Running title: Ligand-recognition pocket of human $\alpha 5 \beta 1$

Summary

Integrin $\alpha 5 \beta 1$ is a key receptor for the extracellular matrix protein fibronectin. Antagonists of human $\alpha 5 \beta 1$ have therapeutic potential as anti-angiogenic agents in cancer and diseases of the eye. However, the structure of the integrin is unsolved and the atomic basis of fibronectin and antagonist binding by $\alpha 5 \beta 1$ is poorly understood. Here we demonstrate that zebrafish $\alpha 5 \beta 1$ integrins do not interact with human fibronectin or the human $\alpha 5 \beta 1$ antagonists JSM6427 and cyclic peptide CRRETAWAC. Zebrafish $\alpha 5 \beta 1$ integrins do bind zebrafish fibronectin-1, and mutagenesis of residues on the upper surface and side of the zebrafish $\alpha 5$ subunit β -propeller domain shows that these residues are important for the recognition of RGD and synergy sites in fibronectin. Using a gain-of-function analysis involving swapping regions of the zebrafish $\alpha 5$ subunit with the corresponding regions of human $\alpha 5$ we show that blades 1-4 of the β -propeller are required for human fibronectin recognition, suggesting that fibronectin binding involves a broad interface on the side and upper face of the β -propeller domain. We find that the loop connecting blades 2 and 3 of the β -propeller (D3-A3 loop) contains residues critical for antagonist recognition, with a minor role played by residues in neighbouring loops. A new homology model of human $\alpha 5 \beta 1$ supports an important function for D3-A3 loop residues Trp-157 and Ala-158 in the binding of antagonists. These results will aid the development of reagents that block $\alpha 5 \beta 1$ functions in vivo.

INTRODUCTION

The interactions of integrin receptors with extracellular-matrix macromolecules are critical for development, responses to injury and normal tissue homeostasis [1-3]. Integrin $\alpha 5 \beta 1$ is a fibronectin receptor found on a wide variety of cell types. Two distinct sites in fibronectin are involved in binding to $\alpha 5 \beta 1$; the first lies in the tenth type III repeat (3Fn10) and encompasses the Arg-Gly-Asp (RGD) sequence [4], while a second, weaker, interaction site is found in the ninth type III repeat (3Fn9) and includes the sequence Pro-His-Ser-Arg-Asn (PHSRN; the so-called 'synergy' sequence) [5-7]. These two sequences are separated by 30-40 Å in the tertiary structure of this region of fibronectin [8].

$\alpha 5 \beta 1$ is also highly expressed in pathological situations, for example on many tumour cell types and on activated endothelial cells during the formation of tumour vasculature [9-13]. Moreover, there is evidence that $\alpha 5 \beta 1$ -fibronectin interactions play a key role in diseases of the eye that involve neovascularisation [14-18]. Hence, there is a great deal of interest in the development of antagonists of $\alpha 5 \beta 1$ for therapeutic use [19,20].

Presently, no high resolution structural information has been obtained for $\alpha 5 \beta 1$ -ligand interactions. However, crystal structures of the closely related integrins $\alpha V \beta 3$ and $\alpha IIb \beta 3$ [21-23] show that the RGD sequence binds in a pocket formed by loops on top of the α subunit β -propeller domain and the A-domain of the β subunit (known as βA or βI). Small

molecule antagonists bind in the same pocket [22] thereby preventing ligand recognition. Homology models of $\alpha 5\beta 1$ have been constructed using the structure of $\alpha V\beta 3$ bound to the antagonist cilengitide [24, 25] as a template; these models have aided the rational design of high affinity $\alpha 5\beta 1$ antagonists such as JSM6427 [19]. Phage display technology has also been used to identify high affinity peptide ligands for $\alpha 5\beta 1$ such as the disulphide-bridged, cyclic peptides Cys-Arg-Arg-Glu-Thr-Ala-Trp-Ala-Cys (CRRETAWAC), Cys-Arg-Gly-Asp-Gly-Phe-Cys (CRGDGFC), and Cys-Arg-Gly-Asp-Gly-Trp-Cys (CRGDGWC) [26-27]. These peptides have been shown to interact with loops on the upper face of the $\alpha 5$ subunit β -propeller domain [28-30]. However, few data are currently available concerning the precise mode of antagonist binding by $\alpha 5\beta 1$. In addition, there is controversy concerning the mechanism of fibronectin recognition, specifically whether the synergy site binds directly to the $\alpha 5$ subunit [31], or indirectly supports the binding of RGD to the integrin [32]. Hence, there is a pressing need to define further the mechanisms of ligand binding by $\alpha 5\beta 1$.

Previously, we identified two close homologues of the mammalian $\beta 1$ subunit in zebrafish: $\beta 1$ -1 and $\beta 1$ -2 (also known as $\beta 1a$ and $\beta 1b$) [33]. Here we show that the zebrafish $\alpha 5$ subunit can form functional heterodimers with both zebrafish $\beta 1$ subunits or with human $\beta 1$; however, all of these zebrafish $\alpha 5$ integrins show no binding to human fibronectin or human $\alpha 5\beta 1$ antagonists. This lack of ligand binding enabled us to use a gain-of-function approach to identify the regions of the $\alpha 5$ subunit required for interactions with human fibronectin and antagonists. We demonstrate that a loop region between the second and third blades of the β -propeller (D3-A3 loop) plays a key role in antagonist binding, but a much more extensive region of the β -propeller is necessary for recognition of the whole fibronectin ligand. A new homology model of $\alpha 5\beta 1$, based on the $\alpha IIb\beta 3$ -tirofiban structure [22], supports a prominent function for residues at the apex of the D3-A3 loop in the binding of antagonists.

EXPERIMENTAL

Materials

Peptides GACRRETAWACGA (CRRETAWAC), GACRRETADACGA (CCRETADAC) and GCRGDSPCG (cyclic-RGD) were purchased from Peptide 2.0 Inc. (Chantilly, VA, USA). Peptides were cyclized by oxidation as previously described [28]. Small molecules JSM6427 and JSM6406 were provided by Jerini AG.

Cloning and mutagenesis

Full-length zebrafish $\alpha 5$ cDNA clone was a gift from S. Koshida (Okazaki, Japan). Full-length cDNA clones for two zebrafish $\beta 1$ subunits $\beta 1$ -1 and $\beta 1$ -2 were obtained as previously described [33]. Recombinant soluble versions of human, zebrafish and chimeric integrins fused to the hinge region and C_H2 and C_H3 domains of the human IgG γ 1 chain were made essentially as before [34], using the complete extracellular domain of the $\alpha 5$ subunit and the headpiece of the $\beta 1$ subunit (PSI, hybrid and β I domains). For cloning into the pEE12.2Fc vector [34], an internal Hind III site in zebrafish $\alpha 5$ was altered from AAGCTT to AAAGCTT by overlap extension PCR, creating a silent mutation. Constructs were verified by DNA sequencing. The amino acid sequence of the $\alpha 5$ construct was identical to that predicted by B3DJJ0: UniProtKB/TrEMBL (although note that the signal peptide should be 32, not 14, amino acid residues in length) with the exception that Ser488 in the mature sequence was

substituted by Asn. This substitution lies outside the β -propeller domain and so is unlikely to affect function. The sequences of β 1-1 and β 1-2 were identical to those previously reported (DQ149101 and DQ149102; GenBank). Constructs containing the head region of the β 1-1 or β 1-2 (equivalent to the previously reported β 1TR construct [34]) were made by cloning a PCR product containing residues Gln-21–Pro-475 of β 1-1 (Gln-1–Pro-455 in the mature sequence) or Gln-18–Pro-472 (Gln-1–Pro-455 in the mature sequence) of β 1-2 fused with a murine antibody leader sequence [34,39] into the pV.16hFc vector. The corresponding human α 5- and β 1TR-Fc clones [34] were a gift from J. Askari (University of Manchester). Blade swapping chimeras were created by overlap extension PCR using human α 5 and zebrafish α 5-Fc constructs as templates. W1-3 blade swap contains residues Phe-1–Asp-228 of human α 5, W1-4 swap contains residues Phe-1–Met-281 of human α 5, W2-4 swap contains residues Ile-70–Met-281 of human α 5. Loop-swapping mutations in zebrafish α 5 were created using overlap extension PCR. To determine the sequences for swapping, alignment of zebrafish and human sequences was performed using ClustalW (www.ebi.ac.uk/Tools/clustalw2/index.html). Site-directed mutagenesis was carried out using the QuikChange II XL kit (Stratagene, Dorchester) or by overlap extension PCR. Oligonucleotides for cloning and mutagenesis were supplied by Eurogentec (Seraing, Belgium), oligonucleotides for alanine scanning mutations were a gift from S. Holley (Yale University, CT, USA) or from Eurogentec. Wild-type human α 5-Fc and human β 1TR-Fc constructs were prepared as previously described [34].

A cDNA encoding a cell binding fragment of zebrafish FN-1 (3Fn6-10 including the constitutively included EIIIB domain [35]) was obtained by reverse transcription of RNA from 3-day old zebrafish embryos [33]. The sequence of the cDNA was identical to that predicted by B3DGZ1 (UniProtKB/TrEMBL database; residues Thr1093–Thr1632) but differed from the published sequence [35] at the 3Fn8/9 boundary. The cDNA was cloned into the pCEP-PU expression vector, which encoded a C-terminal FLAG-tag.

Transient transfection of CHO cells

Chinese hamster ovary cells L761h variant [34] were maintained in Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum, 2 mM glutamine and 1% non-essential amino acids (Invitrogen, Paisley). 6-well plates of sub-confluent CHO-L761h cells were transfected with 1 μ g of β 1 construct and 1 μ g of α 5 construct/well using LipofectaminePLUS reagent (Invitrogen) according to the manufacturer's instructions. After 6 days, culture supernatants were harvested by centrifugation at 1000x g for 5 min.

Western Blotting

All the reagents for SDS-PAGE were from Invitrogen except for the protein markers that were obtained from Bio-Rad Laboratories (Hemel Hempstead). Aliquots of cell culture supernatants were run on 3-8 % NuPAGE™ Tris-Acetate gels (Invitrogen) under non-reducing conditions, transferred to nitrocellulose and blotted with anti-human Fc peroxidase conjugate (Stratech Scientific, New Market). Bands were visualized using UptiLight enhanced chemiluminescence reagent (Cheshire Biosciences, Chester).

Solid-phase ligand-binding assays

The 50 kDa cell binding domain of human fibronectin (3Fn6-10; '50K') was produced in *E. coli* as before [6]. The 70 kDa cell binding fragment of zebrafish FN-1 ('70K') was produced by transient transfection of 293-EBNA cells using LipofectAMINE PLUS reagent according

to the manufacturer's instructions. Cells were cultured in DMEM/F12 with Glutamax containing 0.1 unit/ml penicillin, and 10 µg/ml streptomycin for 7 days. 70K was purified from the cell culture medium using anti-FLAG M2 affinity gel (Sigma-Aldrich, Poole) chromatography.

For receptor–ligand binding assays, the binding of biotinylated 50K or 70K fibronectin fragments to recombinant receptors (captured from cell culture supernatants using goat polyclonal anti-human Fc) was measured in the presence of 1mM Mn^{2+} at room temperature as previously described [36]. Measurements obtained were the mean \pm S.D. of four replicate wells. Background binding to wells coated with BSA alone was subtracted from all measurements.

In all assays comparing the binding of fibronectin fragments to wild-type and mutant receptors, the level of ligand binding to mutant receptors was normalised relative to that of wild-type $\alpha 5\beta 1$ -1 by measuring the binding of the anti-human Fc peroxidase conjugated antibody to a parallel set of replicate wells for each receptor [34]. Each experiment shown is representative of at least three separate experiments. Binding or inhibition curves were fitted using global optimization by simulated annealing (GOSA-fit, www.bio-log.biz).

Apparent K_i values for inhibitors were calculated using the formula: $K_i = IC_{50}/(1 + [ligand]/K_D)$, where IC_{50} = concentration of inhibitor for 50% inhibition of binding and K_D = apparent affinity of ligand binding to $\alpha 5\beta 1$. In inhibition assays the concentration of ligand was 2–3 nM and inhibitor concentrations were 0.1–100 µg/ml for CRRETAWAC and 0.1–300 nM for JSM6427 (prepared by serial dilution).

Homology modelling

Alignment of $\alpha 5$ with αV and αIIb , and $\beta 1$ with $\beta 2$ and $\beta 3$ was performed using Clustal W2 (www.ebi.ac.uk). This alignment was identical to that of Xiong and co-workers [21] within the β -propeller and $\beta I/A$ domains. Homology modelling of the $\alpha 5$ β -propeller domain, and $\beta 1$ head region, was carried out using Modeller 9v6 [37] (<http://salilab.org/modeller/release.html>) using the 2vdr structure of $\alpha IIb\beta 3$ [22] as a template, except for residues Arg-220–Tyr-233 of $\alpha 5$ where the 1L5G structure of αV [21] was used as a template. Lowest energy models were chosen, and selected loops were refined using Modeller. Final quality of the model was assessed using PROCHECK [38] (<http://www.ebi.ac.uk/thornton-srv/databases/pdbsum/upload.html>): 87.8% of side chains were in the most favoured regions, 10.9% in additional allowed regions, 0.5% in generously allowed, and 0.8% in disallowed regions of the Ramachandran plot. Residues in disallowed or generously allowed regions of the plot did not contribute to the ligand-binding pocket. DS Vizualizer 2.0 (Accelrys Software Inc.) was used to visualize the model. Docking of a fragment of JSM6427 into the ligand-binding pocket was performed with the constraints of placing the 2-amino group in a suitable position for hydrogen bonding to the carboxylate group of Asp-227 on the $\alpha 5$ subunit and orientation of the carboxylate group of JSM6427 towards the MIDAS cation on the β subunit. The program PyMOL (version 0.99) (<http://www.pymol.org>) was used to display the model.

Results

Characterization of zebrafish $\alpha 5$ integrins

Constructs containing the complete extracellular domain of the zebrafish $\alpha 5$ subunit and the head region of the $\beta 1$ -1 and $\beta 1$ -2 subunits fused to the hinge region and C_{H2} and C_{H3} domains of the Fc region of the human IgG $\gamma 1$ chain were created as described in 'Experimental'. These constructs were chosen because expression of the head and leg regions of the α subunit together with the head region of the β subunit has previously been shown to be sufficient to create a constitutively active integrin [40]. The zebrafish $\alpha 5$ construct (zf $\alpha 5$ -Fc) was transiently co-expressed with $\beta 1$ -1, $\beta 1$ -2 or human $\beta 1$ TR [34] (hu $\beta 1$) Fc constructs in CHO L761h cells. Recombinant integrins were partially purified from the cell culture medium and the formation of heterodimers was examined using Western blotting. The results (Figure 1A) showed that in each case a predominant band at ~240 kDa was observed, corresponding to the expected mass of an α, β -Fc heterodimer. Under reducing conditions two predominant bands were observed at ~50 and ~100 kDa, concordant with the expected sizes of $\alpha 5$ light chain-Fc and $\beta 1$ -Fc subunits, respectively (not shown). Together, these data show that zebrafish $\alpha 5$ can form heterodimers not only with zebrafish $\beta 1$ -1 and $\beta 1$ -2 but also with human $\beta 1$.

Zebrafish $\alpha 5$ integrins bind to zebrafish but not human fibronectin

A recombinant fragment of zebrafish fibronectin-1 (FN-1) containing the $\alpha 5 \beta 1$ binding sites (type III repeats 6-10) was produced in mammalian cells as described in 'Experimental'. Since this fragment has an apparent molecular mass of approx. 70kDa by SDS-PAGE, we refer to this protein as '70K'. The 70K protein has a similar synergy region to human fibronectin (PPSRS in place of PHSRN) and an identical RGD-containing loop (Supplementary Figure S1). To test whether the recombinant integrins were functional, binding of biotin-labelled 70K to recombinant zebrafish $\alpha 5$ integrins was examined in solid-phase assays. Ligand binding was measured in the presence of 1mM Mn^{2+} in order to fully activate the receptors [36]. The results (Figure 2A) showed that each receptor bound strongly to 70K in a concentration-dependent and saturable manner. 70K binding could be inhibited by EDTA or a cyclic RGD peptide, showing that the interaction was specific (Supplementary Figure S2). Apparent affinities could be calculated from the binding curves (Supplementary Table 1) and these data showed that the affinity of zf $\alpha 5 \beta 1$ -1 for FN-1 was about 3-fold higher than that of zf $\alpha 5 \beta 1$ -2. Surprisingly, zf $\alpha 5$ hu $\beta 1$ bound 70K with the highest affinity. We also examined whether the zebrafish integrins could bind to an equivalent recombinant fragment of human fibronectin ('50K' [6]). The data (Figure 2B) showed that there was essentially no binding of zf $\alpha 5 \beta 1$ -1 or zf $\alpha 5 \beta 1$ -2, and only very low binding of zf $\alpha 5$ hu $\beta 1$ to 50K.

Human $\alpha 5$ can form functional heterodimers with zebrafish $\beta 1$ subunits

As described above, we found that zebrafish $\alpha 5$ could associate with human $\beta 1$. We next tested if the human $\alpha 5$ subunit could form heterodimers with the two zebrafish $\beta 1$ subunits. The human $\alpha 5$ -Fc construct (hu $\alpha 5$ -Fc) was co-transfected with hu $\beta 1$, $\beta 1$ -1, or $\beta 1$ -2-Fc constructs in CHO L761h cells. Cell culture supernatants were analysed for the formation of heterodimers as described above (Figure 1B). The results showed that a predominant band of ~260 kDa in each case, the expected size of the heterodimer. The apparent molecular mass of the human $\alpha 5$ heterodimers was observed to be slightly greater than that of the corresponding

zebrafish receptors (Figure 1B), probably due to the presence of additional glycosylation sites in human $\alpha 5$ [41]. Heterodimer formation was also assessed using mAbs recognizing the β -propeller domain of the $\alpha 5$ subunit (Supplementary Figure S3). The epitopes of these mAbs are only expressed when the β -propeller assumes its native fold, and this folding is dependent on the association of $\alpha 5$ with the $\beta 1$ -domain [34]. We found that anti- $\alpha 5$ β -propeller epitopes were expressed to a similar level for hua5 $\beta 1$ -1, hua5 $\beta 1$ -2 and hua5hu $\beta 1$ receptors. No binding of these antibodies was observed when cells were transfected with the $\alpha 5$ subunit alone. Collectively, these data demonstrate that the human $\alpha 5$ subunit can form heterodimers with zebrafish $\beta 1$ -1 and $\beta 1$ -2.

We next examined if the human $\alpha 5$ integrins could bind to the human 50K fibronectin fragment. The results (Figure 2C and Supplementary Table 1) showed that all three receptors bound with high affinity to 50K. This binding was specific since it could be fully inhibited by EDTA or cyclic RGD peptide (Supplementary Figure S2B). We then tested if the human receptors could bind to the zebrafish 70K protein (Figure 2D). We found that the human $\alpha 5$ integrins could interact with zebrafish fibronectin fragment but with markedly lower affinity than with the human protein (Supplementary Table 1).

In summary, we found that zebrafish $\alpha 5$ integrins interacted strongly with the FN-1 fragment but not with the human protein, whereas the human $\alpha 5$ integrins bound preferentially to human fibronectin fragment. To further support these findings we investigated if zfa5 $\beta 1$ -1-Fc could bind to purified human plasma fibronectin (huFN) in an 'inverted' assay in which fibronectin fragments or whole fibronectin are coated onto a 96-well plate and the integrin is in the solution phase. The results (Supplementary Figure S4A) showed that zfa5 $\beta 1$ -1-Fc bound well to 70K but not to 50K or huFN. In contrast, hua5 $\beta 1$ -1-Fc bound poorly to 70K but strongly to 50K or huFN (Supplementary Figure S4B). We also found that zebrafish fibroblasts, which express zfa5 $\beta 1$ -1, spread very well on the 70K zebrafish protein but poorly on the 50K human protein (Supplementary Figure S5), suggesting that our in vitro data is relevant to the function of cell-surface integrins.

Alanine-scanning mutagenesis identifies residues in loops on the side and upper surface of the zebrafish $\alpha 5$ subunit β -propeller involved in the binding of fibronectin

We next examined whether the mechanism of fibronectin binding to zebrafish $\alpha 5$ integrins was similar to that previously reported for human $\alpha 5\beta 1$. In human $\alpha 5$, residues around Phe-187 and Asp-227 are predicted to be important for the binding of the RGD sequence [21,42], while Tyr-208 and Ile-210 appear to play a role in recognition of the synergy region [31]. Based on an alignment with human $\alpha 5$ (Supplementary Figure S7) alanine mutations were made in zebrafish $\alpha 5$ residues in either the RGD (F183A, D224A, D225A) or proposed synergy region (Y204A, L206A) binding sites [31]. These residues lie in loops on the upper face or side of the β -propeller domain (the corresponding residues in human $\alpha 5$ are Phe-187, Asp-227, Asp-228, Tyr-208 and Ile-210). CHO cells were transfected with wild-type or $\alpha 5$ mutants together with $\beta 1$ -1-Fc and recombinant integrins were tested for binding to 70K. The results (Supplementary Figure S6, Table 1) showed that the Tyr-204 or Leu-206 putative synergy region binding site mutations reduced the affinity of ligand binding approx. 30-fold. A previously described mutation of Tyr-204 to asparagine (Y204N) that causes a loss-of-function phenotype in vivo [43] had a more severe effect on ligand recognition than the Y204A mutation. The F183A and D224A putative RGD binding site mutations essentially abrogated ligand recognition. The D225A mutation had an intermediate effect (Supplementary Figure S6, Table 1) and a control mutation K154A in a neighbouring loop

had no effect on ligand binding (not shown). In summary, the same residues appear to be important for recognition of fibronectin by both zebrafish and human $\alpha 5$ integrins.

Zebrafish $\alpha 5$ integrins are not inhibited by human $\alpha 5$ antagonists

We next investigated whether there were any differences between the human and zebrafish integrins in their sensitivity to human $\alpha 5\beta 1$ antagonists. For these assays we used the small molecule JSM6427 (Supplementary Figure S8 [19]) and the cyclic peptide CRRETAWAC [26]. The ability of these compounds to inhibit binding of 50K to human $\alpha 5$ integrins or 70K to zebrafish integrins was tested. The data (Figure 3 A-D) showed that all the human $\alpha 5$ receptors were potently inhibited by JSM6427 and CRRETAWAC but these reagents had little or no effect on the zebrafish heterodimers. In control experiments, the compound JSM6406 (an inactive derivative of JSM6427) and the peptide CRRETADAC in which the essential tryptophan residue is replaced by aspartate were ineffective for blocking 50K binding to hu $\alpha 5\beta 1$ -1 (Supplementary Figure S9). Apparent K_i values calculated from the inhibition curves for JSM6427 and CRRETAWAC (Supplementary Table 2) showed that the affinity of JSM6427 binding was unaffected by the β subunit partner of human $\alpha 5$; similarly, only small differences were observed between the apparent K_i values of CRRETAWAC for hu $\alpha 5\beta 1$ -1, hu $\alpha 5\beta 1$ -2 and hu $\alpha 5$ hu $\beta 1$. Similar K_i values were obtained when JSM6427 or CRRETAWAC were used to inhibit binding of the human $\alpha 5$ integrins to 70K (Supplementary Table 2). These findings show that the α subunit, not the β , determines the specificity and affinity of antagonist binding. Since zebrafish $\alpha 5$ integrins do not recognise human fibronectin or human $\alpha 5$ antagonists, these data suggested that a gain-of-function approach could be employed to define the regions within the $\alpha 5$ subunit that confer ligand-binding specificity.

Swapping blades 1-4 of the zebrafish $\alpha 5$ subunit β -propeller domain results in a complete gain of function for binding to human fibronectin and human $\alpha 5\beta 1$ antagonists

To identify regions of the human $\alpha 5$ subunit that are essential for ligand recognition portions of the zebrafish $\alpha 5$ subunit were exchanged with the corresponding regions of the human subunit (Supplementary Figure S7) and the binding of fibronectin fragments or antagonists tested in solid-phase assays. Previously, we have used a similar approach to show that a region of the human $\alpha 5$ subunit β -propeller encompassing blades 2 and 3 contains key sites involved in ligand recognition [29]. As a first step, we swapped blades 2 and 3 of the zebrafish $\alpha 5$ β -propeller with the human $\alpha 5$ sequence and co-expressed the chimeric $\alpha 5$ subunit with $\beta 1$ -1-Fc subunit. We found that this exchange was not sufficient to create a receptor that bound to human fibronectin (not shown); however, exchange of a larger section of the propeller (blades 1 to 3; W1-3) gave weak gain of 50K binding, and exchange of blades 1 to 4 (W1-W4) resulted in a near-complete gain of binding (Figure 4A). Exchange of blades 2 to 4 (W2-W4) only was not sufficient for full gain of binding, suggesting that all the first four blades are important in forming the ligand-binding pocket for fibronectin. The W1-W4 chimera recognized the 50K human and 70K zebrafish fibronectin fragments with very similar apparent affinities as the wild-type hu $\alpha 5\beta 1$ -1Fc (Figures 4A and 4B, Table 1). The W1-4 chimera also expressed the epitopes of human anti- $\alpha 5$ mAbs to a similar extent as hu $\alpha 5\beta 1$ -1 (Supplementary Figure S10).

We next tested whether the $\alpha 5$ (huW1-W4) $\beta 1$ -1Fc chimeric integrin could recognise the human $\alpha 5$ antagonists. The results (Table 2) showed that the chimera bound these antagonists with essentially the same apparent K_i values as the wild-type hu $\alpha 5\beta 1$ -1. Hence, blades 1-4 of the β -propeller contain all the sequences necessary for fibronectin and antagonist binding.

Swapping a loop region in blade 3 of the β -propeller confers a partial gain of function for binding of human $\alpha 5\beta 1$ antagonists

Although swapping a large region of the β -propeller was necessary for gain of fibronectin binding we reasoned that, since the binding interface of low molecular weight antagonists is likely to cover a much reduced area compared to that of fibronectin, it may be possible to swap only small regions of the β -propeller to gain antagonist binding. We chose to swap predicted loop regions on the top face of the β -propeller in repeats 2 to 4, since previously we have shown that these loops are involved in the binding of RGD and CRRETAWAC [28-30]. Three loop swap mutations were made: KEDTPH to EKEPL (B2-C2 loop), RGRK to SWAA (D3-A3 loop) and RKEIRF to ASSIY (D4-A4 loop) (Supplementary Figure S7). No changes were made to the B3-C3 loop, since it is identical in zebrafish and human $\alpha 5$. These mutations only had a small effect on the affinity of 70K binding (Figure 5A, Table 1). We then examined whether JSM6427 or CRRETAWAC could inhibit 70K binding. The results (Figure 5B,C) showed that the SWAA loop swap mutant was strongly inhibited by the antagonists, whereas these compounds had little or no effect on the EKEPL or ASSIY loop swap mutants. Hence, the D3-A3 loop contains residues that are essential for antagonist recognition. To determine which of these four residues were critical for antagonist binding we made mutants in which one (RGRA), two (RGAA) or three (SGAA) residues were swapped. JSM6427 inhibited the binding of 70K to the SGAA and RGAA mutants but not the RGRA mutant, and more strongly inhibited 70K binding to the SWAA mutant (Figure 6A, Figure 6 legend). In contrast, CRRETAWAC only inhibited the interaction of 70K with the SWAA mutant (Figure 6B). These results indicate that both the tryptophan residue and the first alanine residue in the SWAA sequence play important roles in JSM6427 binding but only the tryptophan residue is critical for gain of CRRETAWAC binding. The serine and the second alanine residues do not appear to be necessary for the gain of JSM6427 binding.

Apparent K_i values for the SWAA mutant (Table 2) showed that the apparent affinity of CRRETAWAC binding was approx 3-fold lower, and that for JSM6427 was approx 10-fold lower, than for wild-type human $\alpha 5$ integrin. Hence, although the D3-A3 loop contains residues that are essential for antagonist recognition other residues outside of this loop may be necessary for a full gain of function.

A triple loop swap results in a complete gain of function for binding of human $\alpha 5\beta 1$ antagonists but only a minor gain of binding to human fibronectin

To investigate whether residues other than those in the SWAA sequence are involved in the binding of the antagonists, a construct with a triple loop swap KEDTPH to EKEPL, RGRK to SWAA and RKEIRF to ASSIY (Supplementary Figure S7) was created. The triple swap only had a minor effect on the affinity of 70K binding (Table 1). We then examined the effects of JSM6427 and CRRETAWAC on 70K binding to this mutant. The results (Supplementary Figure 11A,B) showed that 70K binding to the triple swap mutant was inhibited more potently by the antagonists than the single SWAA swap. Apparent K_i values for the triple swap mutant were very close to those of wild-type hu $\alpha 5\beta 1$ -1 integrin (Table 2).

Hence, the exchanged residues in the B2-C2 and D4-A4 loops also appear to play a role in antagonist binding.

Although the triple loop swap mutant fully restored antagonist binding, this receptor demonstrated only a small increase of binding to 50K (Supplementary Figure 11C). Hence, the triple swap was not sufficient to restore recognition of human fibronectin.

A new homology model of the $\alpha 5\beta 1$ ligand-binding pocket supports a prominent role for D3-A3 loop residues in binding of human $\alpha 5$ antagonists

Homology modelling of human $\alpha 5\beta 1$ has guided the development of antagonists [19,24,25]. However, these models were based on the medium resolution $\alpha V\beta 3$ -cilengitide structure [21]. The $\alpha II\beta 3$ - γ chain peptide structure, 2vdr [23], was chosen as a template for homology modelling of $\alpha 5\beta 1$ rather than the $\alpha V\beta 3$ -cilengitide structure (1L5G) for three reasons: (i) the 2vdr structure is of higher resolution than the 1L5G structure (2.4 versus 3.2 Å), (ii) the 2vdr structure is a high affinity open conformation of the integrin, whereas the 1L5G structure represents a lower affinity closed conformation, (iii) the αV subunit has an aspartate residue in the D3-A3 loop (Asp-150) that interacts with the arginyl side chain of the ligand; there is unlikely to be an equivalent interaction in $\alpha 5$, instead the D3-A3 loop of $\alpha 5$ contains mainly hydrophobic residues and is more similar to αIIb in the same region. However, we used the 1L5G structure for modelling the D4-A4 loop of $\alpha 5$ because the αV subunit has an Asp residue at the same position as Asp-227 of $\alpha 5$ whereas αIIb has a Phe residue. Homology modelling was carried out as described in 'Experimental'. The final model (Figure 7A, Supplementary Figure 12) shows residues that have been proposed to be critical for ligand binding in $\alpha 5$ ([31,42] and this study) or $\beta 1$ [22,24]. On the α subunit side, residues in the D3-A3 and D4-A4 loops (Trp-157, Ala-158 and Asp-227) form walls on either side of the binding pocket for antagonists, while Phe-187 in the B3-C3 loop lines the base of the pocket. Potentially, other residues in these loops and the nearby B2-C2 loop could also participate in antagonist binding. On the β subunit side, residues in the $\beta 1$ - $\alpha 1$ loop of the βI domain (Ser-132 and Tyr-133) form another wall of the pocket and nearby residues Leu-225, Ser-227 and Ser-172 are also predicted to have essential roles [22,24]. Recognition of the synergy site in fibronectin involves residues Tyr-208 and Ile-210, situated in the C3-D4 loop on the side of the β -propeller [31]. A possible binding mode for the guanidine-mimetic region of JSM6427 is shown in Figure 7B.

DISCUSSION

The major findings of this report are the following: (i) the zebrafish $\alpha 5$ subunit can form heterodimers with zebrafish $\beta 1$ -1, $\beta 1$ -2 or human $\beta 1$ subunits but these receptors do not recognise human fibronectin or human $\alpha 5\beta 1$ antagonists, (ii) swapping the first four blades of zebrafish $\alpha 5$ β -propeller domain with those of human $\alpha 5$ endows the chimeric receptor with the ligand binding properties of human $\alpha 5\beta 1$, (iii) exchange of the D3-A3 loop region in zebrafish $\alpha 5$ with the corresponding region of human $\alpha 5$ (residues Ser-156–Ala-159) confers zebrafish $\alpha 5$ integrins with the capacity to recognise human $\alpha 5\beta 1$ antagonists, (iv) residues Trp-157 and Ala-158 are important for the binding of small molecule antagonists, (v) swapping of three loop regions (B2-C2, D3-A3 and D4-A4 loops) is sufficient for complete gain of antagonist binding but not of fibronectin binding (vi) homology modelling of the

$\alpha 5\beta 1$ ligand-binding pocket supports a prominent role for residues in the D3-A3 loop in binding of human $\alpha 5\beta 1$ -specific antagonists.

We found that the zebrafish $\alpha 5$ subunit could form heterodimers with human $\beta 1$ in addition to the two zebrafish β subunits. Similarly, human $\alpha 5$ could form heterodimers with $\beta 1$ -1 and $\beta 1$ -2 as well as the human $\beta 1$ subunit. Formation of heterodimers is known to be dependent upon an association of the β subunit I domain with the upper face of the α subunit β -propeller. One of the most important interactions that promotes heterodimer assembly is the binding of an arginine/lysine residue in the β D- β D' loop of the β I domain to a hydrophobic 'cage' at the centre of the β -propeller [22,44-45]. Significantly, the aromatic residues that form the cage for the Arg/Lys side chain are conserved between human and zebrafish $\alpha 5$. In addition the sequence of the β D- β D' loop is almost identical in $\beta 1$ -1, $\beta 1$ -2 and human $\beta 1$. These features may explain why it is possible to form cross-species heterodimers despite the very long evolutionary separation of humans and fish (~350 My). The high level of identity between the I/A domains of $\beta 1$ -1, $\beta 1$ -2 and human $\beta 1$ [33] may also explain why the specificity and affinity of ligand binding was influenced mainly by the $\alpha 5$ subunit and not by the β .

We do not currently have a clear explanation for why zebrafish $\alpha 5$ integrins are unable to interact with human fibronectin. However, an intriguing feature of zebrafish FN-1 is that a highly conserved threonine residue in the putative integrin-binding face of the molecule [9] is replaced with a much less bulky glycine residue (Supplementary Figure 13). Hence it is possible that steric clashes may interfere with human fibronectin binding to zebrafish $\alpha 5\beta 1$. We found that it was necessary to swap a large section of the β -propeller (repeats 1-4) in order to gain binding to human fibronectin, suggesting that the site of fibronectin binding involves a broad interface. However, it is also possible that a relatively small interface is involved in ligand recognition but the tertiary structure of the ligand-binding loops is dependent upon the folding of adjacent loops throughout blades 1- 4. The key residues involved in fibronectin recognition include Phe-187, Tyr-208, Ile-210, and Asp-227 in blades 3 and 4 of the human $\alpha 5$ subunit [42,33,21], and further studies will be necessary to pinpoint additional essential residues. Previously, it has been shown that the fibrinogen binding site on α IIb involves many residues in blades 2-4, covering a large portion of the upper face and side of the β -propeller [46]. Nearly all these residues are now known to lie in a specialised sub-region of the β -propeller known as the 'cap' [22].

Although zebrafish $\alpha 5$ integrins were unable to bind to human fibronectin, alanine mutagenesis suggested that the same residues involved in the interaction of human fibronectin with the human receptor also participate in zebrafish $\alpha 5$ -FN-1 binding. For example, mutation of F183A and D224A putative RGD binding site residues fully abrogated ligand recognition. In addition, we found that mutation of residues Tyr-204 and Leu-206 in the C3-D4 loop, equivalent to Tyr-208 and Ile-210 in human $\alpha 5$, strongly perturbed ligand recognition. Mutation of either Tyr-204 or Leu-206 to alanine reduced the apparent affinity of fibronectin binding approx. 30-fold, whereas mutation of the corresponding residues in human $\alpha 5$ reduced the affinity of fibronectin binding by 5- and 200-fold, respectively [31]. These data are consistent with previous reports that loss of interaction with the synergy region leads to ~100-fold lower affinity of fibronectin binding [5,6]. A model of the interaction between $\alpha 5\beta 1$ and fibronectin based on X-ray scattering data [31] predicts that the Tyr and Ile/Leu residues on the side of the β -propeller are located 30-40 Å away from the site of RGD binding, which is consistent with the spacing of the synergy region from RGD in fibronectin [8]. In agreement with our in vitro data, mutation of Tyr-204 to Asn results in a

loss-of-function mutation of $\alpha 5$ in zebrafish [43]. The C3-D4 loop of αIIb contains residues essential for fibrinogen binding by $\alpha \text{IIb}\beta 3$ [46], and alternative splicing of this loop can regulate the specificity of ligand interactions in the $\alpha 7$ and αPS subunits [47-49]. In addition this loop contains the binding site of function-blocking mAbs in αIIb and $\alpha 5$ [22,50]. Hence, the C3-D4 loop may form an important secondary site of ligand recognition in many integrins.

Peptides containing the sequence RGDW or RGDF are potent inhibitors of $\beta 3$ integrins. The crystal structure of $\alpha \text{IIb}\beta 3$ bound to the cyclic hexapeptide eptifibatide shows that the GDW sequence has a tight reverse turn following the Asp residue, and that this bend allows the Trp side chain to occupy a hydrophobic pocket formed by Phe-160 and Tyr190 on the αIIb subunit [22]. In contrast, RGDW and RGDF peptides are poor inhibitors of $\alpha 5\beta 1$ but peptides containing the sequences RGDGW or RGDGF are very good $\alpha 5\beta 1$ inhibitors [26,27]. The presence of the Gly residue immediately following the Asp residue may favour a more open (less tight) turn in these peptides when binding to $\alpha 5\beta 1$. As noted previously [24,25], replacement of bulky $\beta 3$ residues Tyr-166, Arg-214 and Arg-216 by Ser-177, Gly-223 and Leu-225, respectively, in $\beta 1$ opens up more space adjacent to the RGD binding pocket. This additional space may allow for the more extended turn in RGDGW/F peptides. In previous homology models of $\alpha 5\beta 1$ [24,25,31], which used the $\alpha \text{V}\beta 3$ structure [21] as the template, the side chain of Trp-157 was pointing away from the pocket. In our new model, Trp-157 and Phe-187 of $\alpha 5$ occupy similar positions to Phe-160 and Tyr-190 in αIIb [22]. The side chains of Trp-157 and Phe-187 are suitably positioned to allow stacking interactions with the aromatic moieties of peptide antagonists, such as the phenyl group of Phe in RGDGF peptides and the indole ring of Trp in RGDGW and RRETAWA. Hence, our model helps to explain why these moieties are critical for high affinity binding of these antagonists.

We found that the specificity of antagonist binding appears to derive mainly from the α subunit. In our model (Figure 7A), residues in human $\beta 1$ predicted to be important for ligand recognition by $\alpha 5\beta 1$ [24] are completely conserved in zebrafish $\beta 1$ -1 and $\beta 1$ -2 [33]. Ligand binding pocket residues in human $\alpha 5$ are also conserved in zebrafish $\alpha 5$, with the important exceptions that Trp-157 is substituted by Gly and Ala-158 by Arg. We have previously shown that Trp-157 in the D3-A3 loop is involved in binding of human $\alpha 5\beta 1$ -specific and $\alpha 5\beta 1$ -selective antagonists such as CRRETAWAC and RGDGW [28-30]. Here we demonstrate that residues in this loop (SWAA) are also important for the binding of small molecule antagonists. Swapping only two loop residues (RGAA mutant) gave a partial gain of function for binding of JSM6427 but no gain of binding for CRRETAWAC. Hence, although the tryptophan residue is essential for high affinity binding of CRRETAWAC, this residue plays a more minor role in the interaction of $\alpha 5\beta 1$ with JSM6427. Instead, our data suggest that Ala-158 has an important function in the binding of this compound either by direct interaction or gaining space for other interactions. The 4-methoxy substituent of the 2-aminopyridine ring of JSM6427 is involved in high affinity binding to $\alpha 5\beta 1$ [19], and our modelling (Figure 7B) suggests that this moiety could interact with residues in the D3-A3 loop region.

JSM6427 is undergoing phase I clinical trials for treatment of age-related macular degeneration. Our findings will aid in the rational design of more potent and specific $\alpha 5\beta 1$ antagonists. Finally, animal models such as zebrafish provide a valuable means of drug screening [51]. However, due to sequence differences in the D3-A3 loop, antagonists of human integrins often do not cross react with integrins of other species [52,53, this study].

Our results suggest that introduction of the SWAA loop swap into the zebrafish $\alpha 5$ gene could create an in-vivo model suitable for drug screening or discovery [54].

Acknowledgements

We thank Drs. Adam Hurlstone, Scott Holley and Jordi Bella for helpful discussions, Simon Williams, Patrick Buckley, and Guillaume Jacquemet for assistance with homology modelling, Scott Holley for gift of oligonucleotides, S. Koshida for zebrafish $\alpha 5$ cDNA, and Janet Askari for human $\alpha 5$ and $\beta 1$ -Fc constructs. We are grateful to Elizabeth Lord, Jennifer Hamilton and Simon Mathers for technical assistance, and Amanda Kelly and Paul Walker for PAC2 cell line and cDNA. We thank Roland Stragies (Jerini AG) for synthesis of JSM6427 and JSM6406, and Ulf Reimer (Jerini AG) and Patrick Bryant for helpful discussion of homology modelling.

Funding

These studies were supported by grants 045225 and 074941 from The Wellcome Trust to MJH.

Declarations of interest

Figures

Figure 1 Preparation and characterization of recombinant soluble α 5 integrins.

(A) Western blotting of recombinant-soluble zebrafish (zf) α 5 β 1-Fc integrins. The expected migration positions of α , β heterodimer and α , α homodimers are indicated by arrows. In each case a predominant band at ~ 240 kDa is observed, at the expected size for the zf α 5 β 1-Fc heterodimer. (B) Western blotting of recombinant-soluble human (hu) α 5 β 1-Fc integrins. A predominant band at ~ 260 kDa is observed, at the expected size for the hu α 5 β 1-Fc heterodimer. These bands are not observed in proteins purified from the supernatants of mock-transfected cells.

Figure 2 Fibronectin binding to recombinant integrins in solid phase assays

(A) Binding of 70K fragment of zebrafish fibronectin to zfa5β1-1, zfa5β1-2 and zfa5huβ1. (B) Binding of 50K fragment of human fibronectin to zfa5β1-1, zfa5β1-2 and zfa5huβ1. (C) Binding of 50K to hua5β1-1, hua5β1-2 and hua5huβ1. (D) Binding of 70K to hua5β1-1, hua5β1-2 and hua5huβ1.

Figure 3 Effect of human α5β1 antagonists on fibronectin binding to recombinant integrins

(A) Effect of JSM6427 on binding of 70K fragment of zebrafish fibronectin to zfa5β1-1, zfa5β1-2 and zfa5huβ1. (B) Effect of CRRETAWAC on binding of 70K to zfa5β1-1, zfa5β1-2 and zfa5huβ1. (C) Effect of JSM6427 on binding of 50K fragment of human fibronectin to hua5β1-1, hua5β1-2 and hua5huβ1. (D) Effect of CRRETAWAC on binding of 50K to hua5β1-1, hua5β1-2 and hua5huβ1. Binding is expressed as a percentage of 70K or 50K binding in absence of inhibitor.

Figure 4 Characterization of chimaeric zebrafish/human α5β1-1 blade swap integrins

Binding of wild-type hua5β1-1, and zfa5(huW1-3)β1-1, zfa5(huW2-4)β1-1 and zfa5(huW1-4)β1-1 blade swap receptors to (A) 50K fragment of human fibronectin and (B) 70K fragment of zebrafish fibronectin. No significant binding of wild-type zfa5β1-1 to 50K was observed in the same assay (not shown).

Figure 5 Characterization of chimaeric zebrafish/human α5β1-1 loop swap integrins

(A) Binding of wild-type zfa5β1-1, zfa5(EPEK)β1-1, zfa5(SWAA)β1-1 and zfa5(ASSIY)β1-1 loop swap receptors to 70K fragment of zebrafish fibronectin. (B) Effect of JSM6427 on binding of loop swap receptors to 70K. (C) Effect of CRRETAWAC on binding of loop swap receptors to 70K. In panels B and C 70K binding is expressed as a percentage of binding in absence of inhibitor.

Figure 6. Effect of human α5β1 antagonists on fibronectin binding to D3-A3 swap mutants

Effect of JSM6427 (A) and CRRETAWAC (B) on binding of zfa5(SGAA)β1-1 swap zfa5(RGAA)β1-1 swap, zfa5(RGRA)β1-1 swap, zfa5(SWAA)β1-1 loop swap and wild-type zfa5β1-1 to 70K fragment of zebrafish fibronectin. One experiment, representative of three separate experiments. In this set of experiments, apparent K_i values for JSM6427 were calculated as 25 ± 4 , 29 ± 6 , and 4.2 ± 0.2 nM (mean \pm SD) for zfa5(SGAA)β1-1, zfa5(RGAA)β1-1, and zfa5(SWAA)β1-1, respectively.

Figure 7 Homology model of the ligand-binding region of human α5β1

A. Ribbon diagram of the α subunit β-propeller domain (green) and β subunit I/A domain (pale cyan). The structure of αIIbβ3 [22] was used as a template for modelling, except for the D4-A4 loop where the structure of αVβ3 [21] was used. Model shows side chains of residues likely to be critical for ligand recognition [22,24,41,30,31, and this study]. Tyr-208 and Ile-210 on the side of the β-propeller contribute to binding of the synergy region of fibronectin, while the other labelled residues contribute to the binding of the RGD sequence in fibronectin and/or α5β1 antagonists. Side chain atoms are depicted as spheres with carbon, nitrogen and oxygen atoms coloured in grey, blue and red, respectively. Residues in the RGD-binding pocket of the corresponding αIIb (or αV) or β3 subunits are indicated in parentheses. The MIDAS cation is depicted by the gold sphere. B. Possible binding mode of JSM6427. A fragment of JSM6427 containing the 4-methoxy-2-aminopyridine ring (guanidine mimetic region) is shown docked into the binding pocket of α5β1. The integrin is shown as a Connolly surface with α5 subunit in green and β1 subunit in pale cyan. Fragment of JSM6427

is depicted as sticks with carbon, nitrogen, oxygen and hydrogen atoms coloured in grey, blue, red and white, respectively. The program PyMOL (version 1.1) was used to display the model.

Tables

Table 1 - Apparent affinities of binding of wild-type and mutant integrins to 70K and 50K fibronectin fragments

Apparent K_D values (nM) for binding to 70K fragment of zebrafish fibronectin or 50K fragment of human fibronectin. Values are mean \pm S.D.; n=3-5 experiments. ND: not determined

integrin	70K	50K
hu α 5 β 1-1	25 \pm 2	1.3 \pm 0.2
zfa5 β 1-1	2.8 \pm 0.2	ND
zfa5 β 1-1(D225A)	42 \pm 14	ND
zfa5 β 1-1(Y204A)	79 \pm 7	ND
zfa5 β 1-1(L206A)	106 \pm 16	ND
zfa5(huW1-4) β 1-1	14 \pm 1	1.3 \pm 0.1
zfa5(EPEK) β 1-1	4.6 \pm 0.1	ND
zfa5(SWAA) β 1-1	1.7 \pm 0.1	ND
zfa5(ASSIY) β 1-1	8.3 \pm 0.3	ND
Triple swap	5.8 \pm 0.4	ND

Table 2 - Apparent K_i values of JSM6427 and CRRETAWAC for wild-type and chimaeric α 5 β 1-1 integrins

integrin	JSM6427		CRRETAWAC	
	70K	50K	70K	50K
hu α 5 β 1-1	ND	0.65 \pm 0.15	ND	47 \pm 9
zfa5(huW1-W4) β 1-1	ND	0.75 \pm 0.04	ND	31 \pm 12
zfa5(SWAA) β 1-1	7.2 \pm 2.4	ND	126 \pm 43	ND
Triple swap	1.21 \pm 0.04	ND	76 \pm 20	ND

Apparent K_i values (nM) for 70K fragment of zebrafish fibronectin or 50K fragment of human fibronectin binding to recombinant integrins. Values are mean \pm S.D.; n=3-6 experiments. ND: not determined.
