#### Abstract

Dedicated to the memory of José Antonio Mejías, a talented scientist, an enthusiastic researcher and an honest person.

#### Abstract

A series of $a b$ initio quantum chemistry calculations on a trinuclear mixed-valence system $\left[\left(\mathrm{NH}_{3}\right)_{6} \mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{+3}$ have been performed in order to simultaneously evaluate its magnetic and electronic parameters, namely the magnetic coupling constants $J_{l}$ and $J_{2}$, the electron transfer integrals $t_{l}$ and $t_{2}$, and the exchange-transfer terms $h_{l}$ and $h_{2}$. The procedure is based on the use of the effective Hamiltonian theory. The results evidence the presence of two ferromagnetic interactions in this compound, in good agreement with the behaviour found in the real system $\left[\mathrm{L}_{3} \mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{+3}$, where $\mathrm{L}=\mathrm{N}$-permethyl-(1R,2R)-cyclohexenediamine. Regarding electron transfer terms, their values are about one order larger than the corresponding magnetic coupling constants, and essentially controlled by the direct interactions through the Cu d orbitals. The exchange-transfer terms are non negligible, their amplitudes being similar to the $J_{I}$ constant.

## Keywords

Electron transfer, magnetic coupling, mixed-valence systems, biomimetic compounds

## 1. Introduction

The reduction of $\mathrm{O}_{2}$ to give $\mathrm{H}_{2} \mathrm{O}$ is one of the most relevant reactions in nature. In biological systems, this process is catalyzed by the metalloenzymes, in particular by those containing active Cu sites [1-3]. In these enzymes, Cu exists in mononuclear and polynuclear configurations, although the nuclearity of the active site does not correlate directly with the type of reactivity (they can function as dioxygenases, monooxygenases and oxidases). Multicopper oxidase enzymes such as laccase, ascorbate oxidase or ceruloplasmin couple the four-electron reduction of $\mathrm{O}_{2}$ to water with the one-electron oxidation of electron-rich substrates. The active site is a trinuclear Cu cluster, coupled to a Cu site (blue Cu site) $13 \AA$ distant from the $\mathrm{Cu}_{3}$ cluster, which provides the fourth electron [1-3].
Many efforts have been driven to understand the mechanism of this reaction. In particular, biochemical synthesis research has focus on the synthesis of biomimetic models that reproduce the topology and reactivity of the natural ones. Among them, Cole et al. [4] have reported the self-assembly synthesis of a trinuclear $\mathrm{Cu} / \mathrm{O}_{2}$ cluster, with a $\mathrm{Cu}_{3}(\mu-\mathrm{O})_{2}$ core, of formula $\quad\left[\mathrm{L}_{3} \mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{3+}, \quad \mathrm{L}=\mathrm{N}$-permethyl-(1R,2R)cyclohexenediamine (Figure 1). This compound represents the first example of 3:1 metal: $\mathrm{O}_{2}$ stoichiometry in reactions between metal complexes and $\mathrm{O}_{2}$. Generally each of the Cu centres supplies only one electron. Therefore one-, two- or four-electron reduction of $\mathrm{O}_{2}$ has a $1: 1,2: 1$ or $4: 1$ metal: $\mathrm{O}_{2}$ stoichiometry, respectively. In the case of the complex isolated by Cole et al. the four electrons are provided by three copper ions, which leads to a mixed-valence $\left[\mathrm{Cu}_{2}(\mathrm{II}) \mathrm{Cu}(\mathrm{III})\right]$ system. X-ray structure analysis, UVvis spectra, NMR susceptibility, SQUID and MCD data $[4,5]$ are all consistent with a description of a localised mixed-valence system (type II in Robin and Day classification), with two $\mathrm{Cu}(\mathrm{II})$ ions ferromagnetically coupled (an $\mathrm{S}=1$ electronic ground state), and one diamagnetic $\mathrm{Cu}(\mathrm{III})$ centre. The singlet-triplet splitting is only of $+14 \mathrm{~cm}^{-1}$. All three Cu centres have square-planar coordination environments, with shorter $\mathrm{Cu}-\mathrm{O}$ bonds in the case of $\mathrm{Cu}(\mathrm{III})$ centre. The distortion does not arise from crystal packing effects since it is also present in solution [1], but it is related to a firstorder Jahn-Teller effect. Root et al. [5] stated that this effect together with a weak electronic coupling can explain the localised nature of the mixed-valence system. From a theoretical point of view, this system is a simplified model of polynuclear mixed valence systems. Modelling the properties of them remains one of the open challenges in molecular magnetism, in particular, to elucidate the interplay between electronic
delocalization and magnetic interactions in these compounds [6]. Three types of interactions can be distinguished in the $\left[\mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{+3}$ core, as shown in Figure 2, namely magnetic exchange coupling $J$, electron transfer, $t$, and the exchange-transfer term [7], $h$, also called singlet-displacement operator [8]. The magnetic exchange reverses the spin on two neighbour sites, the electron transfer constant moves the electron to a neighbour hole and the exchange-transfer term moves the pair of electrons, coupled in a singlet, toward a hole placed in a neighbour position. Thus a singlet on sites $a$ and $c$, the site $b$ containing a hole, is displaced to the positions $a$ and $b$, the hole being in $c$.
Different theoretical works have tried to elucidate the origin of the ferromagnetic coupling $[5,9,10,11]$ and quantify the stabilization produced by the Jahn-Teller distortion [5,12]. Density functional theory (DFT) based calculations on a model system, where L ligands are replaced by $\mathrm{NH}_{3}$ groups correctly reproduce the triplet ground state, but largely overestimate the triplet-singlet separation $\left(J=878 \mathrm{~cm}^{-1}[5], \mathrm{J}=72-550 \mathrm{~cm}^{-1}\right.$ [9]; $\mathrm{J}=231 \mathrm{~cm}^{-1}$ [10]; $\mathrm{J}=806-2934 \mathrm{~cm}^{-1}$ [11]). Any evaluation of the electronic coupling has been reported, except a rude estimation from the energies of the magnetic orbitals [5], nor of the exchange-transfer term.
In this field, an alternative to DFT based methods lies in the use of extended configuration interaction (CI) approaches, in particular, difference dedicated CI (DDCI) calculations [13]. The main advantage of this method is to take into account dynamical correlation effects at a reduced computational cost compared to a conventional CI calculation. In fact, the central idea is to obtain the energies and eigenvectors of the desired states from a truncated CI expansion, where all the double excitations from two inactive occupied orbitals toward two inactive virtual ones (the most numerous ones) are eliminated, since they contribute neither to the magnetic coupling constant nor to the electron transfer integrals. The method provides estimates of the exchange coupling constants and hopping integrals in good agreement with the experimental values both in molecular and periodic systems [14-24]. This approach has also been recently used to study a series of ( $\mu_{3}$-hydroxo)- and ( $\mu_{3}$-oxo)-bridged trinuclear Cu (II) models by Chalupsk et al.[25] and Le Guennic et al. [26].
The aim of the present work is to evaluate all the electronic and magnetic parameters governing the properties of this system from $a b$ initio quantum chemistry calculations. DDCI method is employed to determine the energies and wavefunctions of the lowlying states of the system. Combined with effective Hamiltonian theory it is possible to simultaneously extract the electronic and magnetic coupling constants and the

Formatted: Font: Italic
Formatted: Font: Italic
exchange-transfer terms. Also a direct estimate of the relative stability of the local forms is obtained as well as a measure of the on-site Coulomb energies ( $U_{a}=U_{c}, U_{b}$ ).
The manuscript is organised as follows: the real system and the model employed in calculations are described in Section 2 and the method in Section 3. Results are reported in Section 4, and main conclusions are summarized in Section 5.

## 2. Description of the real and model systems

The real system contains two non-equivalent $\left[\mathrm{L}_{3} \mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{+3}$ clusters for each unit cell, both with $\mathrm{C}_{2}$ symmetry. Table 1 collects the main geometrical parameters of both clusters ( A and B ), the main difference being the O-O distance ( $2.26 \AA$ and $2.36 \AA$, respectively). We have employed the experimental geometries from x-ray diffraction data for this system, and both inequivalent structures have been analyzed. Any symmetry constraint has been imposed, at difference with previous theoretical works. In order to reduce the computational cost, the external L ligands are replaced by $\mathrm{NH}_{3}$ groups, maintaining the original position of N atoms, where the H atoms are placed in such a way the $\mathrm{C}_{2}$ axis is preserved. This change could affect the amplitude of the interactions under consideration, but only a minor effect is expected, at least for $J$, as suggest previous works where the impact of external ligands on $J$ has been considered [11,20]. Figure 1 represents the structure A of the real system and three views of the corresponding model.
In all the calculations core electrons of $\mathrm{Cu}, \mathrm{O}$ and N atoms were replaced with effective core potentials, where the $(9 \mathrm{~s} 6 \mathrm{p} 6 \mathrm{~d}) /[3 \mathrm{~s} 3 \mathrm{p} 4 \mathrm{~d}]$ set was used for the valence electrons of Cu atoms, $(5 \mathrm{~s} 6 \mathrm{p} 1 \mathrm{~d}) /[2 \mathrm{~s} 3 \mathrm{p} 1 \mathrm{~d}]$ set for O atoms and (5s5p1d)/[2s3p1d] set for N atoms [27]. A double-zeta basis set has been employed for H atoms. CI calculations are performed by means of CASDI code [2 $\underline{8}$ ] on the basis of the ground triplet molecular orbitals.

## 3. How to obtain the amplitude of the coupling constants

### 3.1. Identification of the effective parameters

The mixed-valence $\left[\mathrm{Cu}_{3} \mathrm{O}_{2}\right]^{+3}$ core contains two $\mathrm{Cu}(\mathrm{II})$ atoms and a single $\mathrm{Cu}(\mathrm{III})$ one. As well known, a $\mathrm{Cu}(\mathrm{II})$ atom in a pseudo-square planar coordination places the unpaired electron on a molecular orbital, essentially $\mathrm{Cu} \mathrm{dx}{ }^{2}-\mathrm{y}^{2}$ but with tails on the four
neighbour atoms. Let us call $a, b$ and $c$ these unpaired orbitals, $a$ and $c$ being related by a $\mathrm{C}_{2}$ axis.
In order to extract the effective parameters, let us consider the neutral determinants with $S_{z}=0$ that can be built on the basis of the localized orbitals: $\{|a \bar{b}\rangle,|\bar{a} b\rangle,|b \bar{c}\rangle,|\bar{b} c\rangle,|a \bar{c}\rangle,|\bar{a} c\rangle\}$. They constitute the model space_ $\Sigma$. The corresponding ionic determinants $\{|a \bar{a}\rangle,|b \bar{b}\rangle,|c \bar{c}\rangle\}$ are high in energy, due to the on-site Coulomb repulsion $U, U_{m}=E_{m \bar{m}}-E_{m \bar{n}} \quad\{m, n\}=\{a, b, c\}$. The Hamiltonian spanned by such a model space can be written as:

$$
\begin{array}{cccccc}
|a \bar{b}\rangle & |\bar{a} b\rangle & |b \bar{c}\rangle & |\bar{b}\rangle & |a \bar{c}\rangle & |\bar{a} c\rangle \\
\hline J_{2} & -J_{2} & h_{2} & -t_{1}-h_{2} & -t_{2}-h_{1} & h_{1} \\
& J_{2} & -t_{1}-h_{2} & h_{2} & h_{1} & -t_{2}-h_{1}  \tag{1}\\
& & J_{2} & -J_{2} & t_{2}+h_{1} & -h_{1} \\
& & & J_{2} & -h_{1} & t_{2}+h_{1} \\
& & & & J_{1}+\varepsilon & -J_{1} \\
& & & & & J_{1}+\varepsilon
\end{array}
$$

or on the basis of their six combinations:

$$
\begin{array}{cccccc}
\left|S_{a b}\right\rangle & \left|S_{b c}\right\rangle & \left|S_{a c}\right\rangle & \left|T_{a b}\right\rangle & \left|T_{b c}\right\rangle & \left|T_{a c}\right\rangle \\
\hline 2 J_{2} & t_{1}+2 h_{2} & -t_{2}-2 h_{1} & 0 & 0 & 0 \\
& 2 J_{2} & t_{2}+2 h_{1} & 0 & 0 & 0  \tag{2}\\
& & 2 J_{1}+\varepsilon & 0 & 0 & 0 \\
& & & 0 & -t_{1} & -t_{2} \\
& & & & 0 & t_{2} \\
& & & & & \varepsilon \\
\hline
\end{array}
$$

where $\left|S_{m n}\right\rangle=(|m \bar{n}\rangle-|\bar{m} n\rangle) / \sqrt{2}$ and $\left|T_{m n}\right\rangle=(|m \bar{n}\rangle+|\bar{m} n\rangle) / \sqrt{2}$ for $\{m, n\}=\{a, b, c\}$. The zero of energy is that of the triplet states $\left|T_{a b}\right\rangle$ or $\left|T_{b c}\right\rangle$. The term $\varepsilon$ represents the stabilization of the hole localized on site $b$ with respect to those situations where the hole is placed on site $a$ or $c$, that is, it quantifies the extension of the Jahn-Teller distortion. Since the Cu atoms form an isosceles triangle, two different magnetic coupling constants can be distinguished, $J_{1}$ between sites $a$ and $c$ and $J_{2}$, between sites $a(c)$ and $b$ (Figure 2). These constants are defined according to the Heisenberg Hamiltonian: $\hat{H}_{\text {Heis }}=-2 J_{i j}\left(\hat{S}_{i} \hat{S}_{j}-1 / 4\right)$, where the singlet-triplet separation is equal to $2 J$, and then $J$ is positive for a ferromagnetic system. Similarly, two different electron
transfer integrals can be identified, as shown in Figure 2. The term $t_{l}$ couples the electron delocalization between sites $a$ and $c$, and $t_{2}$ permits the direct transfer between sites $a$ and $b$ or $b$ and $c$. Notice that the sign of the overlap of $\mathrm{Cu}_{a} \mathrm{~d}$ and $\mathrm{Cu}_{b} \mathrm{~d}$ orbitals $\left(\propto t_{a b}\right.$ ) is opposite to that of $\mathrm{Cu}_{b}$ and $\mathrm{Cu}_{c}$ orbitals ( $\propto t_{b c}$ ) (see scheme in Table 2). Then $t_{2}=t_{a b}=-t_{b c}$. For the same reason, it is expected that $t_{1}$ and $t_{2}$ have opposite sign. Regarding the exchange-transfer term, the operator $h_{l}$ produces an anti-clockwise singlet displacement [8], in such a way that, a singlet on sites $a$ and $b$, with spins up and down, respectively, is displaced to sites $c$ (up) and $a$ (down). This movement can be conceived as a two-step pathway (Figure 3), where firstly the electron in site $b$ is transferred to site $a$, followed by a second transfer toward $c$. This effect scales as $t_{2} t_{1} /\left(U_{a}+\varepsilon\right)$. The coupling of $|\bar{a} c\rangle$ with $|a \bar{b}\rangle$ is also equal to $h_{l}$, but in this case the displacement is clockwise. On the other hand, the operator $h_{2}$ controls the clockwise movement of the singlet: a singlet on sites $a$ and $b$ is displaced to sites $b$ and $c$. As for $h_{l}$, this effect can be identified with a two-step pathway, involving the ionic $|b \bar{b}\rangle$ determinant, scaling as $\left(t_{2}\right)^{2} / U_{b}$. Moreover, the term $h_{l}$ contributes to the coupling between the $|a \bar{b}\rangle$ and $|a \bar{c}\rangle$ determinants, since it represents an indirect pathway for the electron transfer between sites $b$ and c (Figure 4). The same holds for the $h_{2}$ term and the electron transfer between sites $a$ and $b$ [8].

In summary, the magnetic and electronic constants, $J, t$ and $h$, correspond to coupling terms of an Hamiltonian built on the basis of the neutral determinants resulting from the distribution of two electrons on three active orbitals, $a, b$ and $c$. The next question is how these matrix elements can be isolated from the energies and wavefunctions provided by a set of CI calculations.

### 3.2. The machinery

The diagonalization of the Hamiltonian matrix on the basis of the neutral determinants (eq.1) (or their corresponding combinations in eq. 2) gives six eigenstates: three singlet and three triplet states, where two singlet (triplet) states are of symmetry A (B) and one singlet (triplet) state of symmetry B (A). Their energies can be written from the basic parameters as:

$$
\begin{array}{cc}
E_{S_{3}}=2 J_{2}+t_{1}+2 h_{2} & E_{T_{2}}=-t_{1} \\
E_{S_{1}, S_{2}}=\left((M+N) \mp \sqrt{(M-N)^{2}+8\left(t_{2}+2 h_{1}\right)^{2}}\right) / 2 & E_{T_{1}, T_{3}}=\left(\left(t_{1}+\varepsilon\right) \mp \sqrt{\left(t_{1}-\varepsilon\right)^{2}+8 t_{2}^{2}}\right) / 2 \tag{3}
\end{array}
$$

where $M=2 J_{2}-t_{l}-2 h_{2}$ and $N=2 J_{l}+\varepsilon$. Notice that the singlet displacement terms only appear on the singlet eigenvalues, since they stabilize the singlet but not the triplet states. The resulting spectrum depends on the relative values of the seven parameters involved. (Here, in order to simplify the discussion of the results, the labels of these states correspond to the distribution obtained from our CI calculations. That is, it makes use of a posteriori information, once the wavefunctions have been analyzed. Otherwise, there is no way to sort these states, prior to the determination of the effective parameters). Since there are only five energy-differences, it is clear that these parameters can not be univocally defined just from the spectrum. Also the information contained on the wavefunctions is necessary, and this is the goal of the effective Hamiltonian theory. This strategy has been previously used in the study of magnetic systems as well as the evaluation of electron transfer constants in mixed-valence systems [14, 21-24, 29-34]. A detailed description of the method can be found in Refs. [8,22], only the most striking points are provided here.

Let us consider the model space $\mathrm{S}=\{|a \bar{b}\rangle,|\bar{a} b\rangle,|b \bar{c}\rangle,|\bar{b} c\rangle,|a \bar{c}\rangle,|\bar{a} c\rangle\}$ spanned by the six neutral determinants. Also it is possible to use their six combinations: $\left\{\left|S_{a b}\right\rangle,\left|S_{b c}\right\rangle,\left|S_{a c}\right\rangle,\left|T_{a b}\right\rangle,\left|T_{b c}\right\rangle,\left|T_{a c}\right\rangle\right\}$. Its projector is:

$$
\begin{equation*}
\hat{P}_{S}=\sum_{i \in S}\left|\phi_{i}\right\rangle\left\langle\phi_{i}\right| \tag{4}
\end{equation*}
$$

From DDCI calculations we can obtain six approximated solutions $\left\{\left|\Phi_{k}\right\rangle, k=1,6\right\}$ to the exact Hamiltonian, which hereafter will be considered as exact. These solutions have the largest components in the model space $\Sigma$, with energies $E_{k}$. They constitute the target space $\Sigma^{\prime}$. Now we define an effective Hamiltonian in $\Sigma$ such as its six eigenvalues are exact, then equal to $E_{k}$, and its eigenvectors are projections of the corresponding exact eigenvectors in the model space. This is the definition of Bloch effective Hamiltonian [35]:

$$
\begin{equation*}
\hat{H}_{e f f}^{B l o c h}\left|\hat{P}_{S} \Phi_{k}\right\rangle=E_{k}\left|\hat{P}_{S} \Phi_{k}\right\rangle \tag{5}
\end{equation*}
$$

This basic equation leads to the spectral definition of the Bloch effective Hamiltonian [35]:

$$
\begin{equation*}
\hat{H}_{e f f}^{\text {Bloch }}=\sum_{k=1,6}\left|\hat{P}_{S} \Phi_{k}\right\rangle E_{k}\left\langle\hat{P}_{S} \Phi_{k}^{\dagger}\right| \tag{6}
\end{equation*}
$$

where $\left|\hat{P}_{S} \Phi_{k}^{\dagger}\right\rangle$ represents the biorthogonal vector associated to $\left|\hat{P}_{S} \Phi_{k}\right\rangle$, defined by:

$$
\begin{equation*}
\left|\hat{P}_{S} \Phi_{k}^{\dagger}\right\rangle=S^{-1}\left|\hat{P}_{S} \Phi_{k}\right\rangle \tag{7}
\end{equation*}
$$

where $S$ is the overlap matrix of the projections of the solutions of the exact Hamiltonian onto the model space:

$$
\begin{equation*}
S_{i j}=\left\langle\hat{P}_{S} \Phi_{i} \mid \hat{P}_{S} \Phi_{j}\right\rangle \tag{8}
\end{equation*}
$$

In our case, all the calculations have been carried out in the $\mathrm{C}_{2}$ symmetry group. The active orbitals are the symmetry-adapted combinations of the localized $a, b$ and $c$ orbitals:

$$
\left.g=\frac{a+c}{\sqrt{2}} \quad \begin{array}{ll}
u=\alpha \frac{a-c}{\sqrt{2}}+\beta b  \tag{9}\\
u^{\prime}=\beta \frac{a-c}{\sqrt{2}}-\alpha b
\end{array}\right\} \alpha>\beta>0
$$

where $g$ belongs to the A irreducible representation and $u$ and $u$ ' to the B one. Then prior to perform the projections of the CI wavefunctions on the model space, we need to determine the $\alpha / \beta$ ratio by a localizing unitary transformation. Next, the normalized projections on the model space can be written as:

$$
\begin{array}{ll}
\left|\hat{P}_{S}^{1} \Phi_{1}\right\rangle=-\delta\left(\left|S_{a b}\right\rangle-\left|S_{b c}\right\rangle\right)+\gamma\left|S_{a c}\right\rangle & \gamma>\delta>0 \\
\left|\hat{P}_{S}{ }^{1} \Phi_{2}\right\rangle=\gamma^{\prime}\left(\left|S_{a b}\right\rangle-\left|S_{b c}\right\rangle\right)+\delta^{\prime}\left|S_{a c}\right\rangle \quad \gamma^{\prime}>\delta^{\prime}>0 \\
\left|\hat{P}_{S}{ }^{1} \Phi_{3}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|S_{a b}\right\rangle+\left|S_{b c}\right\rangle\right) &  \tag{10}\\
\left|\hat{P}_{S}^{3} \Phi_{1}\right\rangle=-\delta^{\prime \prime}\left(\left|T_{a b}\right\rangle-\left|T_{b c}\right\rangle\right)+\gamma^{\prime \prime}\left|T_{a c}\right\rangle \quad \gamma^{\prime \prime}>\delta^{\prime \prime}>0 \\
\left|\hat{P}_{S}^{3} \Phi_{2}\right\rangle=\frac{1}{\sqrt{2}}\left(\left|T_{a b}\right\rangle+\left|T_{b c}\right\rangle\right) \\
\left|\hat{P}_{S}^{3} \Phi_{3}\right\rangle=\gamma^{\prime \prime \prime}\left(\left|T_{a b}\right\rangle-\left|T_{b c}\right\rangle\right)+\delta^{\prime \prime \prime}\left|T_{a c}\right\rangle \quad \gamma^{\prime \prime \prime}>\delta^{\prime \prime \prime}>0
\end{array}
$$

where the equivalences between the $\left|S_{a b}\right\rangle\left(\left|T_{a b}\right\rangle\right)$ and $\left|S_{b c}\right\rangle\left(\left|T_{b c}\right\rangle\right)$ combinations are due to symmetric reasons, imposed by the structure of the cluster. The non-null elements of the overlap matrix are:

$$
\begin{align*}
& \left\langle\hat{P}_{S}^{1} \Phi_{2} \mid \hat{P}_{S}^{1} \Phi_{1}\right\rangle=-\delta \gamma^{\prime}+\gamma \delta^{\prime}=p \\
& \left\langle\hat{P}_{S}^{3} \Phi_{3} \mid \hat{P}_{S}^{3} \Phi_{1}\right\rangle=-\delta^{\prime \prime} \gamma^{\prime \prime \prime}+\gamma^{\prime \prime} \delta^{\prime \prime \prime}=q \tag{11}
\end{align*}
$$

The biorthogonal vectors are then defined by:

$$
\begin{align*}
& \left|\hat{P}_{S}^{1} \Phi_{1}^{\dagger}\right\rangle=\frac{1}{1-p^{2}}\left(\left|\hat{P}_{S}^{1} \Phi_{1}\right\rangle-p\left|\hat{P}_{S}^{1} \Phi_{2}\right\rangle\right) \\
& \left|\hat{P}_{S}^{1} \Phi_{2}^{\dagger}\right\rangle=\frac{1}{1-p^{2}}\left(-p\left|\hat{P}_{S}{ }^{1} \Phi_{1}\right\rangle+\left|\hat{P}_{S}^{1} \Phi_{2}\right\rangle\right) \\
& \left|\hat{P}_{S}^{3} \Phi_{1}^{\dagger}\right\rangle=\frac{1}{1-q^{2}}\left(\left|\hat{P}_{S}{ }^{3} \Phi_{1}\right\rangle-q\left|\hat{P}_{S}^{3} \Phi_{3}\right\rangle\right)  \tag{12}\\
& \left|\hat{P}_{S}^{3} \Phi_{3}^{\dagger}\right\rangle=\frac{1}{1-q^{2}}\left(-q\left|\hat{P}_{S}{ }^{3} \Phi_{1}\right\rangle+\left|\hat{P}_{S}^{3} \Phi_{3}\right\rangle\right) \\
& \left|\hat{P}_{S}{ }^{1} \Phi_{3}^{\dagger}\right\rangle=\left|\hat{P}_{S}{ }^{1} \Phi_{3}\right\rangle ;\left|\hat{P}_{S}{ }^{3} \Phi_{2}^{\dagger}\right\rangle=\left|\hat{P}_{S}^{3} \Phi_{2}\right\rangle
\end{align*}
$$

and now, the effective elements can be evaluated from the spectral definition of the Bloch Hamiltonian. For instance, the hopping integral $t_{2}$ can be obtained from:

$$
\begin{aligned}
t_{2}=\left\langle T_{b c}\right| \hat{H}_{e f f}\left|T_{a c}\right\rangle & =\left\langle T_{b c} \mid \hat{P}_{S}^{3} \Phi_{1}\right\rangle E_{T_{1}}\left\langle\hat{P}_{S}{ }^{3} \Phi_{1}^{\dagger} \mid T_{a c}\right\rangle+\left\langle T_{b c} \mid \hat{P}_{S}{ }^{3} \Phi_{2}\right\rangle E_{T_{2}}\left\langle\hat{P}_{S}{ }^{3} \Phi_{2}^{\dagger} \mid T_{a c}\right\rangle+ \\
& +\left\langle T_{b c} \mid \hat{P} S_{S}^{3} \Phi_{3}\right\rangle E_{T_{3}}\left\langle\hat{P}_{S}{ }^{3} \Phi_{3}^{\dagger} \mid T_{a c}\right\rangle
\end{aligned}
$$

## 4. Results

All the calculations have been performed at DDCI level on the basis of the molecular orbitals of the lowest triplet state. Figure 5 shows two views of the active $u$ and $u$ ' orbitals for cluster A, which present a pronounced degree of localization ( $\alpha=0.99731$ in eq. 9). A very similar description is obtained for cluster $B$, where $\alpha=0.99838$.
Figure 6 reports the spectrum of the six low-lying states of cluster A, as well as their normalized projections on the model space. The six states are distributed in two sets, separated by a gap of around $29000 \mathrm{~cm}^{-1}$, which is approximately the amplitude of $\varepsilon$, i.e., the relative stabilization of the hole localized on site $b$ with respect to those situations where the hole is placed on site $a$ or $c$.

The analysis of the DDCI wavefunctions of both clusters shows that the ground state corresponds to a triplet state, largely dominated by the $\left|T_{a c}\right\rangle$ component $(99 \%$ of the projected wavefunction is represented by this contribution). The two active electrons are localized on the two symmetry-equivalent Cu atoms, $\mathrm{Cu}_{a}$ and $\mathrm{Cu}_{c}$. This description is in agreement with the localized mixed-valence nature of this system, supported by all the available experimental data. The lowest excited state is the corresponding singlet state,

## Deleted:

essentially represented by the $\left|S_{a c}\right\rangle$ component (Figure 6). That is, the two lowest states of the trinuclear system are practically equivalent to those resulting from a binuclear complex, with two electrons distributed on two sites. In this particular case, it could be pertinent to evaluate the magnetic coupling constant between sites $a$ and $c, J_{l}$, directly from the energy difference between these two states. The resulting values are $J_{l}=43.7$ $\mathrm{cm}^{-1}$ for cluster A, and $J_{I}=46.3 \mathrm{~cm}^{-1}$ for cluster B. These amplitudes are overestimated with respect to the experimental value (experimental singlet-triplet separation of +14 $\mathrm{cm}^{-1}$ ), but they are in really better agreement that any of the previous evaluations based on DFT calculations [5,9,10,11]. Moreover, it is worth to notice that several works have recently shown that DDCI approach slightly overestimates the ferromagnetic coupling constants $[24,3 \underline{2}, 3 \underline{6}]$, and that spin-orbit effects are not taken into account in our calculations, which can also affect the singlet-triplet separation.

The four remaining states correspond to the symmetric and antisymmetric combination of the $\left|S_{a b}\right\rangle\left(\left|T_{a b}\right\rangle\right)$ and $\left|S_{b c}\right\rangle\left(\left|T_{b c}\right\rangle\right)$ components. So, the rest of parameters can not be evaluated directly from energy differences, and can only be determined with the help of effective Hamiltonians. It is important to mention that the use of effective Hamiltonian theory is a general procedure, that can be employed independently of the degree of localization of the low-lying states, while the evaluation of the magnetic coupling constant from the energy difference is only possible due to the fact that both the lowest singlet and ground triplet states present quite large weight on a unique component $\left(\left|S_{a c}\right\rangle\right.$ and $\left|T_{a c}\right\rangle$ components, respectively). The so-obtained values of the effective parameters $J, t$ and $h$ for clusters A and B are reported on Table 2. Also it is shown the stabilization energy $\varepsilon$, and the on-site Coulomb repulsion terms, $U_{a}$ and $U_{b}$. As expected, the effective parameters for both clusters are quite similar in values and trends, and the $J_{I}$ values are in good agreement with those extracted from the energy differences. The energies of the lowest singlet and triplet states on the basis of the effective parameters are shown in eq. 3 as $\mathrm{E}_{\mathrm{S} 1}$ and $\mathrm{E}_{\mathrm{T} 1}$. Both of them depend not only on $J_{l}$ but also on the rest of parameters. The fact that the singlet-triplet energy difference matches the $2 J_{1}$ value is due to a compensation of the other parameters, and a verification of the localized nature of the two lowest states.
The ferromagnetic nature of the magnetic coupling constants is in agreement with the Goodenough and Kanamori rules [37] and magnetostructural relationships reported by

Ruiz et al. for binuclear oxo-bridged $\mathrm{Cu}(\mathrm{II})$ complexes [38]. They predict ferromagnetic coupling for those systems with $\mathrm{Cu}-\mathrm{O}-\mathrm{Cu}$ bridges close to $90^{\circ}$. However in this system, the main structural parameter governing the amplitude and sign of the different parameters is not the $\mathrm{Cu}-\mathrm{O}-\mathrm{Cu}$ bond angle, but the dihedral $\mathrm{Cu}-\mathrm{O}-\mathrm{O}-\mathrm{Cu}$ angle and the $\mathrm{Cu}-\mathrm{Cu}$ distance. The small dihedral $\mathrm{Cu}-\mathrm{O}-\mathrm{O}-\mathrm{Cu}$ angles produce an inefficient overlap of the oxygen bridging atoms with the Cu 3 d orbitals. O 2 p orbitals are practically orthogonal to the plane containing $\mathrm{Cu}_{a}$ and $\mathrm{Cu}_{c}$ atoms (see Figures 5 c and 5 d ). This particular structure has an important impact on the nature and amplitude of the interactions.
Regarding the magnetic coupling, two contributions with opposite signs can be distinguished: $J=J_{F}+J_{A F}=2 K-4 t^{2} / U$, where the former term corresponds to the direct exchange which produces a ferromagnetic contribution, the latter term takes into account the coupling through the bridging ligands. The geometry of the system imposes a reduced contribution of the oxygen atoms on the coupling, the main mechanism being the direct interaction between the Cu atoms, instead of the superexchange through the bridging atoms. Then, the smaller the $\mathrm{Cu}-\mathrm{Cu}$ distance, the larger the direct exchange is, and consequently, the ferromagnetic contribution governs the interaction. This explains why $J_{2}$ is larger than $J_{\underline{I}}$ for each cluster.
Also the electron transfer integrals follow this trend. The amplitude of the electronic coupling constants are essentially controlled by the $\mathrm{Cu}-\mathrm{Cu}$ distance, that is, by the through-space component of the electronic coupling, while the through-bond one plays a minor role. Consequently, $t_{2}$ is larger than $t_{l}$, since the $\mathrm{Cu}_{a}-\mathrm{Cu}_{\mathrm{b}}$ distance is smaller than the $\mathrm{Cu}_{a}-\mathrm{Cu}_{c}$ one. Moreover, the signs are different, due to the d-d overlap, which is positive for d orbitals in sites $a$ and $b$, but negative for those in sites $a$ and $c$, as shown in the inset in Table 2. Also notice that $t_{2}=t_{a b}=-t_{b c}$ for the same reason. As mentioned above, the reported $t_{2}$ in Table 2 is the mean value of the effective matrix elements $\left\langle T_{b c}\right| \hat{H}_{e f f}\left|T_{a c}\right\rangle$ and $\left\langle T_{a c}\right| \hat{H}_{e f f}\left|T_{b c}\right\rangle$, which can be different due to the non-hermiticity of the Bloch Hamiltonian. For cluster A, $\left\langle T_{b c}\right| \hat{H}_{e f f}\left|T_{a c}\right\rangle=1394 \quad \mathrm{~cm}^{-1}$, while $\left\langle T_{a c}\right| \hat{H}_{e f f}\left|T_{b c}\right\rangle=1539 \mathrm{~cm}^{-1}$, which represents only a deviation of $5 \%$ with respect to the mean value $t_{2} \equiv \underline{1467 \mathrm{~cm}^{-1}}$. A slightly larger deviation ( $12 \%$ ) is found for cluster B, where $\left\langle T_{b c}\right| \hat{H}_{e f f}\left|T_{a c}\right\rangle=1340 \mathrm{~cm}^{-1}$ and $\left\langle T_{a c}\right| \hat{H}_{e f f}\left|T_{b c}\right\rangle=1057 \mathrm{~cm}^{-1}$.

Since the two lowest states are strongly localized on the $\left|T_{a c}\right\rangle$ and $\left|S_{a c}\right\rangle$ components, it is possible to obtain an estimate of the direct exchange between sites $a$ and $c, K_{a c}$, from the composition of the lowest singlet wavefunction, the singlet-triplet energy difference and the electron transfer integral $t_{a c}=t_{l}$ (see a detailed description of the procedure in Ref. 22). The so-obtained $2 K_{a c}$ value is $106.5 \mathrm{~cm}^{-1}$ for cluster A and $101.2 \mathrm{~cm}^{-1}$ for
 respectively, the global constant being governed by the direct interaction between sites $a$ and $c$.

On the other hand, the singlet-displacement terms are non-negligible, being of the same order than the $\underline{J}_{\underline{I}-}$ magnetic coupling constants as suggested by Blondin and Girerd [7]. Since $h_{1}=t_{2} t_{1} /\left(U_{a}+\varepsilon\right)$ and $h_{2}=t_{2}^{2} / U_{b}$, it is possible to evaluate the on-site Coulomb repulsion terms from the singlet-displacement and hopping integral amplitudes, the soobtained value being around 6 eV , with only small differences between sites $a(c)$ and $b$. For cluster B the reported value for $h_{1}$ must be dealt with caution since it is on the limit of accuracy of the procedure. Consequently, the corresponding $U_{a}$ value is not reported.

Comparing the parameters for clusters A and B, the main differences come from the hopping integrals and the stabilisation energy $\varepsilon$. Even when the geometrical parameters for A and B are quite close, the Jahn-Teller distortion seems to be more efficient from an energetic point of view for cluster B than for A, with a differential stabilisation of 0.3 eV . This suggests that the degree of localization on cluster B is larger than in cluster A, which is in line with smaller electronic coupling constants (hopping integrals) for B than A.

## 5. Conclusions

The magnetic and electronic local parameters acting on a mixed-valence $\left[\mathrm{Cu}_{2}(\mathrm{II}) \mathrm{Cu}(\mathrm{III})\right]$ compound are evaluated by means of extended CI calculations and the use of the effective Hamiltonian theory. The results confirm the ferromagnetic nature of the system, and provide estimates of the electron transfer terms and the singletdisplacement operators. Also the extension of the Jahn-Teller distortion is quantified. The strategy is completely general, and can be employed
independently of the degree of localization of the system. Since all the information is mapped on a model Hamiltonian, it is possible to check the presence of additional interactions (with non-null elements on the hamiltonian matrix), avoiding any possible bias due to the choice of a too limited set of effective parameters. Works are in progress in order to elucidate the impact of the nature of the bridging ligand on the magnetic properties of this complex.

## Acknowledgments

I would like to deeply acknowledge Dr. Juan Antonio Anta and Dr. Sofía Calero for taking the initiative to edit this special issue in honor of Dr. José Antonio Mejías, as well as for their invitation to participate in it. I am also very grateful to E. Iglesias for his careful reading of this manuscript as a way to pay homage to his friend José Antonio.
