Is the spin transition in Fe²⁺-bearing perovskite visible in seismology?

Razvan Caracas,¹ David Mainprice,² and Christine Thomas³

Received 18 March 2010; revised 5 June 2010; accepted 14 June 2010; published 15 July 2010.

[1] We determine the elasticity of FeSiO₃ perovskite for various spin configurations using density-functional theory calculations. The elastic moduli and the bulk seismic wave velocities are weakly affected by the spin transition. However we show that the intrinsic differences in seismic anisotropy between the high-spin and low-spin phases of Fe-bearing perovskite coupled with lattice preferred orientation that can develop due and during the convection may lead to distinct seismic signatures between the top and the bottom of the lower mantle. These signatures should be detectable in observations and they need to be taken into account in tomographic studies of the Earth's lower mantle. **Citation:** Caracas, R., D. Mainprice, and C. Thomas (2010), Is the spin transition in Fe²⁺-bearing perovskite visible in seismology?, *Geophys. Res. Lett.*, 37, L13309, doi:10.1029/2010GL043320.

1. Introduction

[2] It is now well established that the Fe-bearing minerals exhibit spin transitions under pressure. Magnesio-wustite has been extensively studied from both experimental and computational points of view and its phase diagram and spin transition have been thoroughly mapped out [e.g., Lin *et al.*, 2005; Lin and Tsuchiya, 2008]. In the last years more and more evidence emerged, from both experimental and theoretical sides, that points to a magnetic phase transition also in Fe²⁺-bearing perovskite [Badro *et al.*, 2004; McCammon *et al.*, 2008; Lin *et al.*, 2007] and post-perovskite [Lin *et al.*, 2008] at high-pressure. The change in Mössbauer signal [McCammon *et al.*, 2008; Lin *et al.*, 2008] and X-ray emission spectra [Badro *et al.*, 2004; Lin *et al.*, 2008] over a narrow pressure range have been interpreted as the signature of the spin transition, though there is current disagreement between the different experimental groups regarding this interpretation. Other experimental studies observed a continuous spin transition from high-spin state to low-spin state for ferrous iron for both perovskite [Li *et al.*, 2004, 2006] and post-perovskite [Jackson *et al.*, 2009], but ferric iron might remain in a high-spin state, while another set of experiments observe the persistence of non-vanishing spin up to high pressure in perovskite [Jackson *et al.*, 2005].

[3] First-principles calculations based on density functional theory (DFT) suggest that Fe-bearing MgSiO₃ perovskite undergoes a spin transition from high-spin state to low-spin state [Bengtson *et al.*, 2008; Stackhouse *et al.*, 2007; Umemoto *et al.*, 2008]. The transition pressure is highly dependent on the iron content: up to about 25% Fe the transition pressure remains constant while at iron concentrations larger than about 25% the transition pressure decreases dramatically with increasing iron content [Bengtson *et al.*, 2008]. The spin transition is associated with a structural distortion: the volume collapse of the iron atoms due to the electron pairing is accommodated in the structure by a displacement that breaks the symmetry of the structure and changes the local coordination environment [Bengtson *et al.*, 2008; Umemoto *et al.*, 2008]. Non-randomized structures obtained only from replacement of Mg by Fe in the Pbnm structure lead to much higher transition pressures [Stackhouse *et al.*, 2007; Caracas and Cohen, 2005; Fang and Ahuja, 2008] or to iron disproportionation [Zhang and Oganov, 2006].

[4] Using a different approach than in the previous theoretical studies, recently we investigated the dynamical stability of Pbnm FeSiO₃ perovskite and show the existence of unstable phonon modes. Following their corresponding eigendisplacements we found various monoclinic and triclinic configurations with intermediate spin state competitive to the high-spin antiferromagnetic structure and eventually a triclinic low-spin structure, which is the stable phase above about 37 GPa. The intermediate spin structures exhibit only minor displacements relative to the high-spin orthorhombic structures, while the triclinic low-spin structure is strongly distorted. Consequently we focus in the following only on the high-spin ferro-, antiferro-magnetic and the low-spin structures as most representative for the FeSiO₃ perovskite system at pressures characteristic to the lower mantle.

2. Computational Details

[5] Hereinafter we understand by high-spin, intermediate-spin and low-spin states the electronic configurations with a net residual magnetic moment of respectively, 4, 2 and 0 Bohr magnetons for each Fe atom, equivalent to 4, 2 and 0 unpaired d electrons per Fe site. This is quite an artificial and simplified way of representing magnetization, especially in metallic systems where orbital hybridization and electron delocalization due both to the lattice periodicity and the metallic character of the bonding oftentimes lead to non-integer Fermi band occupations and thus to non-integer values of the remnant magnetization.

[6] We use density-functional theory [Hohenberg and Kohn, 1964; Kohn and Sham, 1965] in the ABINIT implementation [Gonze *et al.*, 2002, 2005b, 2009], which is based on planewaves and pseudopotentials. We perform all the

^aResults obtained from static calculations at 90 GPa. For the triclinic structure we only list the non-zero constants.

static calculations using the planar-augmented wavefunction (PAW) formalism. Then for the relaxed structures we compute the full elastic constants tensor and the phonons in the Brillouin zone center in the framework of the density functional perturbation theory (DFPT) [Baroni *et al.*, 1987; Gonze and Lee, 1997; Baroni *et al.*, 2001; Gonze *et al.*, 2005a] using standard norm-conserving Troullier-Martins pseudopotentials. Here the elastic constants are expressed as the derivative of the energy with respect to lattice strains [Hamann *et al.*, 2005]. The atomic relaxations due to strain are taken into account from the phonon and dielectric calculations by inverting a matrix containing the interatomic force constants, the couplings with the strains and the couplings with the electric fields.

[7] We use the local density approximation for the exchange-correlation energy both DFT and DFPT calculations. As usual with planewave basis sets, the numerical accuracy of the calculation can be improved by increasing the cut-off kinetic energy of the planewaves and the density of the sampling of the Brillouin zone [Payne *et al.*, 1992]. Here we use a 35 Eh cut-off energy for the kinetic energy of the planewaves. We sample the reciprocal space using a $6 \times 6 \times 6$ regular grid of special k points according to the Monkhorst-Pack scheme [Monkhorst and Pack, 1976]. These parameters ensure a precision of the calculation better than 1 mEh per unit cell in energy and better than 1GPa in pressure.

3. Results and Discussion

[8] Because Fe-bearing perovskite is the major mineral of the Earth's lower mantle it obviously received a particular attention from both the experimental and computational community. The elastic constants of MgSiO₃ perovskite have been previously reported in several theoretical [e.g., Cohen, 1987; Karki *et al.*, 1998; Oganov *et al.*, 2001; Wentzcovitch *et al.*, 2004; Caracas and Cohen, 2005, 2007] and experimental [Yeganeh-Haeri *et al.*, 1989; Sinelnikov *et al.*, 1998] studies. The seismic properties of a homogeneous

aggregate of perovskite are close to the values estimated for PREM though not identical, and corrections due to at least to temperature, chemical composition, redox state of iron and iron spin state need to be considered to account for these discrepancies. However many of these corrections are still unknown. In this paper we discuss in detail the effect on the seismic properties of the iron spin transition in perovskite.

[9] The elasticity of the (Mg,Fe)SiO₃ perovskite has been addressed so far considering only the high-spin state of iron. Two approaches were used. First is to compute the elastic tensors of the end member MgSiO₃ and FeSiO₃ terms and perform a linear interpolation along the solid solution. These studies [Li *et al.*, 2005; Caracas and Cohen, 2005, 2007, 2008; Stackhouse *et al.*, 2006] showed that the effect of iron is to lower both the compressional and the shear seismic wave velocities. For average pyrolitic compositions (10% ferrous iron on the Mg site) the decrease in velocities is of about 0.17 km/s at 120 GPa [Caracas and Cohen, 2005, 2007], which corresponds to reduction with respect to pure MgSO₃. The second approach is to effectively build the crystal structures with the desired Fe content by replacing Mg with ferrous iron [Kieffer *et al.*, 2002]. This latter approach is more correct, but is more computationally intensive while the departure from linear scaling along the solid solution might be very small. Here we use the first approach, computing the elastic constants tensor for the FeSiO₃ term and studying the differences between various spin states.

[10] MgSiO₃ perovskite has an orthorhombic structure with 20 atoms per unit cell and Pbnm space group. The structure exhibits a three-dimensional network of SiO₆ octahedra, each two neighboring octahedra sharing one oxygen atom along each of the cartesian directions, and the larger Mg cations sitting in the interoctahedral space. It has 9 independent elastic constants: C₁₁, C₂₂, C₃₃, C₁₂, C₁₃, C₂₃, C₄₄, C₅₅ and C₆₆.

[11] For the FeSiO₃ end-member term we consider both the ferromagnetic (FM) and the antiferromagnetic (AFM) configurations, even though the latter one is the most stable; the energy difference between the two is of about 5 mHa per formula unit and is weakly dependent of the pressure [Caracas and Cohen, 2005]. This corresponds to roughly 1000K, meaning that at mantle conditions the two configurations can coexist. When performing the calculations we impose a residual magnetic moment of 4 magneton-Bohrs for each Fe site in case of the FM configuration. The magnetic moment for the AFM is allowed to freely relax and settles to 3.4 magneton-Bohrs at 90 GPa; it is weakly varying with pressure. For the low-spin structure the calculation is non-spin-polarized. The FM and AFM magnetic structures are metallic and have orthorhombic symmetry and the LS is insulating with triclinic symmetry.

[12] Table 1 lists the elastic constants, the density and the bulk seismic properties computed for the FM, AFM and the LS structures of FeSiO₃ at 90 GPa. Except for C₁₂, C₁₃ and C₂₃, all the off-diagonal elastic constants of the triclinic LS structure are smaller than 1 GPa. Essentially the triclinic distortions allow only a rearrangement of the structure to accommodate the smaller low-spin Fe ions, but preserves the quasi-orthorhombic character of the lattice.

[13] The differences between the FM and AFM elastic constants tensors are minimal. The largest discrepancies

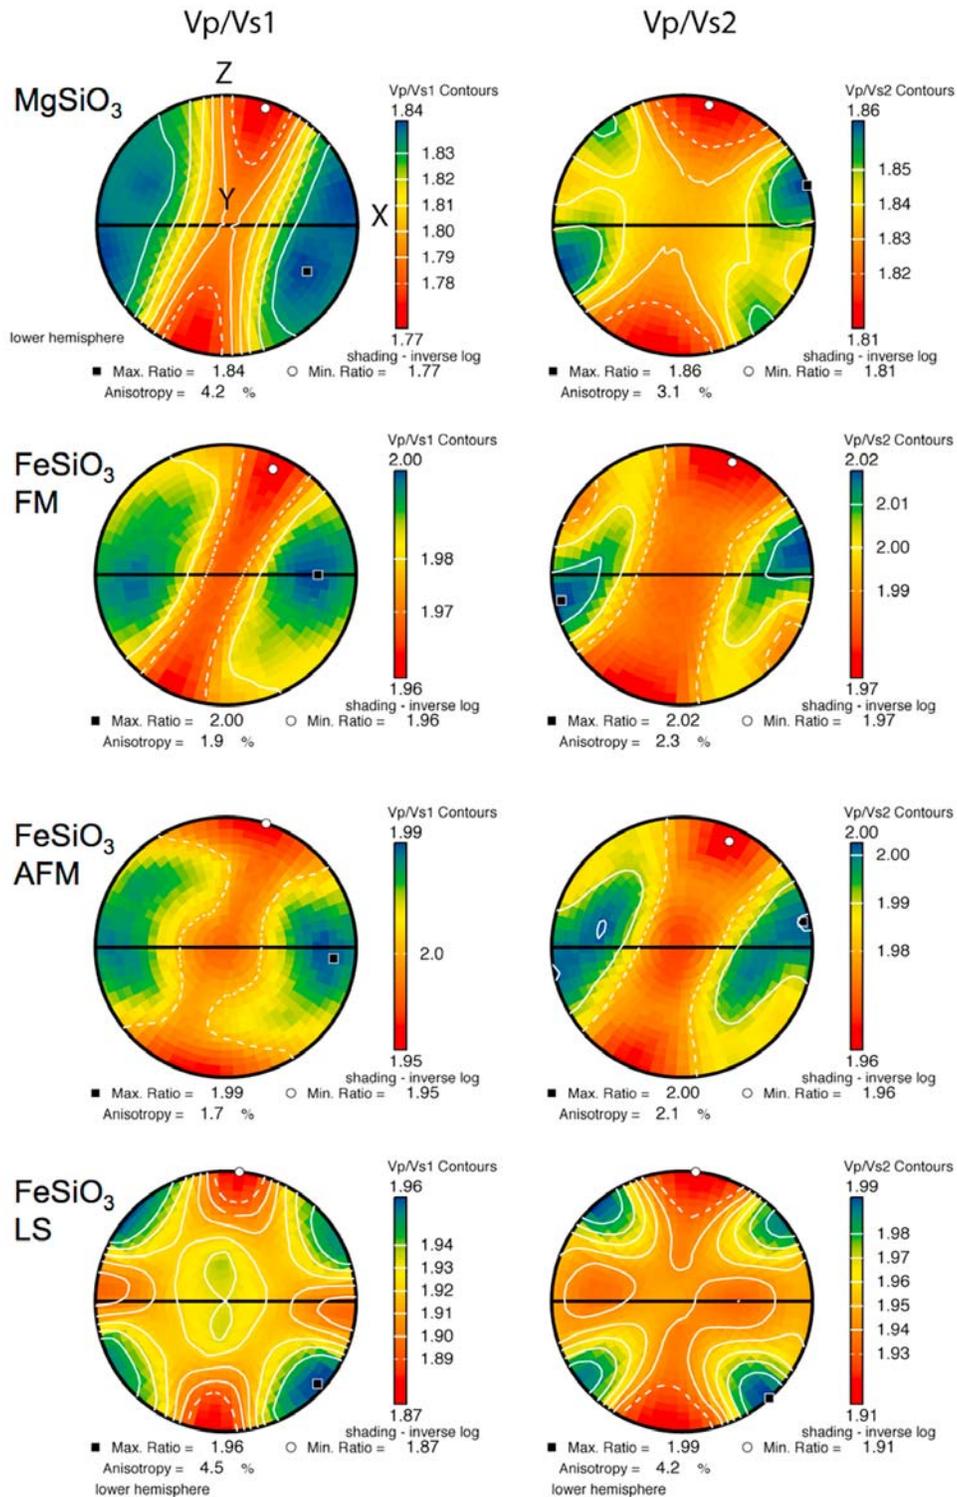

Figure 1. The predicted seismic anisotropy for Vp and Vs for MgSiO_3 and FeSiO_3 perovskites with various spin configurations for polycrystalline aggregates, based on single crystal elastic constants reported in Table 1 and VPSC predicted crystal preferred orientations for MgSiO_3 in simple shear for a shear strain of 1.73. The Voigt-Ruess-Hill average was used for elastic properties. X, Y and Z are the finite strain axes.

are on the C_{11} and C_{13} constants, of respectively -34 and $+16$ GPa, while all the others are less than 10 GPa. The difference of density is on the order of 0.01 g/cm^3 , of the elastic moduli less than 3, resulting in quasi-identical bulk seismic velocities for homogeneous aggregates. On the other

hand the differences between the high-spin and the low-spin structures are considerable, going as high as 141 GPa for the C_{33} elastic constant. The density difference is also significant with the LS structure denser by 0.26 g/cm^3 , than the AFM, namely almost 4%. The change in density is correctly

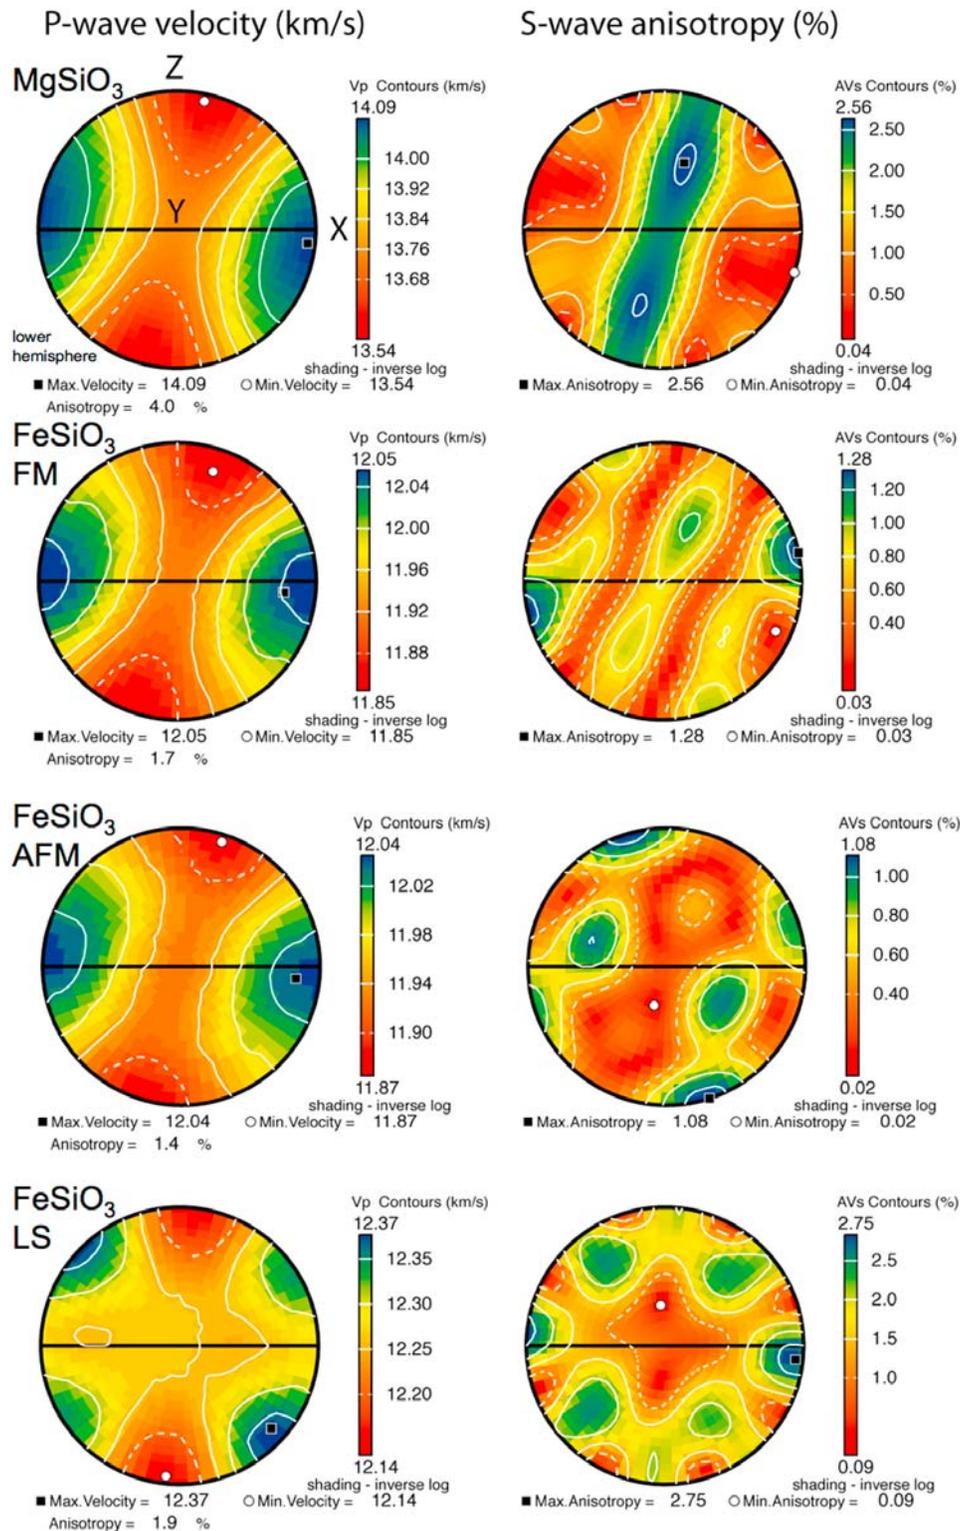

Figure 2. The predicted seismic anisotropy for various spin configurations in pure FeSiO_3 and MgSiO_3 perovskite coupled with lattice preferred orientation. We use the computed elastic constants from Table 1 for FeSiO_3 at 90 GPa and 0 K and the experimental measurements at room temperature and 90 GPa for MgSiO_3 . The LS configuration has distinctively low values (red) along the normal (Z direction) to the flow (XY) plane and in the flow plane (XY).

represented in changes in elastic moduli and seismic wave velocities, with larger values for LS structure. The absolute differences are larger for the bulk moduli (K), on the order of about 41–42 GPa, than for the shear moduli (G), on the order

of 19–22 GPa. The Young modulus, defined as $Y = (9KG)/(3K+G)$ shows similar values between FM and AFM that are lower than LS by about 50 GPa. The Poisson ratio, $\mu = Y/2G - 1$, is in the range 0.31–0.33 for all the structures at

90 GPa, larger than most ceramics, but usual for Fe-bearing perovskites at high pressure [Caracas and Cohen, 2007].

[14] In terms of seismic wave velocities for homogeneous bulk aggregates the FM and AFM are hardly distinguishable with differences on the order of 0.01 km/s for compressional wave velocities (V_p) and 0.04 km/s for shear wave velocities (V_s). The differences are more important with respect to the LS structure, through which the V_p travel with 0.18 km/s faster than in AFM and the V_s travel 0.12 km/s faster than in AFM. These absolute velocity differences correspond to respectively only 1.5% and 1.8% relative difference.

[15] If we assume a linear dependence of the seismic properties along the (Mg,Fe)SiO₃ solid solution, then for a pyrolytic mantle with an average 8 at. % ferrous iron in perovskite [Kesson et al., 1998] the difference in seismic wave velocities between the high-spin and low-spin configurations will be of only 0.12% for V_p and 0.15% for V_s . Even considering a larger iron content, like 15 at. %, which is closer to the upper acceptable limit for pyrolyte, these differences go up to only 0.23% and 0.29% respectively for V_p and V_s . These values are definitely too low to be detectable using current seismological techniques and body waves, as they would only lead to very small travel time differences in waves bottoming at different depths. Also, since the transition takes place over a large pressure range it will not produce any reflectors detectable with seismic body waves. It was shown based on thermodynamical considerations and later observed in experimental measurements that during the spin transitions an elastic anomaly develops that leads to a considerable reduction in wave velocities [Speziale et al., 2007]. However it is also highly temperature-dependent such that at lower mantle temperatures where the iron spin transition takes place in perovskite the variation of the seismic properties will be smooth and undetectable seismically.

[16] If the bulk seismic wave velocities are not strongly affected by the spin transition in Fe-bearing perovskite, things are different when one looks at the seismic anisotropy (Figure 1). The MgSiO₃ and the orthorhombic high-spin FeSiO₃ perovskites, show similar anisotropy patterns. The minimum velocities are along the normal to the X direction and the maximum velocities are along the X direction. The amount of V_p anisotropy is on the order of 5–7% for both MgSiO₃ and FeSiO₃. The V_s anisotropy is different between the two compositions, and more importantly between the high-spin and the low-spin phases of iron-bearing silicate. The HS FeSiO₃ structures have V_s anisotropies up to 1.08% (AFM) and 1.28% (FM); the low-spin FeSiO₃ and MgSiO₃ have V_s anisotropy up to respectively 2.75% and 2.56%. Consequently alloying Mg-perovskite with the HS Fe or with LS Fe has opposite effects: HS tends to decrease the anisotropy relative to pure MgSiO₃ while LS enhances this anisotropy.

[17] Moreover, the patterns of anisotropy for both V_p and V_s between the high-spin and the low-spin Fe phases are significantly different. The bulk of the lower mantle is highly isotropic, with deviations of only about 0.5%, though there are regions where a certain seismic anisotropy is observed, like at the top, close to the transition zone [Wookey et al., 2002] and at the bottom, close to the boundary with the D'' layer [Cornier, 1999; Kendall and Silver, 1998; Karato and Karki, 2001; Kustowski et al., 2008] with values going up to about 1%. In these settings

lattice preferred orientation could develop because of the convection cells and would align a majority of Fe-bearing perovskite crystals. Differences in spin state would induce differences in the seismic anisotropy pattern between the top and the bottom parts of the lower mantle. Therefore, a pattern like this should be detectable in observations of anisotropy at the base of the transition zone and into the lower mantle [e.g., Wookey et al., 2002] and the D'' region for waves with different turning depths, even for pyrolytic Fe concentrations. Due to the pattern of fast and slow velocities (Figure 2) it could also introduce larger travel time differences for waves with different turning depths than suggested above. That then needs to be taken into account as corrections in tomographic studies. Moreover our results show that lateral heterogeneities that induce these fluctuations of the anisotropy visible in tomographic studies can be due not only to mineralogical and chemical variations but also to iron spin variations (induced by differences in temperature and/or iron distribution and concentration) coupled with lattice preferred orientation.

[18] **Acknowledgments.** The work was facilitated by the PROCOPÉ exchange program. The calculations were performed on the jade machine at CINES under computational grant st12816.
