Protonated neurotransmitters have been produced in the gas phase *via* a novel photochemical scheme: complexes of the species of interest, 1-phenylethylamine, 2-amino-1-phenylethanol and the diastereo-isomers, ephedrine and pseudoephedrine, with a suitable proton donor, phenol (or indole), are produced in a supersonic expansion and ionised by resonant two photon ionisation of the donor. Efficient proton transfer generates the protonated neurotransmitters, complexed to a phenoxy radical. Absorption of infrared radiation, and subsequent evaporation of the phenoxy tag, coupled with time of flight mass spectrometry, provides vibrational spectra of the protonated (and also hydrated) complexes for comparison with the results of quantum chemical computation. Comparison with the conformational structures of the neutral neurotransmitters (established previously) reveals the effect of protonation on their structure. The photochemical proton transfer strategy allows spectra to be recorded from individual laser shots and their quality compares favourably with that obtained using electro-spray or matrix assisted laser desorption ion sources.

1. Introduction

The conformational preferences of neutral ethanolamines and their hydrated complexes, isolated in the gas phase, including 2-amino-1-phenylethanol [1,2], the diastereoisomers ephedrine and pseudoephedrine [3,4], and the catecholamines noradrenaline and adrenaline [5,6] (see Scheme 1), have been characterised recently using a combination of quantum chemical computation, infrared ion-dip spectroscopy and ultraviolet rotational band contour analysis [7]. In every case their favoured structures are stabilised through intramolecular hydrogen bonding ($\text{OH} \rightarrow \text{N}$) between the functional groups on the flexible ethanolamine side-chain which preferentially adopts an extended configuration relative to the aromatic ring.

Under physiological conditions the ethanolamine neurotransmitters exist predominantly as protonated ions and their conformational landscapes are radically altered [8-13] but until very recently virtually all direct spectroscopically based structural investigations of biomolecules conducted in the gas phase have focused on neutral molecules and their hydrated complexes [14]. Protonated biomolecular ions, cationic complexes and hydrated ionic complexes simply could not be probed in this way. This has been due, principally, to the problem of generating selectively protonated, and solvated biomolecular ions in sufficient number densities and at low enough temperatures in the gas phase to allow their resolved spectroscopic interrogation and analysis, though their ‘averaged shapes’ could be explored indirectly, through mass spectrometric ion mobility studies [15,16].

Several ways of overcoming the number density restriction have now been developed, each based upon the coupling of ionisation techniques such as electro-spray

(ESI), or matrix assisted laser desorption (MALDI), [17-25], or electron impact, [26-33] or electrical discharge [34-38] with mass filtering, and cumulative storage in ion traps to enhance their number densities. Their molecular structures have been probed through resonant single, or multiphoton infrared photodissociation spectroscopy. In general, single photon absorption is sufficient for dissociation of weakly bound complexes (typically, with ‘reporter’ partners such as Ar, N₂ or H₂O) [26-38] but resonantly enhanced multi-photon absorption is required to fragment the bare, uncomplexed ions or proton bound complexes [17, 21, 22]. Comparisons with high-level quantum chemical calculations facilitate spectral assignments to specific structures and the sensitivity of their near infrared bands, in particular those associated with OH and NH stretching modes, to local hydrogen bonded environments, identifies specific inter- and intra-molecular interactions.

An alternative and experimentally simpler, photochemical strategy for the creation of singly protonated ions avoids the need for mass filters and ion traps [39, 40] and follows the sequence shown in Scheme 2. This photochemical strategy is based upon efficient, exothermic proton transfer within an ionised donor-acceptor complex [AH...B]⁺ to produce the protonated species, BH⁺, tagged through hydrogen bonding to the radical, [BH⁺...A], step 2 in Scheme 2. Absorption of infra-red radiation, monitored by loss of the radical “tag”, step 3, provides an infra-red fingerprint of the ‘tagged’ protonated species. The strategy is a close relative of the method developed by Dopfer [38], involving proton transfer from Lewis acids such as H₃⁺ to weakly bound or hydrogen bonded molecular complexes, recently used for example, to generate the near IR spectra of protonated imidazole tagged with one or two hydrogen bonded water

1
2 molecules, $[\text{Imid.H}^+(\text{H}_2\text{O})_{1,2}]$. The future inclusion of step 4 in Scheme 2, ‘vibrationally
3 assisted’ photodissociation [41] using, for example, tunable IR +1064 nm or 532 nm
4 radiation, will offer a means of generating IR spectra of *bare* protonated species.
5
6
7

8 In the initial “proof of principle” stage of development, using steps 1 – 3 only, the
9 new strategy has enabled the generation, IR spectroscopic detection and in combination
10 with quantum chemical computations, structural assignment of ‘phenoxy tagged’
11 protonated 2-aminoethanol [40]; the phenoxy ‘reporter’ was found to exert only a
12 minimal effect on the geometry of the protonated species to which it was attached,
13 despite the strong hydrogen bond linking it to the protonated ion. The present paper
14 develops this initial study firstly, to enhance the sensitivity of the technique; then to apply
15 it to a series of (tagged) protonated neurotransmitters, including 2-amino-1-phenylethanol
16 (a noradrenaline analogue), ephedrine and its mono-hydrate, and pseudoephedrine, as
17 well as protonated 1-phenylethylamine and imidazole (see Scheme 1).

28 **2. Methodology**

29 The experimental techniques employed follow those used previously [40].
30
31 Mixtures of the proton donor (phenol) and proton acceptor were heated (80-100 °C) and
32 expanded in dry (or moistened) helium or argon through a pulsed molecular valve
33 (General Valve, orifice diameter 0.5 mm). The resulting supersonic beam was skimmed
34 (Beam Dynamics, diameter 1 mm) and intersected by two laser beams in the ion-source
35 region of a linear time-of-flight mass spectrometer (R.M. Jordan). Tuneable UV radiation
36 (270-280 nm) was produced by the frequency doubled output of a YAG pumped dye
37 laser (Spectra-Physics GCR-170 and LAS-105) while IR radiation (2.5-3.5 μm) was
38 produced by difference frequency mixing (in a lithium niobate crystal) of the output of a

1
2 YAG pumped dye laser (Continuum Powerlite 8010, ND6000 and IRP module) with the
3
4 YAG fundamental. Typical pulse energies were ~ 0.5 mJ (UV) and ~ 4 mJ (IR).
5

6 Time-of-flight mass spectra of the complex, phenol...imidazole⁺, [P-Imid]⁺,
7
8 recorded in the presence and absence of IR radiation are shown for illustration in Figure
9
10 1, together with its infrared photodissociation spectrum. Although ion peaks associated
11
12 with the binary complex [P-Imid]⁺ and bare protonated imidazole, Imid-H⁺, generated
13
14 through spontaneous dissociation, were both observed in the absence of IR radiation
15
16 fragmentation of the complex was enhanced by infrared absorption at 3483 cm^{-1} ,
17
18 (corresponding to one of the NH bands in the IR spectrum of the ionic complex).^{*}
19

20
21 Substantial gains in the signal to noise ratio were obtained by delaying the IR
22
23 pulse by 300-400 ns relative to the UV laser pulse. During this time the ion population
24
25 was accelerated towards the detector; absorption of infrared radiation, and subsequent
26
27 dissociation of the complex, produced the fragment ion, Imid-H⁺ at a different position of
28
29 the extraction region, resulting in an arrival time distinct from that of ions produced by
30
31 spontaneous dissociation following UV excitation alone, see Figure 1. This ‘offset’
32
33 allowed the IR photo-fragment channel and hence the IR absorption spectrum of the
34
35 parent ion, to be recorded against a near zero background, providing a substantial
36
37 improvement in the signal to noise. Thus the weak cluster of features centred around
38
39 3160 cm^{-1} , associated with the overlapping CH stretching modes of protonated imidazole
40
41 [33] were clearly observed in the fragment channel, spectrum (a), but were submerged in
42
43 the background noise of the spectrum measured by depletion of the parent ion, spectrum
44
45 (b). This experimental “trick” allowed high-quality spectra of protonated species to be
46
47

48 ^{*} The ion peaks associated with phenol (P⁺), its mono-hydrate (P.H₂O)⁺ and its dimer (P₂)⁺, which also
49 appeared in the time of flight spectrum, conveniently facilitated accurate mass calibration
50

1
2 recorded quickly and efficiently without the need for a more complex experimental
3 system of mass filters or ion traps.
4

5
6 Quantum chemical computations were performed using the GAUSSIAN 03
7 program [41]. Initial structures of bare protonated amines and their complexes with the
8 phenoxy radical were optimised using density functional theory (B3LYP functional with
9 a 6-31+G* basis set) and their harmonic vibrational wavenumbers were computed.
10
11 Single point MP2/6-311++G** calculations, which included a (harmonic) zero point
12 energy correction, provided their relative energies. Infrared frequencies associated with
13 the OH and NH stretch modes were scaled by 0.976 and 0.956, respectively, following
14 previous practice [1 – 6].
15
16
17
18
19
20
21

22 The conformational notation, A/G refers to the arrangement (*Anti* or *Gauche*) of
23 the C_{arom}C_αC_βN and OC_αC_βN atom chains, respectively (see Scheme 1). The labels ‘a’
24 and ‘b’ reflect the inversion of the (chiral) methyl-amino group in ephedrine and
25 pseudoephedrine, which results in a doubling of the conformational space. Complexes
26 with the phenoxy radical are denoted by the mode of clustering: addition to a non-
27 hydrogen bonded NH group (NH-add), or insertion across the intramolecular hydrogen
28 bonds between NH and O of the side-chain (NH-ins), or between the NH and the π-
29 system of the aromatic ring (π-ins).

39 **3. Results**

40 **3.1. Overview**

41
42 The initial geometry optimisations (B3LYP/6-31+G*) of the cationic complexes
43 of the three neurotransmitters and of 1-phenylethylamine, starting from the optimised
44 neutral geometries of hydrogen bonded, AH → N structures, resulted in facile proton
45

58
59
60

1
2 transfer, leading to structures of the type $[A...H^+B]$. Alternative starting geometries in
3
4 which the phenol was hydrogen bonded to the hydroxyl group, $AH \rightarrow O$, in the
5
6 ethanolamine acceptors led to the cationic or charge-transferred structures, $[AH^+...B]$ or
7
8 $[AH...B^+]$. In common with complexes involving the generic acceptor, 2-aminoethanol
9
10 [39, 40] these structures were located at substantially higher relative energies, ~ 50 -100 kJ
11
12 mol^{-1} , and their computed vibrational spectra did not reproduce the experimental data.
13

14
15 Near infrared photodissociation spectra of the series of cationic complexes,
16
17 recorded in each case *via* the delayed fragment channel, are collected together in Figure
18
19 2; those generated by the ethanolamines are similar to the spectrum obtained previously
20
21 for 2-aminoethanol, as expected for a proton transferred structure. They all display a band
22
23 centred at $\sim 3650\text{ cm}^{-1}$, associated with a non-hydrogen bonded 'free' alcoholic OH group
24
25 (*c.f.* ethanol) and two bands (in 2-amino-1-phenylethanol) or a single band (in the
26
27 ephedra) associated with non-hydrogen bonded or *intra*-molecular hydrogen-bonded
28
29 $(NH^+ \rightarrow OH)$ amino groups, appearing in the region 3200 - 3300 cm^{-1} . The onset of the
30
31 broad and intense band associated with the intermolecular hydrogen bond, $NH^+ \rightarrow OPh$,
32
33 linking the protonated ion to the phenoxy radical, anticipated at low wavenumbers, <3000
34
35 cm^{-1} , is clearly evident in the spectrum associated with 1-phenylethylamine. The inset in
36
37 Figure 2 compares the IR features associated with the OH band, generated through
38
39 photodissociation of two alternative proton donor complexes, $[ephedrine-phenol]^+$ and
40
41 $[ephedrine-indole]^+$. The two spectra are virtually identical, reinforcing the view that the
42
43 'tag', be it the phenoxy or the de-protonated indole residue, does not significantly perturb
44
45 its protonated partner.

The widths of the OH and NH band contours, 20-40 cm^{-1} FWHM, are substantially greater than those recorded in ion-dip experiments of the corresponding jet-cooled neutral species, $\sim 5 \text{ cm}^{-1}$ [1-7]. The broader widths are a consequence of the production method. Resonant one-colour two-photon ionisation promotes an exothermic proton transfer step (typically $\sim 60 \text{ kJ mol}^{-1}$ for a primary or secondary amine) [43, 44] to create a spread of internal energies in the protonated ion complex $[\text{A}\dots\text{H}^+\text{B}]$ which extends beyond its dissociation threshold – hence the spontaneous generation of the bare protonated BH^+ ions detected in the t.o.f. mass spectra: the infra-red photodissociation spectra reflect the excitation of a succession of unresolved ‘hot’ sequence bands.

3.2. 1-Phenylethylamine (PEA)

Computed (B3LYP/6-31+G*) structures of bare PEA.H^+ and its phenoxy complex are shown in Figure 3 and their relative energies and geometrical parameters are given in Table 1. The bare protonated ion displays a single structure with two hydrogen bonds linking the NH_3^+ group to the π -system of the aromatic ring [45] but the complex presents three distinct structures, labelled (a), (b) and (c), all lying within $\sim 4 \text{ kJmol}^{-1}$ of the global minimum structure, (a). In each case, the phenoxy ‘tag’ causes only a mild perturbation to the geometry of the protonated species, see Table 1.

The experimental infra-red photodissociation (IRPD) spectrum of the cationic complex(es), shown in Figure 3, displays two relatively sharp features at 3350 cm^{-1} and 3290 cm^{-1} , and a very broad, red-shifted feature at $< 3200 \text{ cm}^{-1}$. They are assigned to the three NH stretching modes expected for a proton transferred structure although it is not possible to estimate their relative contributions, given the good agreement between experiment and computation for each of the three possible complex structures .

3.3. 2-Amino 1-phenyl ethanol (APE)

The lowest-lying computed structures and IR spectra of bare and complexed APE.H⁺ are shown in Figure 4, and their relative energies and structural parameters are given in Table 2. There are four potential binding sites in the protonated complex, [PhO...APE.H⁺], located at the NH₃⁺ and OH groups but in common with protonated 2-aminoethanol [39, 40], structures involving the hydroxyl group are far less energetically favoured (by ~20 kJ mol⁻¹).

In each case the protonated ethanolamine side chain adopts a folded, GG structure in the minimum energy configuration. In the bare ion, APE.H⁺, this structure is calculated to lie at an energy ~6 kJ mol⁻¹ below that of the extended, AG conformer, in contrast to the neutral molecule, where the AG conformer is marginally favoured [1, 2, 46]. In the 'tagged' ion the minimum energy conformer is associated with two, almost isoenergetic, GG conformational structures, GG-NH-add and GG- π -ins. They are stabilised by an intramolecular, NH⁺ \rightarrow OH, hydrogen bond, reversing the principal interaction of the neutral species, and the GG conformation is further stabilised by an NH⁺ \rightarrow π interaction with the aromatic ring.

The experimental IRPD spectrum of the ionised phenol-APE complex, also shown in Figure 4, displays a band at 3650 cm⁻¹ (OH) and two further bands at 3360 cm⁻¹ and 3250 cm⁻¹ (NH), as expected for the protonated complex, PhO...APE.H⁺. The non-bonded OH group is insensitive to conformational change but the spacing of the computed symmetric and antisymmetric NH₂ modes for the two lowest-lying GG complexes are slightly different. The bands at 3360 cm⁻¹ and 3250 cm⁻¹ are quite broad

1
2 and a shoulder on the low frequency side of the peak centred at 3360 cm^{-1} band suggests
3
4 the population of both structures.
5

6 7 **3.4. Ephedrine and Pseudoephedrine**

8
9 Figures 5 and 6 present the energetically low-lying computed structures of the
10 bare and phenoxy complexed protonated diastereoisomers, ephedrine and
11 pseudoephedrine, together with their near infrared photodissociation spectra. Their
12 relative energies and selected structural data are presented in Tables 3 and 4. Like APE,
13 the protonated conformers are all stabilised by an intramolecular hydrogen bond, $\text{NH}^+ \rightarrow$
14 OH; the folded (GGa) structures also benefit from an interaction with the aromatic ring,
15 $\text{NH}^+ \rightarrow \pi$. In protonated ephedrine this strongly favours the folded global minimum
16 conformation, GGa; the extended, AGa conformer, lies $\sim 10\text{ kJ mol}^{-1}$ higher in energy.
17 In contrast, the corresponding structures in the protonated diastereoisomer,
18 *pseudoephedrine*, are nearly isoenergetic.
19
20
21
22
23
24
25
26
27
28

29 Addition of a bound phenoxy radical does not alter their conformational
30 landscapes significantly. The preference for a folded configuration is retained in the
31 protonated ephedrine complex. The global minimum structure, GGa- π -ins, is now also
32 favoured by a π - π interaction between the aromatic rings; the alternative folded structure,
33 GGa-NH-ins, lies $\sim 4\text{ kJ mol}^{-1}$ higher in energy. Complexes with extended, AGa side-
34 chain conformations all lie at much higher relative energies ($>11\text{ kJ mol}^{-1}$) again in
35 marked contrast to pseudoephedrine, where the extended (AGb-NH-add) and folded
36 (GGa- π -ins and GGa-NH-ins) complexes all lie within 4 kJ mol^{-1} of the global minimum
37 structure, AGa-NH-add, see Figure 5 and Table 3.

The experimental IRPD spectra shown in Figures 5 and 6 are in substantial agreement with the spectra computed for each of the energetically low-lying phenoxy tagged protonated structures. Given their computed relative energies, the experimental spectrum associated with protonated ephedrine can be assigned predominantly, to the single (folded) structure, GGa- π -ins. The corresponding data for the protonated pseudoephedrine complex(es) do not allow unequivocal structural assignment(s).

3.5 Hydrated ephedrine

Figure 7 presents a 'proof of principle' IR photodissociation spectrum recorded in the 'OH stretch' region, of the hydrated cationic complex of indole and ephedrine, monitored via the depletion of the singly hydrated ion peak, [indole..ephedrine..H₂O]⁺ and also via the enhancement of the fragment ion, [indole..ephedrine]⁺. The computed global minimum structure of the untagged hydrated ion, [ephedrine.H⁺...H₂O], is also shown. Like the free ion, ephedrine.H⁺, the folded GGa conformation is strongly favoured; the relative energy calculated for the lowest-lying extended conformation, AGb, is ~5 kJ mol⁻¹. In both cases the DFT calculations generate a structure in which the water molecule is bound via a linear H-bond to the protonated amino group: the protonated ion is predicted to display symmetric and antisymmetric OH bands at ~3625 cm⁻¹ and ~3750 cm⁻¹, respectively, while the OH group on the protonated ephedrine remains at ~3645 cm⁻¹. The experimental IR photodissociation spectrum of the tagged ion suggests a more complex structure. The (unshifted) band at ~3650 cm⁻¹ corresponds well with an assignment to the OH group on the ethanolamine side chain, but the location of the other two bands, between ~3,700 cm⁻¹ and 3,750 cm⁻¹, suggests a perturbed

1
2 structure, most likely involving an interaction between the bound water molecule and the
3
4 lone pair electrons on the hydroxyl group of the ephedrine or the indole residue.
5

6 **4. Discussion**

7 **4.1. Conformational landscapes**

8
9
10 The conformational landscapes of the protonated molecules are the product of a
11 subtle balance between a number of competing, and cooperative effects including
12 intramolecular hydrogen bonding, predominantly $\text{NH}^+ \rightarrow \text{O}$ and $\text{NH}^+ \rightarrow \pi$, but also other
13 non-bonded interactions including butane-like interactions between neighbouring methyl
14 groups and between the *N*-methyl group and the aromatic ring in ephedrine and
15 pseudoephedrine. These types of interaction also shape the conformational landscape of
16 the neutral species [1-7] but the outcome can be radically altered by protonation. The
17 diastereoisomers, ephedrine and pseudoephedrine provide a good case study.
18
19
20
21
22
23
24
25
26

27 In the neutral ethanolamines [3] and in protonated pseudoephedrine, the energies
28 of the two lowest-lying folded and extended conformers, GGa and AGa, are very similar.
29 Protonation of ephedrine, however, increases their relative energies (from 3 kJ mol^{-1} to
30 11 kJ mol^{-1}) and switches the favoured conformation from an extended, AGa, to a folded,
31 GGa, configuration. A similar trend is found for neutral [1,2] and protonated APE. The
32 most apparent change in bonding following protonation is a reversal in the direction of
33 the intramolecular hydrogen bond of the ethanolamine side-chain from $\text{OH} \rightarrow \text{N}$ in the
34 neutral to $\text{NH}^+ \rightarrow \text{OH}$ in the protonated ion. This is reflected in the displacement of the
35 corresponding vibrational transitions: in the neutral ethanolamines, $\nu(\text{OH})$ shifts towards
36 low wavenumbers, located at $\approx 3520 \text{ cm}^{-1}$ and the $\nu(\text{NH})$ band appears at $\approx 3430 \text{ cm}^{-1}$ but
37 in the protonated ions $\nu(\text{OH})$ is found at $\approx 3650 \text{ cm}^{-1}$ but the $\nu(\text{NH})$ band(s) shift towards
38

1
2 lower wavenumbers, typically $\sim 3250\text{-}3350\text{ cm}^{-1}$. Their folded geometries also benefit
3
4 from an interaction between the protonated amino group and the aromatic ring, $\text{NH}^+ \rightarrow \pi$.
5

6 The preference for a folded configuration in protonated ephedrine, and APE.H⁺
7
8 indicated by computation with some support from experiment, is perhaps unsurprising
9
10 when the energetics of the competing interactions are estimated. The interaction energy
11
12 of the ammonium ion, NH_4^+ with water ($\sim 75\text{ kJ mol}^{-1}$) [47-50] or with benzene ($\sim 70\text{ kJ}$
13
14 mol^{-1}) [51,52] is an order of magnitude greater than that of the butane-like methyl-methyl
15
16 interaction ($\sim 5\text{ kJ mol}^{-1}$) [53-55] and substantially greater than that associated with
17
18 hydrogen bonded interactions in neutral molecules (e.g. $\sim 25\text{ kJ mol}^{-1}$ for $\text{HOH} \rightarrow \text{NH}_3$
19
20 and $\sim 8\text{ kJ mol}^{-1}$ for $\text{NH}_3 \rightarrow \text{benzene}$ [56,57]). While the hydrogen bonds in the protonated
21
22 ephedrines are far from optimal because of the geometrical constraints, $\text{NH}^+ \dots \text{O}$
23
24 distances and angles $\sim 200\text{ pm}$ and $\sim 110^\circ$, cf. 160 pm and 180° in $\text{NH}_4^+ \rightarrow \text{OH}_2$ [57], the
25
26 additional interaction with the aromatic ring in the folded GGa conformation readily
27
28 compensates the unfavourable *gauche* arrangement of the neighbouring methyl groups.
29
30 This contrasts with the neutral ephedrines, where the stabilisation provided by an $\text{NH} \rightarrow$
31
32 π hydrogen bond with the aromatic ring is much smaller and is of a similar magnitude to
33
34 the energy difference between the *trans* and *gauche* configurations of the neighbouring
35
36 methyl groups [3]. The change in absolute configuration of one of the chiral carbon
37
38 centres, from (1R,2S)-ephedrine to (1S,2S)-pseudoephedrine, and the subsequent
39
40 modulation of the non-covalent interaction between the methyl groups, has a significant
41
42 effect on the relative stabilities of the folded and extended configurations.
43
44

45 The behaviour of protonated pseudoephedrine, where the folded and extended
46
47 conformers are almost isoenergetic, can be rationalised by the influence of competing
48
49
50

1
2 interactions in the folded, GGa, structure. Optimisation of the geometry for one
3 intramolecular hydrogen bond can only be achieved by sacrificing, at least to some
4 degree, the other. The $\text{NH}^+ \rightarrow \text{O}$ hydrogen bond is markedly longer in the GGa
5 conformer of protonated pseudoephedrine than in the other structures: 220 pm and 103°
6 *versus* ~ 200 pm and $\sim 110^\circ$. Conversely the interaction with the aromatic ring is stronger:
7 the $\text{NH}^+ \dots$ 'centre of ring' distance and angle is ~ 320 pm and 130° (*c.f.* ~ 350 pm and 120°
8 for the GGa conformer of protonated ephedrine) although still far from optimal (*c.f.* ~ 220
9 pm and $\sim 160^\circ$ in $\text{NH}_4^+ \rightarrow$ benzene [57]). The deciding factor is the interaction between
10 the neighbouring methyl groups which is controlled by the absolute chirality of the
11 molecule. In pseudoephedrine, "optimisation" of the geometry of the $\text{NH}^+ \rightarrow \text{O}$ hydrogen
12 bond would require the methyl groups to adopt a more eclipsed form while the opposite
13 is true for the $\text{NH}^+ \rightarrow \pi$ hydrogen bond. Switching of the configuration about a single
14 chiral carbon, in ephedrine, reverses this dependence. The result, in the GGa conformer
15 of pseudoephedrine, is two geometrically non-optimal hydrogen bonds and the raising of
16 the energy of the folded structure relative to that of the extended AGa conformer.

33 **4.2. Comments on future applications of the photochemical protonation method**

34
35 Using the phenol (or indole) cation as a proton source within a molecular complex
36 provides a means of producing spectroscopically useful number densities of 'tagged'
37 protonated biomolecules in the gas-phase. Combination of the photochemical proton
38 transfer mechanism, time of flight mass spectrometry and IRPD detection allows data to
39 be recorded in single laser shots without the need for ion trapping; the spectra presented
40 in the present article were collected in a matter of hours without compromising signal to
41 noise. It is now possible to record infrared fingerprints of a wide range of protonated

biomolecular ions in the gas phase (including for example, both aliphatic and aromatic amino acids and small peptides, using laser ablation sources [58]) with a relatively simple experimental arrangement. The future implementation of the ‘vibrationally assisted’ photo-dissociation step (4) promises spectroscopic access to the bare ions as well.

On the negative side (but see below) the resolution is currently inferior to that provided by infrared ion-dip spectroscopy of jet-cooled neutral molecules [1-7, 14] and protonated molecular complexes [26-38] and the width of the spectral bands limits the ability to distinguish between species with similar vibrational spectra. The NH stretch region of APE where a partially resolved shoulder on the principal band (3360 cm^{-1}) was tentatively assigned to an alternative complex, see Figure 4, provides a good example. The combination of excess energy from the 2-photon excitation process, $\sim 100\text{ kJ mol}^{-1}$, depending on the ionisation energy of the complex and the kinetic energy of the ejected photoelectron [39, 40], with the energy released from the proton transfer reaction, $\sim 50\text{ kJ mol}^{-1}$, [43, 44] results in substantial internal excitation of the complex. Single-point MP2/6-311++G** energy calculations on the DFT optimised geometries indicate binding energies $\sim 100\text{ kJ mol}^{-1}$, well within the estimated upper limit of the internal energy, $\sim 150\text{ kJ mol}^{-1}$. Given the levels of internal excitation the relative populations of contributing conformations may be dictated both by entropic and enthalpic factors.

Fortunately, a number of experimental improvements are in prospect, promising amelioration of some of these constraints, particularly the production of internally cooled, untagged protonated ions, which requires ionisation of the proton donor within the collision region of a supersonic expansion and their selective detection by resonant, vibrationally assisted photodissociation. The potential for future development, coupled

1
2 with the simplicity and efficiency of the experiment, promise to make the photochemical
3
4 scheme an attractive companion to more established methods for the spectroscopic
5
6 examination of many protonated biomolecules, particularly in the small molecule region
7
8 (< 1000 amu).
9

10 **5. Conclusions**

11
12 A new photochemical method has been used to record the near IR spectra of a
13
14 series of protonated neurotransmitters, including the noradrenaline analogue, 2-amino-1-
15
16 phenylethanol, the diastereoisomers ephedrine and pseudoephedrine, and 1-
17
18 phenylethylamine, in the gas-phase. Photoionisation of the phenol chromophore in a
19
20 molecular complex and subsequent proton transfer to the amine partner provides an
21
22 efficient and selective means of producing protonated ions which avoids the need for
23
24 mass filters and ion traps. Spectroscopic information has been obtained using infrared
25
26 photodissociation of the complex between the protonated species and the phenoxy
27
28 fragment to provide a near IR spectrum of the protonated molecule. The spectra are
29
30 comparable in quality and bandwidth with those obtained using ESI or MALDI sources
31
32 while the efficiency of the proton transfer and the ability to obtain high-quality
33
34 spectroscopic data quickly, provide a significant gain in sensitivity and saving in time
35
36

37 DFT and *ab initio* quantum chemical computations allow the assignment of
38
39 experimental spectra to specific conformers or groups of conformers which in turn, allow
40
41 detailed analysis of their conformational landscapes. Comparisons with the preferred
42
43 conformations of neutral ethanolamines have revealed the influence of protonation on
44
45 their conformational structures. The preferred side-chain structure in ephedrine is altered
46
47 by protonation, from an extended to a folded configuration but in its diastereoisomer,
48
49

57
58
59
60

1
2 pseudoephedrine (differing only in the chirality of a single carbon), their relative
3 potential energies remain closely spaced. The preferred side chain conformations are
4 controlled by a delicate balance between different non-bonded interactions, including
5 intramolecular $\text{NH}^+ \rightarrow \text{O}$ and $\text{NH}^+ \rightarrow \pi$ hydrogen bonding and methyl-methyl interactions;
6 the conformational landscapes are also sensitive to, and can be altered by the local
7 configuration about chiral centres.

Table Captions

Table 1. Computed relative energies, dihedral angles and hydrogen bond distances/angles for protonated 1-phenyl ethylamine (PEA) and its complexes with the phenoxy radical: (i) MP2/6-311++G**//B3LYP/6-31+G*, (ii) B3LYP/6-31+G* optimisation.

Table 2. Computed relative energies, dihedral angles and hydrogen bond distances/angles for protonated 2-amino 1-phenylethanol (APE) and its complexes with the phenoxy radical: (i) MP2/6-311++G**//B3LYP/6-31+G*, (ii) B3LYP/6-31+G* optimisation.

Table 3. Computed relative energies, dihedral angles and hydrogen bond distances/angles for protonated ephedrine (Eph) and its complexes with the phenoxy radical: (i) MP2/6-311++G**//B3LYP/6-31+G*, (ii) B3LYP/6-31+G* optimisation.

Table 4. Computed relative energies, dihedral angles and hydrogen bond distances/angles for protonated pseudoephedrine (Peph) and its complexes with the phenoxy radical: (a) MP2/6-311++G**//B3LYP/6-31+G*, (b) B3LYP/6-31+G* optimisation.

1. Complexes of the biomolecule of interest (B) with a proton donor (AH) are produced in a cold molecular beam and ionised by resonant UV two-photon ionisation.
 2. Exothermic, proton transfer within the cation generates the protonated biomolecule (H^+B), initially complexed with a radical (A).
 3. The complexes fragment, either thermally or through infrared photon excitation. The IR 'photo-dissociation spectrum' provides an absorption spectrum of the weakly bound, protonated biomolecular complex, $A...H^+B$.
 4. The free protonated biomolecule can also be dissociated through resonant, vibrationally mediated excitation ($IR + \text{visible or UV}$) or multiphoton IR excitation to generate a vibrational spectrum of the *free* ion, BH^+ .

Comment [P1]: Change "nhv(IR)" on the scheme, to "IR + nhv"

20
21 **Figure 1.** (a) Time-of-flight mass spectra and (b) infra-red photodissociation spectra
22 of the cationic complex between phenol and imidazole.

23
24 **Figure 2.** Infra-red photodissociation spectra of the cationic complexes between phenol
25 and a variety of amines, including 1-phenylethylamine (PEA), 2-amino-1-
26 phenylethanol (APE) and the diastereoisomers ephedrine (Eph) and
27 pseudephedrine (Peph). Inset shows spectra generated by photo-dissociation of
28 $[\text{phenol-ephedrine}]^+$ and $[\text{indole-ephedrine}]^+$ complexes.
29 The apparent structure on the bands around 3650 cm^{-1} is the result of a
30 reduction in infra-red power by atmospheric water absorption.

31
32 **Figure 3.** Infra-red photodissociation spectrum of the cationic complex between phenol
33 and 1-phenylethylamine and corresponding spectra computed for the low-lying
34 conformers of protonated PEA and its complexes with the phenoxy radical. The
35 intensity of the strongly hydrogen bonded NH group ($NH \rightarrow OPh$) at $\sim 2900\text{ cm}^{-1}$
36 ¹, has been reduced by a factor of 10 for clarity.

37
38 **Figure 4.** Infra-red photodissociation spectrum of the cationic complex between phenol
39 and 2-amino-1-phenylethanol (APE) and corresponding spectra computed for
40 the low-lying conformers of protonated APE and its complexes with the
41 phenoxy radical. The intensity of the strongly hydrogen bonded NH group at \sim
42 2800 cm^{-1} has been reduced by a factor of 10 for clarity.

43
44 **Figure 5.** Infra-red photodissociation spectrum of the cationic complex between phenol
45 and ephedrine (Eph) and corresponding spectra computed for the low-lying
46 conformers of protonated Eph and its complexes with the phenoxy radical. The
47 intensity of the strongly hydrogen bonded NH group at $\sim 3000\text{ cm}^{-1}$ has been
48 reduced by a factor of 10 for clarity.
