Industrial Location at the Intra-metropolitan Level: The Role of Agglomeration Economies*

Josep-Maria Arauzo-Carod (♣): josepmaria.arauzo@urv.cat

Elisabet Viladecans-Marsal (♠): eviladecans@ub.edu

First received: June 2006

Accepted: July 2007

Abstract:

The objective of this paper is to analyse the influence of agglomeration economies on location decisions taken by new firms inside metropolitan areas. As we assume that these economies differ according to firms' level of technology, our sample comprises new firms from high, intermediate and low technology industries. We are particularly interested in analysing the effects of agglomeration economies that are felt over very short distances (inside the metropolitan areas). We introduce in our estimation the effect of the central city as a determinant for the location of new firms in the rest of the metropolitan area.

Keywords: industrial location, cities, metropolitan areas, agglomeration economies

Sites industriels au niveau intramétropolitain :

le rôle des économies d'urbanisation

Josep-Maria Arauzo-Carod et Elisabet Viladecans-Marsal

Résumé

L'objectif de cet article est d'analyser l'influence des économies d'urbanisation sur les décisions prises par de nouvelles entreprises concernant l'installation de leur site dans des zones métropolitaines. Partant de l'hypothèse que ces économies diffèrent en fonction du niveau technologique des entreprises, notre échantillon comprend des entreprises nouvelles d'un niveau technologique élevé, intermédiaire et bas. Nous nous intéressons particulièrement à l'analyse des effets des économies d'urbanisation qui sont ressenties sur de très courtes distances (à l'intérieur des zones métropolitaines). Nous introduisons dans notre estimation l'effet de la ville centrale comme déterminant dans le choix des sites des nouvelles entreprises dans le reste de la zone métropolitaine.

Mots-clés : sites industriels, ville, zone métropolitaine, économies d'urbanisation.

Industriestandorte auf intrametropolitane Ebene: die Rolle der Agglomerationswirtschaften

Josep-Maria Arauzo-Carod and Elisabet Viladecans-Marsal

Abstract:

Mit diesem Beitrag soll der Einfluss von Agglomerationswirtschaften auf die Standortentscheidungen von neuen Firmen in metropolitanen Gebieten untersucht werden. Da wir annehmen, dass diese Wirtschaften je nach dem technologischen Niveau der Firmen unterschiedlich ausfallen, enthält unsere Stichprobe neue Firmen aus Branchen mit hohem, mittlerem und niedrigerem technologischen Niveau. Insbesondere interessieren wir uns für die Analyse der Auswirkungen von Agglomerationswirtschaften, die über sehr kurze Entfernungen hinweg (innerhalb der metropolitanen Gebiete) spürbar werden. In unserer Schätzung berücksichtigen wir die Auswirkung der zentralen Stadt als Determinanten für den Standort neuer Firmen im übrigen metropolitanen Gebiet.

Ubicación industrial en un nivel intrametropolitano: el papel de las economías de aglomeración

Josep-Maria Arauzo-Carod and Elisabet Viladecans-Marsal

Abstract:

El objetivo de este artículo es analizar qué influencia ejercen las economías de aglomeración cuando las nuevas empresas eligen su ubicación en áreas metropolitanas. Suponiendo que estas economías difieren en función del nivel de tecnología de las empresas, en nuestra muestra abarcamos nuevas empresas de industrias con tecnologías alta, intermedia y baja. No interesa en particular analizar los efectos de las economías de aglomeración que se hacen palpables sobre distancias muy cortas (dentro de áreas metropolitanas). En nuestro cálculo introducimos el efecto de la ciudad central como determinante para ubicar las nuevas empresas en el resto del área metropolitana.

1. Introduction

The geographical concentration of production and employment is an established fact, both in the United States and in the European Union. Spain is no exception: at the end of the nineties the three biggest provincesⁱ accounted for 37% of total employment and for 41% of industrial employment (VILADECANS, 2004). When the analysis is carried out for a single manufacturing sector, this unequal geographical distribution becomes even greater: in the case of the Paper and the Chemical Products industries these employment percentages rise to 57% and 55% respectively. The entry of new firms also shows high geographical concentration since, between 1992 and 1996, 44% of new industrial firms were located in the 13 biggest Spanish metropolitan areasⁱⁱ. The geographic concentration of an economic activity can be analysed with various indexes and methodologies. In the case of Spain, a number of articles have analysed the concentration of its manufacturing activities using different databases and methodologies (see, for example, ALONSO et al. 2004 and PALUZIE et al. 2004). Both these analyses conclude that the level of concentration is very high and that this level differs considerably between industries.

The economic literature identifies several factors that may contribute to an explanation of the localization patterns of new manufacturing activities: input costs, availability of raw materials, infrastructure stock, local tax level, and the incentives offered by industrial and regional policies, and even, for some activities, the weather. Though many factors influence different aspects of the location decision of industrial firms, in this paper we will concentrate on the influence of agglomeration economies. There is a substantial body of empirical literature on the nature and the extent of agglomeration economies (see ROSENTHAL and STRANGE, 2004, for a survey). Most papers analyse the effects of agglomeration economies

1
2
3 at the regional or metropolitan level. The reason for this approach is probably data
4 availability, but it entails several methodological problems. These problems can be mitigated
5
6 by focusing on intra-metropolitan location, assuming that some of the factors that influence
7
8 the location of new firms are common to all the alternative locations inside a given
9
10 metropolitan area. Another reason for the interest in the intra-metropolitan location patterns is
11
12 the need to establish whether higher production costs in central cities produce dispersion in
13
14 the location of new industrial firms towards the periphery of the metropolitan areas or,
15
16 alternatively, whether the economic environment of the central city, including the costs, can
17
18 still attract certain specific firms. So it is also worth analysing the location of new firms for a
19
20 variety of industries, in order to test for differences in suburbanization patterns. In fact, one of
21
22 the main contributions of our analysis is not that we are analysing why a metropolitan area
23
24 with more agglomeration economies receives more new firms than another with fewer such
25
26 economies, but rather what actually happens inside each metropolitan area. Empirically, our
27
28 methodology involves the introduction of dummies for each metropolitan area, which allows
29
30 us to control for all the common factors inside the area, some of which are not easily
31
32 measured.

40
41
42

43 This paper follows the line of research into the location of new firms in Spanish cities started
44
45 in ARAUZO (2005), ARAUZO and MANJÓN (2004) and COSTA *et al.* (2004), but focuses
46
47 above all on the location patterns of new manufacturing firms inside the 13 biggest Spanish
48
49 metropolitan areas. This approach represents an improvement, because we study the micro-
50
51 empirics of agglomeration economies at this geographical level. We also aim to establish
52
53 whether the location of new manufacturing firms has undergone a process of suburbanisation
54
55 and whether these new firms locate in the surrounding areas of big cities or, alternatively,
56
57 whether they locate near the centre. In fact, our hypothesis is that by the mid-eighties some
58
59
60

1
2
3 new firms had started to operate in the suburbs of big cities but, without exception, still within
4 the metropolitan areas. So what we see is that these firms enjoy the advantages of proximity
5 to the big city, especially communication infrastructures, and also pay less than before. For
6 the empirical analysis we use a database of the new firms in six different manufacturing
7 activities in the 13 biggest Spanish metropolitan areas for the period 1992-1996.

15
16

17 The paper is organised as follows: in the second section we present an overview of the
18 influence of agglomeration economies on firm location at the intra-metropolitan level and
19 introduce the process of suburbanisation and the role of the central city as a possible new
20 tendency in the intra-metropolitan location of these activities. In the third section we present
21 our empirical analysis, first describing the database, then discussing the evidence for the
22 location of these firms and finally performing the econometric specification. The fourth
23 section presents the results, and the fifth section concludes.

40

41 2.1 Agglomeration economies and the creation of new firms

42
43

44 The empirical literature that analyses the influence of agglomeration economies on industrial
45 activity already has a long tradition. Several approaches have been applied to analyse the
46 effect of these economies on the behaviour of firms. ROSENTHAL and STRANGE (2004)
47 classify agglomeration economies in three groups, depending on their scope: industrial,
48 geographic and temporal. Apart from these three different but complementary approaches, in
49 the empirical analysis, there are different ways to test the influence of agglomeration
50 economies on firms' behaviour: the effect on their productivity, on their employment growth,
51 and on their wages (see ROSENTHAL and STRANGE, 2003, WHEATON and LEWIS, 2002
52
53

57
58
59
60

1
2
3 and the seminal works of GLAESER *et al.*, 1992 and HENDERSON *et al.* 1995, as good
4 examples of these different approaches). Finally, some empirical studies have analysed the
5 influence of agglomeration economies on the location of employment or firms, in general, and
6 on the location of new plants in particular. This latter approach is the one in which we are
7 interested for our analysis. FIGUEIREDO *et al.* (2002), GUIMARÃES *et al.* (2004 and
8 2000), HOLL (2004a and 2004b) and ROSENTHAL and STRANGE (2003 and 2004) are
9 good examples of analyses of the location of new firms, and COUGHLIN and SEGEV
10 (2000), LIST (2001), and WOODWARD (1992) are good examples of analyses of location
11 determinants of multinational firms. We should stress that in most of the references we
12 mention, the empirical analysis has been performed with microdata (new firms locating in
13 different geographical areas). This is a considerable advantage with regard to an aggregated
14 analysis (one that uses the whole employment of an area, for example) because when we use
15 individual data the problem of the endogenous agglomeration economy variables disappears.
16 Though the empirical analyses in these papers are applied to different countries and use
17 different databases, most of them analyse the location of firms at the local level and introduce
18 as explanatory variables the characteristics of the economic environment used as proxies of
19 agglomeration economies. They conclude that, to different degrees, these variables have a
20 clear implication in the geographical distribution of new industrial activities. In the Spanish
21 case, some recent papers have also analysed the determinants of new firm location at the local
22 level: ALAÑÓN *et al.* (2007), ARAUZO (2005 and 2007), ARAUZO and MANJÓN (2004),
23 COSTA *et al.* (2004) and HOLL (2004a). All these papers have in common their use of local
24 data, Spanish municipalities, and the use of the economic environment of the firm as an
25 explanatory variable, in some cases specifically called “agglomeration economies”.

2.2 Agglomeration economies and the intra-metropolitan location of firms

1
2
3 Most papers analyse the effect of agglomeration economies on firm location at the regional or
4 metropolitan level. The reason for this approach is probably data availability, but this
5 approach entails several problems. First, with the exception of some countries like the US, the
6 number of regions or metropolitan areas tends to be quite small, which means that the
7 geographical variation in locational factors may be also quite limited. And second, the pure
8 effect of agglomeration economies may be difficult to identify in inter-metropolitan analyses
9 because there are so many locational factors which may influence inter-metropolitan location
10 (and are sometimes very difficult to quantify) and which may be correlated with
11 agglomeration economies. This problem can be mitigated by focusing on intra-metropolitan
12 location and assuming that some of these factors are common to all the alternative
13 locations/municipalities inside a given metropolitan area.

25
26
27
28
29
30
31

32 There is a long tradition of analysing intra-metropolitan industrial location in the United
33 States. The works of ERICKSON and WASYLENKO (1980), CARLINO and MILLS (1987),
34 BOARNET (1994), DEITZ (1998), OUWERSLOOT and RIETVELD (2000) and
35 ROSENTHAL and STRANGE (2005) are good examples. The last of these papers
36 specifically analyses the influence of agglomeration economies at this geographical scale.
37 More recently, and since more disaggregated data have become available, other papers have
38 been published with the same objective but performing the empirical application in
39 metropolitan areas in other countries (BAUDEWYNS (1999) in Belgium, WU (1999) in
40 China, MAOH *et al.* (2005) in Canada and CHAKRAVORTY *et al.* (2005) in India or VAN
41 SOEST *et al.* (2006) in Holland, for example). These papers, however, analyse the location of
42 firms inside a single metropolitan area. The only paper analysing intra-metropolitan location
43 with a database covering several metropolitan areas is ROSENTHAL and STRANGE (2003).
44 With many different metropolitan areas to draw on, these authors are able to control for

3 location factors in a specific metropolitan area by including fixed effects in the estimated
4
5 equation.
6
7
8
9

10 It should be noted that the demographic and economic structure of a metropolitan area is not
11 homogeneous. In fact, the analysis applied to the intra-metropolitan level normally separates
12 the central city from the periphery (comprising the rest of the municipalities of the
13 metropolitan area). This is another reason for the interest in intra-metropolitan location
14 patterns: to establish whether higher production costs in central cities (due to land costs,
15 wages, congestion, transport costs, among others) could produce dispersion or
16 suburbanisation in the location of some new industrial firms towards the periphery of the
17 metropolitan areas or, alternatively, whether the economic environment of the central cities
18 can still attract specific activities.

27
28
29
30
31
32
33

34 Some authors believe that certain specific traits make the suburbanisation process less acute
35 in Europe – especially in Spain – than in the US. This, however, is not strictly true because
36 suburbanisation is an ongoing process in metropolitan areas in Spain: in terms of economic
37 activity it started in the mid-eighties, just after the economic/industrial crisis, and in terms of
38 population in the nineties. In fact, the intensity of urban sprawl has accelerated in the last two
39 decades, possibly as a consequence of rising personal incomes and the changing economic
40 structure. Therefore, although the starting points are different, the fundamental problems of
41 metropolitan areas in the US, Europe and Spain in particular are similar. The analysis we
42 perform here may also have interesting implications for scenarios outside Spain. In spite of
43 this interest, few studies have analysed the interdependencies between central cities and their
44 suburbs in the Spanish (or European) case (SOLE¹ and VILADECANS, 2004, is one).

1
2
3 The empirical data show that traditionally the concentration of high-tech activities is higher in
4 the centre of the metropolitan area. There is a high presence of well-qualified young people
5 and more new high-tech firms are created than in the rest of the area (though the exit rate of
6 these new firms is also high, ARAUZO, 2005). Central cities are suitable settings for the
7 learning process of young people and also for the location of high technology firms. However,
8 in recent years the increasing costs of congestion, the deterioration of the amenities and the
9 soaring wage levels have led to a growing migration from the centres of the metropolitan
10 areas towards the periphery. These sprawl movements affect not only the population but
11 certain manufacturing firms and even some services activities as well (BODENMAN, 2000).
12 The suburbanisation of traditional manufacturing activities, which use large surface areas, is a
13 widely accepted process.

32 This paper seeks to go a step further and, in addition to the analysis of location patterns of
33 new industrial firms at the intra-metropolitan level, analyses whether these firms tend to
34 locate in the centre of the metropolitan area or on the periphery. We also wish to test whether
35 the process of suburbanisation affects high-tech activities which make less use of land and
36 have less need for inputs from big urban agglomerations. To this end we analyse the location
37 of new firms in several industries in order to identify any differences in their location patterns.

50
51
52
53
54

55 3. The empirical analysis

56 3.1 The territorial unit of analysis

57 As explained above, the main objective of this paper is to analyse the location decisions of
58 new firms at the intra-metropolitan level: that is to say, to use the municipalities belonging to
59 each of the metropolitan areas as geographical units. In Spain there is no formal
60

1
2
3 administrative record of metropolitan areas and the jurisdictions belonging to them. In spite of
4
5 this constraint, we define the metropolitan areas of 13 big Spanish cities on the basis of
6
7 economic and geographical criteria. These areas are chosen because they represent most of
8
9 the bigger metropolitan agglomerations in Spain and, as we will see, most entries of new
10
11 firms.
12
13

14
15
16
17 The metropolitan area considered for each city covers the land within a 35 kilometre radius of
18
19 the centre. This geographical criterion is also used in the Spanish Ministry of Public
20
21 Administrations' report on big cities and the areas of urban influence published in 2001. Due
22
23 to limitations of the statistical sources, jurisdictions with less than 3,000 inhabitants are not
24
25 considered. Finally, we obtain a database of 13 central cities (Alacant, Palma de Mallorca,
26
27 Barcelona, Córdoba, Donostia, Madrid, Málaga, Murcia, Gijón, Sevilla, València, Bilbao and
28
29 Zaragoza). Adding the jurisdictions that belong to their metropolitan areas, the sample
30
31 comprises 330 municipalities. The number of municipalities in each metropolitan area varies,
32
33 depending on the urban structure and, above all, on the size of the central city.
34
35
36
37
38
39
40

41 3.2. The database

42
43 Our main database is the REI (Spanish Industrial Establishments Register), which provides
44
45 plant-level microdata on the location of new industrial establishments at a local level. The
46
47 basic unit for the REI is a business establishment, a single physical location where industrial
48
49 operations are performed. Specifically, we know the municipality where each new industrial
50
51 establishment starts its activity, the year of opening, the sector and the number of employees.
52
53
54 Our database covers the period from 1992 to 1996.
55
56
57
58
59
60

1
2
3 Our point of departure is the fact that location patterns differ across sectors, since different
4 industries require specific characteristics to perform their manufacturing activities
5 successfully. To simplify our analysis, we use the OECD classification (OECD, 2001) to
6 divide manufacturing activities according to their technological intensity. We thus identify
7 high, intermediate and low technology sectors, and selected six specific 2-digit sectors
8 belonging to previous technology groups (see Table A.1 in the Appendix for a more detailed
9 explanation): 1) High technology sector: R&D machinery; 2) Intermediate technology sectors:
10 Machinery and equipment and Chemical products; and 3) Low technology sectors: Food and
11 beverages, Textiles and Leatherⁱⁱⁱ. These activities present differing productive characteristics
12 (i.e., level of productivity, degree of innovation, labor skills and presence of foreign
13 investment), while their patterns of geographical distribution in the territory also differ. The
14 first of these manufacturing sectors can be considered high-tech, the second and the third as
15 representing a medium level of technology, while the remaining three are traditional
16 manufacturing activities. It is interesting to determine whether the influence of agglomeration
17 economies on the respective location patterns differs in line with their technological levels.
18 Previous studies suggest that different types of agglomeration economies have different
19 effects. For example, most of the evidence indicates that localization economies are more
20 important for traditional activities, whereas urbanization economies have a more pronounced
21 impact on high-tech activities.

22
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50
51 During the period analysed (from 1992 to 1996) 5,569 new manufacturing establishments
52 began their activity in the 13 metropolitan areas under consideration (see Table 1). Most of
53 them belonged to low technology sectors (3,570), followed by intermediate sectors (1,549)
54 and, at some distance, by high sectors (450). Most of the entering firms were small, as almost
55 83% of entrants had ten employees or fewer (see Table A.2, in the Appendix). It seems to
56
57
58
59
60

1
2
3 exist a relation between firm size and technological level: the high technology entrants had a
4
5 mean of 11.5 employees, compared with 8.0 for intermediate technology firms and 7.6 for
6
7 low technology firms. This evidence is not exclusive to entrants, but in fact it reflects the size
8
9 distribution of all Spanish manufacturing firms.
10
11

12
13
14
15 [INSERT TABLE 1 ABOUT HERE]
16
17

18
19
20 Comparing the sectoral distribution of new firms in the municipalities of our 13 metropolitan
21
22 areas with the rest of Spanish municipalities, our municipalities are specialised in high and
23
24 intermediate technology sectors, while in the rest of municipalities low technological sectors
25
26 predominate.
27
28

29
30
31 Before using econometric tools to analyse firms' location patterns, we will consider some
32
33 descriptive statistics on the geographical location of these new establishments at the intra-
34
35 metropolitan level. The mean distance of new entrants from the central city in their
36
37 metropolitan area increases as the technological level of the firm decreases. On average, then,
38
39 new R&D and machinery firms locate 8.75 km from the central city, new Machinery and
40
41 equipment firms 10.64 km away, and new Chemical products firms 12.35 km away. In the
42
43 low technology sectors, the distances were 11.64 km for new firms in Food and beverages,
44
45 19.82 km for Textiles, and 25.86 km for Leather. This evidence points to the fact that new
46
47 high-tech manufacturing firms seem to prefer to locate their productive establishments close
48
49 to the central city in their metropolitan area. This finding is in line with reports elsewhere that
50
51 suggest that the central city has specific inputs related to the most advanced activities and
52
53 which make them more attractive.
54
55
56
57
58
59
60

1
2
3 These location patterns can also be studied by establishing the distribution of new firms
4 between the central city in the area and the periphery (i.e. the rest of municipalities in the
5 metropolitan area). Our data (displayed in Table 2) show that new firms in high technology
6 sectors are more concentrated in the central city of the metropolitan area (where 47.3% of
7 new entrants locate), while new firms in intermediate and low technology sectors are more
8 spread out: 68.1% of new entrants in intermediate technology sectors are in the periphery and
9 69.8% of new firms in low technology sectors.

22 [INSERT TABLE 2 ABOUT HERE]
23
24
25
26

27 Table 2 shows that the higher the technological level of new entrants, the higher their
28 concentration at the core of the metropolitan area. This specific location pattern emerges
29 because high technology firms seem to require the kind of environment offered by central
30 cities more than that offered by the periphery. On the basis of this, our hypothesis is that new
31 firms in the most advanced manufacturing sectors will prefer to locate their activities in, or
32 very close to, the city centre itself.

38
39
40
41
42

43 3.3 The econometric specification

44
45
46 When conducting location analyses, there are various methodological issues concerning the
47 data that must be taken into consideration. One of these is the so-called “zero problem”.
48 Specifically, our data shows that of the 330 municipalities in the areas analysed, 321 were
49 chosen as a site by one or more industrial establishments^{iv}. This means we are analysing
50 location decisions that affect 97% of municipalities, but this situation changes when we shift
51 our analysis and examine each industry separately. The situation in which a large number of
52 territories (municipalities) receive no industrial establishments (zero entries) is reasonable if
53
54
55
56
57
58
59
60

1
2
3 we are working at a very disaggregated geographical level like the municipality, or at a
4
5 disaggregated industry level. Specifically, if we take into account the sectoral differences of
6
7 those entrants, some specific patterns arise (see Table 3). While for high technological sectors
8
9 only 33.9% of the municipalities received new firms, in Food products and beverages 73.9%
10
11 of the municipalities were chosen by at least one firm. So, our industry-level data present the
12
13 “zero problem”.
14
15

16
17
18
19
20 [INSERT TABLE 3 ABOUT HERE]
21
22
23

24 The Poisson model can deal with this "zero problem". This count model^v shows how many
25
26 times each location (municipality) is chosen by an establishment. This implies that increasing
27
28 alternative locations when we analyse the phenomenon at a local level does not constitute a
29
30 major problem^{vi} as it does with other models like the conditional logit, for instance (in our
31
32 case, highly disaggregated data means having more zeros). Hence, municipalities in which
33
34 $y=0$ (i.e. municipalities where no establishment is located) are relevant because values of
35
36 independent variables in these locations explain why they have not been chosen by new
37
38 entrants^{vii}.
39
40
41
42
43
44

45 Like many studies of industrial location (see ARAUZO, 2005; CIEŚLIK, 2005; ARAUZO
46
47 and MANJÓN, 2004; HOLL, 2004a and 2004b; LIST, 2001; and WU, 1999), in this paper we
48
49 model the number of new firm locations in each municipality (between 1992 and 1996) as a
50
51 Poisson-distributed random variable in which the parameter λ_i is related to the regressors
52
53 vector x_i that measures local characteristics. Specifically, we consider that the probability that
54
55 a municipality will attract a firm depends on the specific attributes of the municipality
56
57 (CIEŚLIK, 2005):
58
59
60

$$\Pr(y_i|x_i) = \frac{e^{-\lambda_i} \lambda_i^{y_i}}{y_i!}, \quad y_i = 0,1,2,\dots,n \quad (1)$$

where λ_i is dependent on the vector of explanatory variables (local characteristics):

$$\ln \lambda_i = \beta' x_i \quad (2)$$

and where β denotes a vector of coefficients of explanatory variables to be estimated. But the Poisson model assumes that conditional mean and variance functions equal λ_i :

$$E[y_i|x_i] = \text{var}[y_i|x_i] = \lambda_i \quad (3)$$

There is a generalized version of the Poisson model (the Negative Binomial model) that introduces an individual unobserved effect into the conditional mean:

$$\ln \lambda_i = \beta' x_i + \varepsilon_i \quad (4)$$

where ε_i shows either a specification error or some cross-sectional heterogeneity with $\exp(\varepsilon_i)$ having a gamma distribution with mean 1.0 and variance α .

As mentioned, one of the advantages of Poisson models is that they deal with the “zero problem”. However, in so doing they make two important assumptions that need to be taken into account. The first assumption is that the mean and the variance should be equal is often violated when Poisson models are used to model the industrial location phenomenon, given the concentration of industrial establishments in specific areas (this causes the variance to be greater than the mean, which is known as the “overdispersion problem”). This problem can be solved by using a negative binomial model, which allows the variance to exceed the mean. In the Negative Binomial model the variance equals:

$$\text{var}[y_i|x_i] = E[y_i|x_i] \{1 + \alpha E[y_i|x_i]\} \quad (5)$$

1
2
3 If α is zero, then the conditional variance is equal to the conditional mean and the Poisson and
4
5 Negative Binomial models are the same.
6
7
8
9

10
11 The second assumption is the excess zero problem, that is, the existence of a large number of
12
13 observations that take the value zero: for the phenomenon of industrial location, this occurs in
14
15 the municipalities where no industrial establishments are located. Poisson models can deal
16
17 with the existence of some observations with value zero, but not with an excessive number^{viii}.
18
19 This second problem can also be overcome by using a negative binomial model.
20
21
22
23
24

25 The descriptive statistics of the entrants (Table 4) display signs of overdispersion for all the
26
27 industries considered (CAMERON and TRIVEDI, 1998), and there is also an important “zero
28
29 problem” for all industries. These results point to the possibility of using other count data
30
31 models that can deal with these technical shortcomings.
32
33
34
35
36

37 [INSERT TABLE 4 ABOUT HERE]
38
39
40
41

42 Even though we assume that the Poisson model is not the count data model that fits our data
43
44 best, we still estimated this model (Table 5) so as to perform a Poisson goodness-of-fit test^{ix}.
45
46 Our results showed a large chi-square value which confirms that the Poisson model is not a
47
48 good choice.
49
50

51 [INSERT TABLE 5 ABOUT HERE]
52
53
54

55 Given the results of the previous test, we decided to estimate a Negative Binomial Model
56
57 (Table 6). Nevertheless, so as to confirm the validity of this decision, we performed another
58
59 test in order to choose between the Poisson or Negative Binomial models. We refer to the
60
likelihood ratio test of $\alpha=0$, which is a test of the overdispersion of the alpha parameter^x.

[INSERT TABLE 6 ABOUT HERE]

Our results showed alpha to be significantly different from zero, which reinforces our initial assumption that the Poisson model was not the best choice. Thus, we decided to use this subsequent estimation for our empirical results.

3.4 Empirical model and variables

Now that the econometric method and its specification seem clear, we need to find the variables of the vectors of locations attributes. These attributes that, according to the economic literature, theoretically affect firm location have been fully described. But, in the empirical approach, and especially working at local level, it is not easy to find variables to quantify all the factors; our approach, which involves analysing the effect of agglomeration economies on the creation of new firms inside metropolitan areas, solves this problem because we use dummy variables for each metropolitan area to control for all the aspects that affect firm location and that are common within each of the metropolitan areas. The independent variables we introduce in the estimation are those that we consider to be different for each of the municipalities in the metropolitan area. This approach is in line with recent studies that seek to analyse the effect of agglomeration economies over very short distances. ROSENTHAL and STRANGE (2003) refer to this approach as the microgeography of agglomeration. In our case, we are working within a very small geographical area, i.e. a metropolitan area.

As we stressed above, we aim to analyse the sectoral scope of agglomeration economies (urbanisation economies and location economies)^{xi} inside each of the metropolitan areas

1
2
3 selected. For that reason we need to quantify the two types of agglomeration economies.
4
5 Urbanisation economies can be measured with a range of variables that quantify the economic
6
7 size of each municipality from different points of view. One very common option is to use the
8
9 municipality's Population density. This variable is obtained from the Population Censuses
10
11 compiled by the Spanish National Institute of Statistics. As AUDRETSCH and FRITSCH
12
13 (2002, p. 120) note, "population density here represents all kinds of regional influences, such
14
15 as availability of qualified labour, house prices, local demand and the level of knowledge
16
17 spillovers. Including population density instead of indicators for these individual effects in the
18
19 regression avoids the problem of multicollinearity caused by relatively high levels of
20
21 correlation among these factors". For their part, location economies, which indicate the effect
22
23 of a particular industrial sector's size in an area on the firms in that sector, can be measured
24
25 by the entries of firms of the same manufacturing sector in an earlier period, between 1980
26
27 and 1991 (REI database).
28
29
30
31
32
33

34
35
36 In this way we can proxy the dynamics of the productive structure. In order to analyse the
37
38 suburbanisation process and the influence of the central city on new firms' location, we need
39
40 a variable to measure the physical position of a city inside its metropolitan area. This variable
41
42 is the distance of each municipality from the central city. To measure this distance, we use the
43
44 radial distance from the geographical co-ordinates of each city obtained from the National
45
46 Atlas of Spain (1994) (Spanish Ministry of Public Works, Transports and Environment).
47
48
49
50

51
52
53 Finally, we measure the stock of human capital available for firms, obtained from the
54
55 Population Censuses compiled by the Spanish National Institute of Statistics. Here we choose
56
57 two proxies of this variable: one is Human capital (university-level), which is the percentage
58
59
60

of the population with a university degree, and the other is Human capital (intermediate-level), which is the percentage of the population who (at least) completed secondary school.

After selecting the variables, and in order to test how new manufacturing firms within the metropolitan areas have been attracted by their local characteristics, we estimated the following model of the number of new establishments opened in a municipality as a function of these specific local characteristics:

$$N_{jk} = \beta_1 DEN_j + \beta_2 PE_j + \beta_3 DIST_j + \beta_4 MED_j + \beta_5 UNI_j + \sum_k \beta_k MA_k \quad (6)$$

where N_{jk} is the number of new plants^{xii} of a given industry that open in a municipality j in the metropolitan area k , DEN_j is population density in each municipality; PE_j is the previous entries for the same manufacturing sectors in each municipality; $DIST_j$ is the distance of each municipality from the central city in each metropolitan area; MED_j is the stock of intermediate-level human capital in each municipality; UNI_j is the stock of university-level human capital in each municipality and MA_k are the dummies for each metropolitan area.

4. Results

The results of the estimation of the model are presented in Table 6. As our aim was to identify the specific location patterns of industries with different technological levels, we performed econometric regressions for each of the six industries previously selected. All the estimations have a good explanatory capacity and the likelihood ratio test of alpha, which indicates whether a Poisson or Negative Binomial estimation is more appropriate, favours the latter.

1
2
3 Our results (see Table 6) show that there are certain specific industry location patterns that
4 can be analysed according to specific industrial characteristics and territorial requirements.
5
6 First, the result for the variable used in quantifying the effect of urbanisation economies on
7
8 the location of new firms (Population density) is mixed, since it has a positive influence on
9
10 new entries for firms belonging to low and high technology groups, but has no impact on
11
12 intermediate technology firms. The empirical results of other authors present a great
13
14 dispersion of the population density with regard to the entry of new firms: a mainly positive
15
16 effect (LIST, 2001; WOODWARD, 1992; GUIMARÃES *et al.*, 2000), a mainly negative
17
18 effect (ARAUZO and MANJÓN, 2004; GUIMARÃES *et al.*, 2004; FIGUEIREDO *et al.*,
19
20 2002) and a mixed effect (ARAUZO, 2005; COSTA *et al.*, 2004; COUGHLIN and SEGEV,
21
22 2000). In the literature, this variable has been used as proxy for urbanisation economies and
23
24 for land costs (COUGHLIN and SEGEV, 2000). If we proxy urbanisation economies we
25
26 would expect a positive relationship between them and the location of new firms (given that
27
28 entrants will be positively affected by the existence of urbanisation economies) and if we
29
30 proxy land costs we would expect a negative relationship (given that entrants will avoid
31
32 locating in costly areas)^{xiii}. Though the effect on low technology and high technology
33
34 industries is the same, the reasons for this might differ in these industries: high tech firms
35
36 need an innovative environment, which is usually found in more densely populated cities,
37
38 whereas low tech firms are labour-intensive and need to be located in more densely populated
39
40 cities where larger amounts of labour are available.
41
42
43
44
45
46
47
48
49
50

51
52
53 Second, the effect of the variable which is a proxy of the effect of location economies
54
55 (Previous entries: PE) is positive and significant for all industries. This evidence is very
56
57 common in this type of analysis (see ROSENTHAL and STRANGE, 2003, and COSTA *et*
58
59 *al.*, 2004). Except for the Leather and Food and beverages industries, the smallest coefficient
60

1
2
3 is obtained by R&D Machinery, the most high tech activity of those analysed here. This result
4
5 is not at all surprising since earlier studies of agglomeration economies point out that location
6
7 economies are less intense in more urban areas (big cities) where the urbanisation economies,
8
9 tend to be stronger because of their more diversified productive structure.
10
11

12
13
14
15 Third, the results of the Distance from the central city variable are negative, as we expected,
16
17 and significant for all high and intermediate technology sectors (R&D Machinery, Machinery
18
19 and equipment and Chemical products) and for one of the low technology industries (Food
20
21 and beverages). It should also be noted that the higher the technological level of the industry,
22
23 the higher the negative coefficient of the distance variable was found to be. This means that
24
25 the most advanced activities prefer to locate their establishments within, or as close as
26
27 possible to, the central city itself. Thus, there is a more marked effect for the more highly
28
29 skilled activities which need to maintain good accessibility to the centre of the metropolitan
30
31 areas. These results suggest that, even though a suburbanisation process exists and some firms
32
33 may indeed move away from the centre of the metropolitan areas, they prefer to locate their
34
35 activity close to the central city because it allows them to maintain fluid communications with
36
37 the centre and so benefit from the greater advantages of agglomeration.
38
39
40
41
42

43
44
45 Fourth, the results for Human capital variables show that firms need access to the areas
46
47 inhabited by people with an intermediate educational level, because this workforce is
48
49 necessary in all kinds of activity^{xiv}. But if we look at more educated people (those with a
50
51 university degree), some specific industry patterns emerge: a negative impact for almost all
52
53 industries, which is significant for the intermediate technology industries and for one of the
54
55 low technology industries (Textiles). In previous work (see ARAUZO, 2005, and ARAUZO
56
57 and MANJÓN, 2004, for instance) we concluded that firms prefer to avoid higher wages and
58
59
60

1
2
3 that wages are higher where the population is more skilled. We should stress that human
4 capital data refer to the municipalities in which these individuals live, and not to the
5 municipalities in which they work. Thus, we must take into account the commuting pattern of
6 individuals (even if it is not possible to include this factor in the econometric analysis). Here,
7 it has been demonstrated that, in the Spanish case (CASADO, 2000), individuals with highly
8 qualified occupations commute more. In line with this empirical evidence, we can assume that
9 there is a spatial mismatch between the municipalities in which people live and those in which
10 people work, and that this mismatch is greater for more highly qualified individuals.
11 Additionally, we can also assume that these skilled workers (those holding a university
12 degree) prefer a better environment (residential amenities), do not work in the same
13 municipality as the one in which they live, and work (predominantly) in the high technology
14 sectors. Therefore, it would be logical to find that the location of skilled workers has no
15 influence on the location of high technology firms.

37 5. Conclusions

38
39
40
41
42 The objective of this paper was to analyse the influence of agglomeration economies on the
43 location of new firms within the largest metropolitan areas of Spain, drawing on data for
44 manufacturing firms for the period 1992-1996. In line with recent research and the latest
45 empirical findings, the model incorporates two types of agglomeration economies:
46 urbanisation economies (the influence of the area's economic activity) and localisation
47 economies (the effects of specialisation in one sector on an area as a determining factor in the
48 location of firms belonging to that sector). Some recent empirical analyses assume that the
49 influence of these economies differs according to the industry being analysed. For this reason,
50 we reproduce the analysis for six manufacturing industries that present different productive
51
52
53
54
55
56
57
58
59
60

1
2
3 characteristics (i.e., level of productivity, degree of innovation, labour skills and presence of
4 foreign investment) and different patterns of geographical distribution in the territory. Of
5 these six, one can be considered a high-tech industry, two represent a medium level of
6 technology, while the remaining three are traditional manufacturing activities.
7
8
9
10
11

12
13
14
15
16 We believe that one of the main contributions of this paper is the fact that the empirical
17 analysis is undertaken at the intra-metropolitan level. This approach is in line with recent
18 developments that suggest that what occurs over very short distances, i.e., between the
19 municipalities of a metropolitan area, provides the key to understanding the impact of
20 agglomeration economies. This approach has a further methodological advantage because it
21 allows us to control for aspects that influence firm location and which are also common to all
22 the municipalities belonging to the same metropolitan area. For this reason, we introduce a
23 dummy for each of the metropolitan areas included in the econometric analysis.
24
25
26
27
28
29
30
31
32
33
34

35
36
37
38 Additionally, an analysis of intra-metropolitan location allows us to determine whether higher
39 production costs in central cities lead to new industrial firms taking up dispersed locations in
40 the periphery of metropolitan areas or, alternatively, whether the economic environment of
41 the central city, even those that generate high costs, can still attract certain specific firms.
42 Thus, it is also worth analysing the location of new firms operating in the six chosen sectors
43 in order to test for differences in suburbanization patterns.
44
45
46
47
48
49
50
51

52
53
54
55 In line with recently reported evidence in the literature, our results indicate that agglomeration
56 economies are an important factor in determining the location of new manufacturing firms.
57
58 The location of newly established firms in most of the industries analysed was influenced to
59
60

1
2
3 some extent by the productive environment. However, the influence of agglomeration
4 economies on the location of new firms clearly differed according to the type of industry.
5
6 First, our findings concerning the effect of urbanisation economies on the location of new
7 firms are mixed, since this variable had a positive influence on new entries for firms
8 belonging to the low and high technology groups, but was found to have no impact on
9 intermediate technology firms. Second, in the case of localization economies, our results
10 indicated that this variable had a positive and significant impact on all the industries analysed.
11
12 This suggests that the specialisation of a municipality in a particular industry will always
13 attract new firms in this sector. Third, the results we obtained for the distance from the central
14 city variable were, as expected, negative and significant for all high and intermediate
15 technology sectors and for one of the low technology industries. Interestingly, the higher the
16 technological level of the industry became, the higher was the negative coefficient of the
17 distance variable that we recorded. In line with our initial hypothesis, this means that the most
18 advanced activities prefer to locate their establishments within, or as close as possible to, the
19 central city itself. These results suggest that, even though a suburbanisation process exists and
20 some firms may indeed move away from the centre of the metropolitan areas, they still prefer
21 to locate their activity close to the central city because this allows them to maintain fluid
22 communications with the central city and so benefit from the greater advantages of
23 agglomeration. In terms of policy measures, and given these differences in the location
24 patterns within the manufacturing industries, efforts to attract new firms should take into
25 account the characteristics of the municipalities. The first step in any policy design process
26 should clearly be the identification of industries that are likely to choose a specific area and
27 subsequent promotional efforts should focus on the industries identified in this first stage.

Source: our own calculations, using data from the REI

ⁱ In Spain, the smallest political and administrative units are the cities, understood as municipalities. There are more than 9,000 municipalities of very differing sizes. The next level up in political terms is that of the provinces (of which there are 50 in the Spanish case) and this level is equivalent to the NUTS III.

ⁱⁱ In section 3.1 we provide a detailed description of the characteristics of the Spanish metropolitan areas used in this paper.

ⁱⁱⁱ We expected to obtain different location patterns according to the broad characteristics of each industrial sector (measured in terms of technological level), so it was not necessary to use data from all manufacturing activities.

^{iv} The nine municipalities that did not receive new industrial firms were: San Juan Bautista, Tiana, Cañete de las Torres, Espejo, Hoyo de Manzanares, Teverga, Gorliz, Lekeitio and Plentzia. These are small municipalities with a mean population of 3,759 inhabitants.

^v In those models the dependent variable is a count variable (here, the number of times that an industrial establishment locates in a municipality).

^{vi} Obviously, working at a local level involves more observations than at the regional or national levels. The “problem” is the inbuilt restrictions of the econometric software concerning the maximum number of alternatives that can be estimated using a conditional logit model. Therefore, having more observations constitutes a major “problem”.

^{vii} One problem with this argument is how to choose the samples. Because an undetermined number of firms were not able to locate, we did not count them. All of these are counted as zero.

^{viii} See CAMERON and TRIVEDI (1998) for a detailed discussion as to how zero observations contribute to the likelihood function.

^{ix} The goodness-of-fit test divides the range of the data into intervals. Then, the number of points within each interval is compared to the expected number of points for that interval according to the hypothesized distribution of the data (here the hypothesis should have a Poisson distribution). Here we have used the deviance statistic (see CAMERON and TRIVEDI, 1998).

^x Alpha determines the degree of dispersion. Specifically, if $\alpha=0$, the Negative Binomial distribution is equivalent to a Poisson distribution (and there is no overdispersion).

^{xi} Measuring urbanisation economies at a local level is very common in the empirical literature. See, among others, ARAUZO (2005), ARAUZO and MANJÓN (2004), BARRIOS *et al.* (2006), COUGHLIN and SEGEV

1
2
3
4 (2000), DURANTON and PUGA (2000), FIGUEIREDO *et al.* (2002), GUIMARÃES *et al.* (2000) and
5
6 VILADECANS (2004).
7

8 ^{xii} N_{ij} is a count variable in which we have 0 and non negative values.
9

10 ^{xiii} See ARAUZO (2005) for a more detailed analysis.
11

12 ^{xiv} Nevertheless, empirical work about the incidence of the qualifications of the labour force usually shows
13
14 ambiguous results. For example, HOLL (2004b) finds both a (mainly) positive and a negative effect on firm
15
16 location depending on the industry analysed.
