The reorientation of one paramagnetic molecule in glassy polystyrene is studied by High-Field Electron Paramagnetic Resonance spectroscopy at four different Larmor frequencies between 9.5 and 285 GHz. On increasing the Larmor frequency, the lineshape exhibits larger sensitivity to the rotational motion of the radical. **Unfreezing the rotational dynamics by increasing the reorientation rate leads to considerable line shifts, whereas broadening effects are not dominant. The finding evidences that the paramagnetic molecule undergoes small-angle reorientation in the glassy matrix.**

*Keywords:* Glassy polymers; High-field Electron Paramagnetic Resonance; Rotational dynamics

## 1 Introduction

During the last few years continuous-wave and pulsed high-field Electron Paramagnetic Resonance spectroscopy ( HF-EPR ) techniques were developed involving large polarizing magnetic fields, e.g.  $B_0 \cong 3T$  corresponding to Larmor frequencies about 95GHz ( W band ), [1] or even larger frequencies [2, 3]. HF-EPR is widely used in studies on soft-matter including biology [4] and polymer science [5, 6, 7]. One major feature is the remarkable orientation resolution due to the increased magnitude of the anisotropic Zeeman interaction leading to a wider distribution of resonance frequencies. **It became clearer in the last decade that HF-EPR provides more insight**

8 into the molecular dynamics than the conventional X-band EPR.  
9 A recent topical book [8] and some reviews [4, 9] provide updated  
10 coverage of the field.  
11

12 In the present paper we present a detailed temperature study of the reori-  
13 entation of a small probe molecule in glassy polystyrene ( PS ) by HF-EPR  
14 at four different Larmor frequencies ( 9.5, 95, 190 and 285 GHz ). The study  
15 proves that, on increasing the Larmor frequency, the lineshape exhibits large  
16 sensitivity to the rotational *dynamics* of the radical. **The sensitivity leads**  
17 **to considerable line shifts, whereas broadening effects are not dom-**  
18 **inant. It will be shown that the paramagnetic molecule undergoes**  
19 **small-angle reorientation in the glassy matrix.**

## 24 2 EPR background

25  
26 The EPR signal is detected in paramagnetic systems. Since most polymers  
27 are diamagnetic, paramagnetic probe molecules ( spin probes ) are usually  
28 dissolved in them. The main broadening mechanism of the EPR line shape  
29 of the spin probe is determined by the coupling between the reorientation  
30 of the latter and the relaxation of the electron magnetization  $\mathbf{M}$  via the  
31 anisotropy of the Zeeman and the hyperfine magnetic interactions. When  
32 the molecule rotates, the coupling gives rise to fluctuating magnetic fields  
33 acting on the spin system. The resulting phase shifts and transitions relax the  
34 magnetization and, in turn, broaden and *shift* the different lines contributing  
35 to the pattern of the EPR lineshape [8]. From this respect an elementary tool  
36 to appreciate the sensitivity of the lineshape to the rotational dynamics is the  
37 distance between the outermost peaks of the lineshape  $\Delta B$  ( see [6] for further  
38 details ). **If the spin probe is frozen, the anisotropies of the Zeeman**  
39 **and hyperfine tensors are not averaged and  $\Delta B$  is at the maximum**  
40 **value  $\Delta B = \Delta B_{\infty}$ . When the reorientation rate of the spin probe is**  
41 **still very long but finite, the anisotropies of the magnetic tensors**  
42 **start to be averaged. In this onset regime, if the rotational jumps**  
43 **are *small*,  $\Delta B$  decreases (  $\Delta B < \Delta B_{\infty}$  ) with limited or negligible**  
44 **broadening effects. Differently, if the rotational jumps are *large*,  $\Delta B$**   
45 **is almost unchanged whereas linewidths are more affected. These**  
46 **features are qualitatively known [3]. However, to the best of our**  
47 **knowledge, quantitative studies concerning the above shifts for HF-**  
48 **EPR are missing. Recently, the issue was touched by the present**  
49 **authors [6] and novel results are presented here.**

## 58 3 Experimental details

59  
60 PS was obtained from Aldrich and used as received. The weight-average  
molecular weight is  $M_w=230$  kg mol<sup>-1</sup>, polydispersity  $M_w/M_n = 1.64$  and  
 $T_g=367$  K. The free radical used as spin probe was 2,2,6,6-tetramethyl-1-  
piperidinyloxy (TEMPO) from Aldrich. The spin probe was less than 0.08%  
in weight. X-band EPR measurements were performed using a Varian (Palo  
Alto, CA) E112 spectrometer equipped with a Varian E257 temperature con-

trol unit and a homemade data acquisition system. High field high frequency EPR experiments were carried out on the ultrawide-band EPR spectrometer which is detailed elsewhere [10]. The used frequencies of the spectrometer are  $95\text{GHz}$ ,  $190\text{GHz}$  and  $285\text{GHz}$ . All spectra were recorded and stored in a computer for off-line analysis. Further details are given elsewhere [6].

## 4 Results and discussion

Fig. 1 shows the temperature dependence of the distance  $\Delta B$  at  $9.5\text{GHz}$ ,  $95\text{GHz}$ ,  $190\text{GHz}$ ,  $285\text{GHz}$  of the spin probe TEMPO in PS. The evidence that  $\Delta B$  is still changing at temperatures as low as  $50\text{K}$  proves that the reorientation motion of TEMPO is detectable even at such low temperatures. According to **the qualitative analysis of ref.[3] and** the findings of ref.[6], the changes of  $\Delta B$  with the temperature signal that TEMPO in glassy PS, i.e. at  $T < T_g$ , proceeds by *small* angular jumps. **Note that, according to HF-EPR studies at  $250\text{GHz}$  [3], the almost identical spin probe PDT in supercooled toluene- $d_8$ , i.e. at  $T > T_g$ , was found to reorientate by *large* jumps. The finding is interesting and will deserve further investigation.**

Fig. 1 clearly shows that at lower frequencies  $\Delta B$  changes less and proves the higher sensitivity of HF-EPR to the rotational dynamics. Noticeably, as noted above, the small-angle rotational dynamics affects the *position* of the lines contributing to the pattern of the HF-EPR lineshape more than their *width*. In fact, Fig. 2 shows the temperature dependence of the average linewidth of selected lines of the HF-EPR lineshape. It is seen that the width approaches a plateau value below  $180\text{K}$  signaling less sensitivity to the TEMPO reorientation than the quantity  $\Delta B$  which is a measure of the position of the lines. The interpretation of the large influence of the rotational dynamics on the *position* of the lines depends on the marked frequency-dependence of the latter [5]. Even an elementary discussion of the effect goes beyond the purpose of the present note and will be presented elsewhere.

## 5 Conclusions

The reorientation of one paramagnetic molecule in glassy PS is studied by HF-EPR at four different Larmor frequencies. **The findings of the present paper are twofold. First, it provides further experimental and quantitative evidence of the dynamical lineshifts of the HF-EPR lineshape in the onset regime of the small-angle rotational dynamics when the latter unfreezes. Second, it is also found that the reorientation of molecular guests in disordered glasses may proceed by diffusive steps as well and not necessarily by large angular jumps.**
