2 \phi(\theta_s)^H \mathbf{R}_{i+n}^{-1} \phi(\theta_s),$$

with  $\phi(\theta_s) \stackrel{\text{def}}{=} \phi(\theta_s, 0)$ , which is the optimal SINR given for zero-bandwidth spatial beamformers around  $f_0$  (e.g., see [4, rel.6.66]). Thus, we have proved the following result:

*Result 2:* For temporally white signal of interest and multichannel interferer, the asymptotic SINR at the output of the optimal space-time beamformer is larger than the SINR at the output of the optimal spatial beamformer associated with zero-bandwidth signals around frequency  $f_0$  with same spatial correlations and powers.

Therefore, for a finite number  $K$  of taps, the optimal space-time beamformer can outperform the zero-bandwidth optimal spatial SINR. This point that has never been reported in the literature, will be illustrated in Subsection IV-A.

We now analyze the particular situation of interference whose spectra cancel at least at a common frequency. In this particular case, the following result is proved in Appendix B:

*Result 3:* In the presence of several interferers whose spectra share at least a common frequency null

$\nu_0$  and a temporally white signal of interest of power  $\sigma_s^2$ , we have

$$\lim_{K \rightarrow \infty} \text{SINR}(K) = \frac{\sigma_s^2}{\sigma_n^2} L.$$

This result means that in the presence of interference with at least one common zero in their spectra, space-time processing allows one to reach asymptotically the SINR corresponding to an interference-free context. Let us note that though the asymptotic notion is purely theoretical, we will see in Subsection IV-B that in most practical cases, a small value of the number of taps is sufficient to reach near optimal performance.

#### IV. ILLUSTRATIVE EXAMPLES

This section illustrates Result 2 through numerical experiments and complements the last two results by exhibiting the speed of convergence of the optimal SINR for a limited number of taps to its asymptotic value for both white and bandlimited interference. Moreover, in the latter case, the influence of the fractional bandwidth is examined. Finally, we examine the influence of the time sampling rate on the optimal space-time SINR. We consider throughout this section a uniform linear array with only one interference source where

$$\phi(\theta, f) = [1, e^{j\pi \frac{f_0+f}{f_0} u}, \dots, e^{j(L-1)\pi \frac{f_0+f}{f_0} u}]^T$$

with  $u = \sin(\theta)$  ( $u_s = \sin(\theta_s)$  and  $u_j = \sin(\theta_j)$  for the signal of interest and the interference respectively). The signal of interest is white in the band  $[-\frac{B}{2}; \frac{B}{2}]$ . In all the simulations,  $u_j = 0.3$ ,  $\sigma_n^2 = 0$  dB and  $\sigma_s^2 = 0$  dB.

##### A. White interference case

In this Section, we suppose that the interference is white in the band  $[-\frac{B}{2}; \frac{B}{2}]$ . Thus

$$\lim_{K \rightarrow \infty} \text{SINR}(K) = \max_{f \in I_f} \left\{ \frac{\sigma_s^2}{\sigma_n^2} L \left( 1 - \frac{\sigma_j^2 |\phi(\theta_1, f)^H \phi(\theta_s, f)|^2}{L(\sigma_n^2 + L\sigma_j^2)} \right) \right\}. \quad (7)$$

Fig.1 exhibits the asymptotic optimal space-time SINR for different values of the fractional bandwidth  $B/f_0$  and the optimal spatial zero-bandwidth SINR in the conditions of Result 2, with  $L = 4$  and  $\sigma_j^2 = 10$ . We check that the increase of the fractional bandwidth leads to a reduction of the SINR loss width around the interferer. More precisely, it is straightforward from (7) to prove, that the asymptotic optimal space-time SINR presents a notch behavior around the signal of interest's DOA,

whose width  $\frac{4}{L(1+\frac{B}{2f_0})}$  shrinks when the fractional bandwidth increases. Furthermore from (7), the side-lobe's effects disappear for  $1 + \frac{B}{2f_0} > 2(1 - \frac{B}{2f_0})$ , i.e., for  $\frac{B}{f_0} > \frac{2}{3}$ . Moreover, we see from Fig.1 that the asymptotic optimal space-time SINR outperforms the optimal spatial zero-bandwidth SINR for all fractional bandwidths and signal of interest's DOA, except at the DOA of the interferer. Naturally the impact of these properties reduces for scenarios for which  $L(L + \frac{\sigma_n^2}{\sigma_j^2}) \gg 1$  (7), where the two SINR are very close, as it will be illustrated in Fig.3. Fig.2 compares the optimal space-time SINR to the optimal spatial SINR for  $B/f_0 = 0.5$  at different numbers  $K$  of taps. It shows that the optimal space-time SINR begins outperforming the optimal spatial SINR from only 4 taps.

Fig.1 Optimal asymptotic space-time SINR for different values of the fractional bandwidth, and optimal spatial zero-bandwidth SINR ( $\frac{B}{f_0} = 0$ ) as a function of the signal of interest's DOA.

Fig.2 Optimal space-time SINR for different values of the number of taps and optimal spatial zero-bandwidth SINR, as a function of the signal of interest's DOA.

From now on,  $L = 16$  and  $\sigma_j^2 = 30\text{dB}$ . In Fig.3, we plot the optimal space-time SINR for different values of the number  $K$  of taps, with  $\frac{B}{f_0} = 0.3$ . First we check that the SINR converges to the asymptotic values of the number  $K$  of taps, which is close to the associated optimal spatial SINR. Then, we notice that the convergence is rapid, since the asymptotic bound is nearly reached with  $K = 4$ .

Fig.3 Optimal space-time SINR for different values of the number of taps and optimal spatial zero-bandwidth SINR, as a function of the signal of interest's DOA.

### B. Bandlimited white interference case

Let us suppose that the interference has constant PSD in the band  $[-\frac{b}{2}; \frac{b}{2}]$  with  $b < B$ . We illustrate the speed of convergence of the optimal space-time SINR for a given number of taps to the asymptotic upper-bound given by Result 2. Thus, we plot in Figs.4 and 5 the optimal space-time SINRs for  $b = \frac{3}{4}B$  and  $b = \frac{B}{2}$  respectively (dashed plots) at given numbers of taps and compare them to the asymptotic optimal space-time SINR (solid plot). Let us note that the case  $K = 1$  corresponds to spatial processing and that the SINR degrades when  $b$  increases. In both figures, we check that the optimal SINR (asymptotically w.r.t. the number of taps) is equal to  $\frac{\sigma_s^2}{\sigma_n^2}L$  and that the optimal space-time SINRs converge with the number of taps to the asymptotic optimal space-time SINR. Then, we note that the convergence speed increases when the interference bandwidth decreases. For instance, we observe in Fig.5 (where  $b = B/2$ ) that the optimal space-time SINR with  $K = 4$  taps outperforms the optimal space time-SINR with  $K = 8$  taps of Fig.4 (where  $b = 3B/4$ ).

Fig.4 Optimal space-time SINR for different values of the number of taps, as a function of the signal of interest's DOA for  $b = 3B/4$ .

Fig.5 Optimal space-time SINR for different values of the number of taps, as a function of the signal of interest's DOA for  $b = B/2$ .

### C. Influence of the time sampling frequency

Now, we examine the influence of the time sampling rate on the optimal space-time SINR. In Fig.6, we plot the optimal space-time SINR for two values of the temporal sampling period, i.e.,  $T = \frac{1}{B}$  and  $T = \frac{1}{2B}$  and different values of the number of taps for a white interference in the band  $[-\frac{B}{2}, \frac{B}{2}]$ .

Fig.6 Optimal space-time SINR with  $T = \frac{1}{B}$  (- -) and  $T = \frac{1}{2B}$  (-+-) for different values of the number of taps, as a function of the target's DOA.

First, we observe that in both cases, the SINR seems to converge to the asymptotic SINR given by Result 1, although this result has been proved only for  $T = \frac{1}{B}$ . However, we note that the convergence is much faster for  $T = \frac{1}{2B}$  than for  $T = \frac{1}{B}$ . Consequently, oversampling w.r.t. the Shannon sampling rate allows one to improve the performance for a given number of taps. We note that extensive experiment

confirms these observations. Let us note that the influence of the time sampling rate has been analyzed in [10] for a bandpass tapped delay line implementation of the MMSE algorithm in the case of a two-sensor array. In this paper, the author has also noticed the improvement of performance in terms of SINR due to the use of oversampling, for an array in which each element has only two weights. The physical interpretation is that oversampling increases the correlation between interference components which makes their nulling easier.

#### APPENDIX A: PROOF OF COROLLARY 1

We mimic here the approach of [16, Cor.4.2] that we recall for the convenience of the reader. First, note that for all  $K$ , the  $KL$  eigenvalues of  $\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L}$  lie in  $I_\omega$  and the  $L$  eigenvalues of  $\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega)$  are continuous in  $[-\pi, \pi]$ .

Define the complementary distribution eigenvalue function  $D_K(x) \stackrel{\text{def}}{=} \frac{\text{number of } \lambda_u(\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L}) \geq x}{K}$  which is given by  $\frac{1}{K} \sum_{u=1}^{KL} \mathbb{1}_{[x,M]}(\lambda_u(\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L}))$ , where  $\mathbb{1}_{[x,M]}(\alpha) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{for } \alpha \in [x, M] \\ 0 & \text{elsewhere} \end{cases}$  with  $x < M$ . Using two continuous functions on  $I_\omega$  that provide upper and lower bounds to the indicator function  $\mathbb{1}_{[x,M]}(\alpha)$  and converge to it in the limit, and applying Theorem 1 to these two continuous functions, we straightforwardly obtain

$$\lim_{K \rightarrow \infty} D_K(x) = \frac{1}{2\pi} \sum_{u=1}^L \int_{\omega \in [-\pi, \pi], x \leq \lambda_u(\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega)) \leq M} d\omega.$$

Consequently,  $\lim_{K \rightarrow \infty} D_K(M - \epsilon) = \frac{1}{2\pi} \sum_{u=1}^L \int_{\omega \in [-\pi, \pi], M - \epsilon \leq \lambda_u(\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega)) \leq M} d\omega > 0$  where the strict inequality follows from the continuity of the  $L$  eigenvalues of  $\mathbf{B}^{-1}(\omega)\mathbf{A}(\omega)$  in  $[-\pi, \pi]$ . Since  $\lim_{K \rightarrow \infty} \frac{\text{number of } \lambda_u(\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L}) \in [M - \epsilon, M]}{K} > 0$ , there must be eigenvalues of  $\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L}$  in the interval  $[M - \epsilon, M]$  for arbitrary small  $\epsilon$ . Noting that the space-time setting with  $K$  taps is a special case of a processor with  $K + 1$  taps where the  $K + 1$ st tap weight is set to zero in each channel, we obtain by the inclusion principle in (5) that the larger generalized eigenvalues of  $(\mathbf{A}_{K,L}, \mathbf{B}_{K,L})$ ,  $\lambda_1(\mathbf{B}_{K,L}^{-1}\mathbf{A}_{K,L})$  increases with  $K$  ( $L$  fixed). Consequently, this proves Corollary 1.

#### APPENDIX B: PROOF OF RESULT 2

First, note that if  $\mathcal{S}_j(\nu_0) = 0$  for  $j = 1, \dots, J$  with  $\nu_0 \in [-\frac{B}{2}, \frac{B}{2}]$ , using  $|\mathcal{S}_{j,j'}(f)|^2 \leq \mathcal{S}_j(f)\mathcal{S}_{j'}(f)$ , the different cross power spectral densities  $(\mathcal{S}_{j,j'}(f))_{j \neq j'=1..J}$  cancel at  $\nu_0$  as well. Consequently  $\mathbf{R}_{i+n}(\nu_0) = \frac{\sigma_n^2}{B} \mathbf{I}$  from (3). Then from (6), we obtain

$$\lim_{K \rightarrow \infty} \text{SINR}(K) \geq \frac{\sigma_s^2}{B} \phi(\theta_s, \nu_0)^H \mathbf{R}_{i+n}^{-1}(\nu_0) \phi(\theta_s, \nu_0) = \frac{\sigma_s^2}{\sigma_n^2} \|\phi(\theta_s, \nu_0)\|^2 = \frac{\sigma_s^2}{\sigma_n^2} L.$$

Now, we prove that the limit of  $\text{SINR}(K)$  is upper bounded by  $\frac{\sigma_s^2}{\sigma_n^2}L$ . Using  $\bar{\mathbf{R}}_{i+n,K} \geq \sigma_n^2 \mathbf{I}$ , we have

$$\text{SINR}(K) \leq \frac{\mathbf{w}_K^H \bar{\mathbf{R}}_{s,K} \mathbf{w}_K}{\sigma_n^2 \|\mathbf{w}_K\|^2} \leq \frac{\lambda_1(\bar{\mathbf{R}}_{s,K})}{\sigma_n^2} \quad (8)$$

where  $\bar{\mathbf{R}}_{s,K}$  is block Toeplitz structured. Applying [19, th. 3], dedicated to the limit of the largest eigenvalue of block Toeplitz matrices with non-Toeplitz blocks where the number  $K$  of block tends to infinity, we have<sup>3</sup>

$$\lim_{K \rightarrow \infty} \lambda_1(\bar{\mathbf{R}}_{s,K}) = B \lambda_1(\mathbf{R}_s(f)),$$

where the largest eigenvalue of the rank one matrix  $\mathbf{R}_s(f)$  (4) is  $\frac{\sigma_s^2}{B}L$ . Consequently

$$\lim_{K \rightarrow \infty} \text{SINR}(K) \leq \frac{\sigma_s^2}{\sigma_n^2}L,$$

which proves Result 3.
