## ABSTRACT

The paper applies a decomposition analysis to statistically account for the part played by demographic factors, in differential rates of employment, unemployment, inactivity and recorded sickness, across NUTS level 2 areas. Spatial variation in long-term sickness and disability cannot simply be attributed to prevailing population structures. One interpretation is that the success of supply-side policies could be constrained by the concentration of Incapacity Benefit claimants in demand-deficient areas.

6 ABSTRACT

7  
8 In diesem Beitrag wird eine Dekompositionsanalyse angewandt, um die Rolle  
9 von demografischen Faktoren für die unterschiedlichen Quoten von  
10 Beschäftigung, Arbeitslosigkeit, Inaktivität und Krankschreibungen in den  
11 Gebieten der Stufe NUTS 2 statistisch zu berücksichtigen. Räumliche  
12 Abweichungen bei langfristigen Krankheiten und Behinderungen können nicht  
13 einfach nur auf die vorherrschenden Bevölkerungsstrukturen zurückgeführt  
14 werden. Eine Interpretation lautet, dass der Erfolg von Politiken auf der  
15 Angebotsseite durch die Konzentration der Bezieher von  
16 Erwerbsunfähigkeitsleistungen auf Gebiete mit mangelnder Nachfrage  
17 beeinträchtigt werden könnte.

28 Dr. Allan Little

29 ABSTRACT

30  
31 En este artículo aplico un análisis de descomposición para explicar  
32 estadísticamente qué papel desempeñan los factores demográficos en las  
33 tasas diferenciales de empleo, desempleo, inactividad y enfermedad  
34 documentada en las áreas del nivel NUTS 2. La variación espacial en  
35 enfermedad e incapacidad a largo plazo no pueden atribuirse simplemente a  
36 las estructuras predominantes de la población. Una interpretación es que el  
37 éxito de las políticas de oferta podría estar limitado por la concentración de  
38 solicitantes de prestaciones sociales por incapacidad en áreas con  
39 deficiencias en la demanda.

## I INTRODUCTION

Formatted: Font: Not Bold

Formatted: Line spacing: Double

Inactivity and labour market detachment has increasingly become the focus of attention, in national and supranational policy debates (OECD, 2003; Clasen, Davidson, Ganßmann and Mauer, 2006). In light of the Lisbon Strategy and European Employment Strategy (EES), there has been growing recognition that an increase in labour force participation is a fundamental prerequisite to achieving the overall Lisbon employment objective (namely a 70 per cent employment rate).<sup>ii</sup> The revised EES has retained a priority to “reduce regional disparities in terms of employment” (European Commission, 2005a). The problems faced by those with long-standing health problems are also a common theme across the EU. Participation in the EU-25 is much lower for workers with an illness or disability (Dupre and K, 2003), and this group also spend the most time without work (European Commission, 2005b). Likewise Incapacity Benefit claimants are the primary target group in the UK Government’s Welfare-to-Work strategy and their long-term aspiration to reach an 80 percent employment rate.

In considering some of the salient statistics on economic inactivity, the European Commission (2005b) called into question the “commonly held view that ‘inactivity’ is exclusively a ‘supply-side’ problem and that active labour market policies are the only relevant option to mobilise the inactive workforce” (p.211). Hence they recommended a more comprehensive set of policies that combine active labour market policies with measures to support the creation of opportunities for the inactive. However, in the recent Command Paper, *A New Deal for Welfare: Empowering People to Work* (‘the Green Paper’; Department for Work and Pensions, 2006) it is clear that the

1  
2 Government favours a nationwide, supply-side strategy. The policy approach to  
3 spatial disparities in inactivity has been described as one of 'levelling-up' (O'Leary *et*  
4 *al.*, 2005). The guiding principle is that national initiatives, aimed at increasing  
5 participation among poorly performing demographic groups, will have a greater  
6 impact on areas with a higher concentration of disadvantaged individuals.  
7  
8  
9  
10  
11

12  
13  
14 With the Government's policy agenda in mind, the analytical framework adopted here  
15 is designed to assess the relative importance of 'people' and 'place' factors, in  
16 explaining spatial patterns of non-employment in Britain. A decomposition  
17 methodology is followed, in order to discern the extent to which regional disparities in  
18 employment, unemployment, inactivity and recorded sickness can be attributed to  
19 observable demographic differences on the one hand, and unobservable factors on the  
20 other. If the demographic component is large, this would support the case that a  
21 microeconomic, supply side strategy could be effective in tackling these regional  
22 imbalances.  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33

34 A handful of studies have sought to disentangle the demographic and non-  
35 demographic components of the spatial variation in registered unemployment  
36 (including Pissarides and Wadsworth, 1992; Fieldhouse, 1996; Brown and Sessions,  
37 1997). The present paper employs an Oaxaca-style decomposition, and extends the  
38 analysis to the inactive part of the labour market. In this respect, the forerunner to the  
39 present analysis is provided in a recent discussion paper by O'Leary, Murphy,  
40 Latreille, Blackaby and Sloane (2005). This paper decomposes the rates of  
41 employment, unemployment and inactivity at the broad regional level. In the present  
42 paper, we consider inactivity for reasons of long-term sickness and disability, as  
43  
44

48  
49  
50  
51  
52  
53  
54

1  
2 distinct from other forms of inactivity. Hence we treat the rate of ill health in the  
3 region as a labour market outcome, rather than an exogenous regional endowment.  
4 We also perform the decomposition for thirty-six NUTS level 2 areas - a lower level  
5 of disaggregation than the analysis reported in O'Leary *et al.* (2005). These two  
6 developments prove to be informative, with significant differences in the results  
7 within each broad region, and between the two inactive sub-states.  
8  
9

10  
11 The rest of the paper is organised as follows. Section II provides a selective review of  
12 the literature and outlines our motivation. Sections III and IV describe the data and  
13 decomposition method respectively. There follows a discussion of the results in  
14 Section V. Section VI provides a summary of the key policy implications, and Section  
15 VII summarises.

28 Spatial imbalances in non-employment are a cause for concern. Unemployment,  
29 whether overt or hidden, represents an under-utilisation of local labour resources.  
30 Joblessness is a major cause of low income and social exclusion (Goodman and  
31 Webb, 1994), and informs the way in which local areas see themselves, as either  
32 thriving or depressed (Beatty, Fothergill, Gore and Hetherington, 1997). In particular,  
33 long-term sickness or disability is thought to be one of the most important sources of  
34 'hidden unemployment' in the Britain (Fothergill, 2001). Yet, unlike the ILO  
35 unemployed, disability benefit claimants are much more disconnected from labour  
36 force and much less likely to return to work (Little, 2007).

1  
2  
3 | Cameron and Muellbauer (2004) commented that the “regional dispersion of  
4 employment rates remains a puzzle ... the puzzle deepens when we see that no  
5 comparable rise in the regional dispersion of unemployment rates took place” (p14).  
6  
7  
8 Regional unemployment disparities widened during the late 1980s (Nickell and Bell,  
9 1995) but have since returned to something like their “historic norms” (Dickens,  
10 Gregg, and Wadsworth, 2000). Indeed there has been further convergence in regional  
11 unemployment rates since the turn of the century. Britain’s highest unemployment  
12 rate in 2001 was the North East, but the unemployment rate here fell from 7.4 to 6.4  
13 percent of the working age population by 2005. In contrast, in the lowest  
14 unemployment region - the South East (excluding London) - the rate of  
15 unemployment rose from 3.0 to 3.7 percent (*Regional Trends*, 2006). Concomitantly,  
16 many commentators subscribed to the view expressed by Jackman and Savouri (1999)  
17 that “the regional problem is in essence a problem of unemployment” (p.32) and,  
18 given that “the traditional North-South unemployment divide has all but disappeared”  
19 (p.29), so has the regional problem. There has also been some convergence in  
20 employment and activity rates since 2000, around stable rates for Britain as a whole.  
21  
22 Yet considerable spatial disparities in joblessness remain, manifested largely in non-  
23 participation, particularly among those with health problems. This points to  
24 discrepancies in the scale of so-called hidden unemployment across spatial areas.

41  
42 | Webster (2000) noted that regional differentials in economic inactivity actually  
43 worsened in Britain during the 1990s. Moreover, the geographical dispersion of  
44 inactivity mirrors the pattern of unemployment. For instance, Gregg and Wadsworth  
45 (1998) reported that, on average, an additional percentage point on the regional  
46 unemployment rate is associated with an additional two percentage points on the rate  
47  
48

1  
2 of inactivity. In this context 'MacKay's law' states that the greater the degree of  
3  
4 labour market disadvantage, the less appropriate are the ILO and claimant  
5  
6 unemployment figures as a measure of labour market slack (Mackay, 1999).  
7

Deleted: ¶

8  
9  
10 From a policy perspective, a key analytical problem is that these differentials in the  
11  
12 incidence of hidden unemployment conflate two broad determinants. The first relates  
13  
14 to spatial differences in demographic profile. Individual non-employment risk varies  
15  
16 according to a range of personal, household and socio-economic characteristics (see,  
17  
18 for example, Pissarides and Wadsworth, 1992; Brown and Sessions, 1997; Little,  
19  
20 2007). Axiomatically, spatial variations in non-employment could, in part at least,  
21  
22 reflect a non-uniform geographical distribution of vulnerable workers. The second  
23  
24 explanation relates specifically to the regional dimension, above and beyond the  
25  
26 characteristic differences of the resident population. The underlying structure  
27  
28 governing the operation of each local labour market could determine individual labour  
29  
30 market outcomes.  
31

32  
33  
34 The predominance of either explanation has implications for the appropriate policy  
35  
36 response. In essence, a demographic explanation underpins current British labour  
37  
38 market policy. The Government has emphasised that the geographical dimension of  
39  
40 labour market disadvantage arises from the fact that "disadvantaged groups tend to be  
41  
42 concentrated in the most disadvantaged areas" (p.18; HM Treasury and the  
43  
44 Department for Work and Pensions, 2003). Specifically, the Government highlights  
45  
46 the following groups as being at higher risk of non-employment and concentrated in  
47  
48 poorly performing areas:  
49

- 50  
51 • Disabled people;

- Ethnic minorities;
- People aged over 50;
- People with low or no qualifications;
- People living in rented accommodation.
- Lone Parents

A purely demographic explanation would, however, ignore the historical context to spatial disparities in unemployment and inactivity, which is inexorably bound with the asymmetric effects of de-industrialisation across regions. Beatty and Fothergill (1996) reported that the rise in male inactivity represented the largest single adjustment to job losses in the UK coalfields and, moreover, the largest component of this rise in inactivity was accounted for by the incidence of recorded sickness. Similar adjustment processes have also been noted in Britain's cities (Turok and Edge, 1999) and depressed rural areas (Beatty and Fothergill, 1997).

The impact of de-industrialisation during the 1980s and 1990s remains relevant to the current spatial pattern of inactivity. Beatty *et al.* (2000) argued that the hidden unemployed (particularly older, male and ex-manufacturing workers) tend to fall to the back of the queue for jobs, and remain out of the labour market even when local economic conditions improve. Consequently, a high rate of inactivity can become locked-in to a local economy, even when the employment rate rises. Job creation in thriving industrial sectors has not provided an effective substitute for the disappearance of jobs in manufacturing and heavy industry, in terms of both "quantity and character" (Turok and Edge, 1999). Some empirical support for this view is provided in Little (2007), where the hidden unemployed were found to have a low

1  
2  
3 degree of attachment to the labour force in the period 1995 to 2004 - a period of rising  
4 employment rates.  
5

6  
7  
8 IB claimants may also choose to live in areas of low labour demand (and thus lower  
9 wages), because these areas are associated with lower living costs, although many  
10 benefit claimants are likely to have relatively little choice over where they live. Given  
11 that the level of IB payments is the same across regions, the real value of their income  
12 is thus higher in areas of low employment. Hence poor local economic performance  
13 could also serve to attract IB claimants from high employment areas.  
14  
15  
16  
17  
18  
19

20  
21  
22 Hence both demographic and regional factors are likely to be important in explaining  
23 spatial patterns of non-employment, but the relative weight attached to each of these  
24 explanations is an empirical issue. Empirical studies have sought answers for the  
25 British case. Pissarides and Wadsworth (1992) used LFS data for the period 1979 and  
26 1986 to estimate the extent to which regional unemployment differentials are due to  
27 differences in personal characteristics, the occupational distribution of employment,  
28 or 'unexplained' regional effects. They found that unemployment differentials are  
29 largely explained by observable factors, although there are significant regional effects  
30 in the North of England and Wales. Brown and Sessions (1997) followed the same  
31 methodology, using data from the British Social Attitudes Survey, for the period 1985  
32 to 1991.<sup>iii</sup> Controlling for demographic differences, they found that the risk of  
33 unemployment in the northern regions is high relative to the South East, whereas high  
34 unemployment in London and Scotland was largely attributable to demographics.

1  
2 unemployment are reported, having first accounted for demographic composition and  
3 geographical contextual effects (i.e. industrial and occupational structure). Fieldhouse  
4 reported that, other things being equal, unemployment risk was higher in Wales and  
5 the northern regions of England.  
6  
7  
8  
9

10  
11  
12 Policy makers have also identified that decomposition analyses can be informative in  
13 identifying the potential effectiveness of labour market policy. The *London Project*  
14 *Report* (Prime Minister's Strategy Unit, 2004), for instance, raised important  
15 questions about the underlying reasons for lower employment rates in the capital. This  
16 report proposed that further investigation into the impacts on employment rates was  
17 needed on two main areas, resulting from (1) the characteristics of London's  
18 population; and (2) the operation of the London labour market (*London Project*  
19 *Report*, 2004). Two policy papers followed this report from the Greater London  
20 Authority (Meadows, 2006) and the HM Treasury (HMT, 2006), both of which  
21 decompose London's employment rate. Explanatory factors in these papers cover age,  
22 gender, ethnicity, qualifications, health status and country of birth. The GLA found  
23 that approximately 90 per cent of the difference in employment rates between London  
24 and the rest of the country could be explained by the concentration of several of these  
25 factors in the London population. HM Treasury's findings were broadly in line with  
26 the GLA, but with some differences. For instance, they found that a compositional  
27 explanation could account for about 9 percentage points of the difference between  
28 Inner London and the rest for the UK. The remaining 2.3 percentage point difference  
29 was found to be statistically significant. In Outer London, by contrast, lower  
30 employment rates are entirely accounted for by the characteristics of Londoners.

In each of the studies cited above, the empirical analysis concentrates on either employment or the registered unemployed. A more recent paper by O'Leary *et al.* (2005) decomposed regional variation in all three standard ILO states: employment, unemployment, and inactivity. The decomposition was based on multinomial logit regressions, both including and omitting a control variable for the proportion of individuals with work-limiting health conditions. They found that variation in the rate of inactivity was largely accounted for by unobservable 'structural' factors, rather than compositional differences, but the relative importance of the compositional component rose when regional differences in ill-health were accounted for. The analysis presented here builds on the decomposition of the inactive presented in this discussion paper, at a lower level of spatial disaggregation.

Essentially, the approach adopted by O'Leary *et al.* (2005) treated the proportion of workers with health problems as a demographic endowment of each region. However, in the Labour Force Survey, from which O'Leary *et al.* (2005) derived their measure of ill health, individuals may answer questions on incapacitating conditions in such a way as to avoid contradiction with their employment or benefit status. Currie and Madrian (1999) reviewed studies of various self-rated measures of ill health, and argued that these measures are "not strongly correlated with underlying health as it affects labor market status" (p.3315). For instance, Parsons (1980, 1982) noted that the probability of reporting poor health rises with the potential Social Security benefit level. Sickles and Taubman (1986) found that changes in Social Security benefits and eligibility for transfers influenced self-rated health, as well as the probability of withdrawal from the workforce. In the UK, there has been a significant increase in the number of people *reporting* chronic illness or disability (Faggio and Nickell, 2003),

1  
2  
3 coinciding with the increase in sickness benefit claims but unlikely to be *caused* by  
4 deterioration in health. Health indicators derived from the LFS could therefore be  
5 skewed according to the number of sickness benefit claimants in each region.  
6  
7

8  
9  
10 Unlike O'Leary *et al.* (2005), the analysis in this paper does not rely on the  
11 assumption that the rate of ill health is exogenously determined. Instead, the approach  
12 adopted here allows spatial variations in recorded sickness to be endogenously  
13 determined, both by regional and demographic factors. Job losses, which in Britain  
14 have been spatially concentrated, fall disproportionately on workers who suffer from  
15 ill health (Beatty *et al.*, 2000). Heavy industries are also known to be damaging to  
16 worker's health, such that a higher proportion of displaced workers in traditional  
17 industrial regions were eligible for sickness and disability benefits (*ibid.*). A further  
18 link can be made between the rate of recorded sickness and regional socio-  
19 demographic composition, given that some characteristic groups are more likely to be  
20 in poor health

### 41 42 43 III DATA 44 45 46

47 We pool data from seven cohorts of the QLFS for Great Britain, covering the period  
48 from March 2003 to February 2005. The sample period is restricted by the availability  
49 of sub-regional identifiers, which are unavailable in earlier cohorts. The working-age  
50  
51  
52  
53  
54

Formatted: Font: Not Bold

1  
2 sample comprises 244,687 male and 248,158 female observations, who are not in full-  
3 time education. It should be noted that, by pooling the QLFS data in this way, some  
4 individuals contribute more than one observation to the sample. Using the pooled data  
5 has the benefit of boosting the sample, but it is important to test whether this panel  
6 element makes a significant difference to the results reported here. We thus replicate  
7 the analysis using a sample that is restricted to the first interview for each respondent.  
8 The decomposition results from this cross-sectional data are reported in the Appendix.  
9 The results are not markedly different.

10

12  
13  
14  
15  
16  
17  
18  
19  
20  
21 Future research could extend the type of analysis undertaken here by applying panel  
22 data methods, such as fixed or random effects. The advantage of the panel would lie  
23 in the ability to control for unobservable heterogeneity at the individual level. Multi-  
24 level modelling might also allow unobservable variation at several levels (e.g.  
25 individual, local area and broader regional levels) to be identified. The potential  
26 difficulty with this approach is that multinomial logistic regression with panel data,  
27 can prove to be computationally burdensome.

28  
29  
30  
31  
32  
33  
34  
35  
36  
37 We characterise the working-age population as belonging to four groups:

38  
39  
40  $j = 0$  employed (ILO definition);

41  
42  $j = 1$  unemployed (ILO definition);

43  
44  $j = 2$  recorded sickness - inactive due to long-term sickness or disability;

45  
46  
47  $j = 3$  other inactive - for reasons other than long-term sickness or disability.  
48

56  
57  
58  
59  
60

1  
2  
3 | The International Labour Organisation (ILO) definition of employment covers  
4 employees, the self-employed, unpaid family workers and those on government  
5 employment and training programmes. ILO unemployment refers to those who are (1)  
6 without a job, have actively sought work in the last 4 weeks and are available to start  
7 in the next 2 weeks; or (2) out of work, have found a job and are waiting to start in the  
8 next 2 weeks (Office for National Statistics, 2001). Those who do not meet the criteria  
9 above are classified as economically inactive ( $j = 2$  or  $j = 3$ ). Recorded sickness ( $j =$   
10 2) refers to respondents who give their main reason for being out of the labour market  
11 as long-term sickness or disability. Importantly, not all of the recorded sick left the  
12 labour market because of their health problems. Beatty and Fothergill (1999) reported  
13 that nearly half of the male long-term sick left their last job for reasons other than  
14 their health condition, with approximately one quarter having faced compulsory  
15 severance. The 'other inactive' state ( $j = 3$ ) encompasses a number of sub-groups and  
16 a substantial degree of behavioural heterogeneity (e.g. Gregg and Wadsworth, 1998;  
17 Little, 2007). The sample is not large enough to withstand further separation of  $j = 3$   
18 into sub-groups of inactivity, because the number of observations in the inactive states  
19 would be too small in some regions. The advantage in separating recorded sickness  
20 from other forms of inactivity arises from the special importance attached to the role  
21 of long-term sickness in concealing the real rate of unemployment.

37  
38  
39  
40

41  
42 | Sample employment rates in Britain are higher for males (83.3 percent) than females  
43 (74.4 percent), primarily because they are less likely to be inactive for reasons other  
44 than sickness (5.8 percent of males compared to 16.5 percent of females). Recorded  
45 sickness accounts for 6.5 percent of the male sample and 5.6 percent of females,  
46 which is higher than the respective proportions of unemployed males and females.

1  
2  
3  
4 Table 1 illustrates the geography of labour market disadvantage in Britain across  
5 standard regions and Nomenclature of Units for Territorial Statistics, level 2 areas  
6 (hereafter NUTS2). These thirty-six NUTS2 areas represent the lowest level of  
7 disaggregation available in the LFS. Sample sizes at NUTS2 range from 17,284 (the  
8 female sample in Outer London) to 1,555 (the male sample in the Highlands and  
9 Islands of Scotland). NUTS2 areas do not constitute local labour markets, which  
10 would be better represented by Travel-to-Work Areas. However, the NUTS2 level  
11 still represents a more fine-grained spatial level of analysis than that reported by  
12 O'Leary *et al.* (2005).

23  
24  
25 TABLE 1  
26  
27

28 Variation in employment is greater across NUTS2 than broadly defined regions.  
29  
30 Three regions (Wales; the North and North West of England) and eight NUTS2 areas  
31 have a male sickness rate in excess of eight percent. High sickness rates coincide with  
32 large urban centres (e.g. Merseyside) and areas that were in the past dominated by  
33 heavy industry (e.g. West Wales and the Valleys).  
34  
35  
36  
37  
38

39  
40 Spatial differences in employment are mirrored largely in the rates of inactivity and  
41 sickness, more so than unemployment. Standard deviation in the sickness rate across  
42 all NUTS2 areas (2.7 for males; 1.9 for females) is larger than the deviation in the  
43 unemployment rate (1.3 for males; 0.8 for females). This is confirmed by the  
44 coefficient of variation (standard deviation / mean x 100), which deflates the

FIGURE 1

Figure 1 illustrates the correlations between unemployment and recorded sickness. A significant correlation coefficient of 0.48 exists between male unemployment and sickness across NUTS2 areas, although the correlation is insignificant for females. There is, however, a statistically significant correlation coefficient of 0.59 between unemployment and 'other' inactivity for females. This is unsurprising, given that hidden unemployment among females includes those who are disqualified from unemployment benefits by virtue of their partner's earnings. In Table 2 we note that approximately three-quarters of these females are looking after the family or home, the majority of which express that they would not like to work.<sup>v</sup>

TABLE 2

Compositional differences between each labour market state are illustrated in Table 3. Recorded sickness ( $j = 2$ ) comprises a high proportion of individuals who are aged 50 or over (61.3 percent in the case of men and 50.4 for women), have no qualifications (43.6 percent for males and 48.6 percent for females) and are living in social housing (45.2 percent for males and 44.5 percent for females).<sup>vi</sup>

TABLE 3

## IV DECOMPOSITION METHOD

Formatted: Font: Not Bold

This section outlines the method used to decompose spatial differentials in labour market outcomes. First we estimate the following multinomial logit model, in order to determine the probability that individual  $i$  chooses labour market state  $j$ :

$$\Pr(Y_i = j) = \frac{\exp^{X_i \beta_j}}{\sum_{j=1}^m \exp^{X_i \beta_j}} \begin{cases} i = 1, 2, 3, \dots, N \\ j = 0, 1, 2, \dots, J \end{cases} \quad (1)$$

where  $X_i$  is a vector of covariates controlling for age, ethnicity, country of birth, education, marital status, housing tenure and time dummies. The covariates cover a key set of personal characteristics, expected to influence the risk of belonging to each labour market state.<sup>vii</sup> When averaged across spatial areas, differences in the mean values of the explanatory variables may explain differences in labour market outcomes.

We follow the decomposition method employed by Neumark (1988), Oaxaca and Ramsom (1994) and, more recently, by O'Leary *et al.* (2005). Estimates of equation (1) are used to obtain differences in the incidence of labour market outcome  $j$ , between region  $r$  and the rest of Britain (denoted by  $R$ ). These differences can be shown to be equal to:

$$\bar{I}_j^r - \bar{I}_j^R = \bar{P}_j^r(X_i^r \hat{\beta}^r) - \bar{P}_j^R(X_i^R \hat{\beta}^R) \quad \text{for } j = 0, 1, 2, \dots, J; \quad (2)$$

where  $\bar{I}_j^r = \frac{1}{n^r} \sum_i P_j^r(X_i^r \hat{\beta}^r) = \bar{P}_j^r(X_i^r \hat{\beta}^r)$ ;  $\bar{I}_j^R = \frac{1}{n^R} \sum_i P_j^R(X_i^R \hat{\beta}^R) = \bar{P}_j^R(X_i^R \hat{\beta}^R)$ .

$P_j^r(\cdot)$  is the predicted probability that individual  $i$  in region  $r$  occupies state  $j$ , based on the estimated coefficients from equation (1).  $\bar{P}_j^r(\cdot)$  is an average of  $P_j^r(\cdot)$  across the regional sample ( $n^r$ ), and is shown to be equivalent to the incidence of state  $j$  in region  $r$  ( $\bar{I}_j^r$ ). The incidence of state  $j$  in the rest of Britain is similarly defined.

Differences in the incidence of state  $j$  can also be shown to be equivalent to:

$$\bar{I}_j^r - \bar{I}_j^R = \left( \begin{aligned} & [\bar{P}_j^r(X_i^r \hat{\beta}^*) - \bar{P}_j^R(X_i^R \hat{\beta}^*)] + \\ & \{ [\bar{P}_j^r(X_i^r \hat{\beta}^r) - \bar{P}_j^r(X_i^r \hat{\beta}^*)] + [\bar{P}_j^R(X_i^R \hat{\beta}^*) - \bar{P}_j^R(X_i^R \hat{\beta}^R)] \} \end{aligned} \right) \quad (3)$$

for  $j = 0, 1, 2, \dots, J$ ;

where  $\hat{\beta}^*$  refers to the estimated coefficients for a pooled sample ( $n^r + n^R$ ). These baseline coefficients are taken to represent the hypothetical case in which the structure governing the labour markets in region  $r$  and the rest of Britain are identical (O'Leary *et al.*, 2005). Using the pooled model for Britain as the baseline structure also ensures that the point of reference for each regional decomposition is the same.

The first term in braces,  $\bar{P}_j^r(X_i^r \hat{\beta}^*) - \bar{P}_j^R(X_i^R \hat{\beta}^*)$ , gives the difference in the incidence of labour market state  $j$  that can be attributed to differences in the mean values of the explanatory variables. This component captures variation in labour market outcomes that can be explained by observable differences in composition.

The remainder of the difference, is due to differences in the coefficients. This reflects variation in the propensity of observably identical individuals to choose state  $j$  in region  $r$ . Elsewhere this has been taken to represent differences in the ‘underlying structure’ governing the labour market in region  $r$ , compared to the rest of Britain (O’Leary *et al.*, 2005). We are cautious in attaching the ‘structural’ tag to this component. Although the Oaxaca-style decomposition is well established there are limitations with this method. Most importantly, the structural component remains a black box. We rely on the assumption that the covariate set is sufficient to capture the demographic differences between spatial areas. However, we cannot rule out the possibility of omitted variable bias, such that the demographic component could be underestimated by the exclusion of additional variables. Strictly speaking, we should treat the observable component as an upper bound on the effect of characteristic composition. The LFS does provide us with a reasonably comprehensive covariate set, covering key personal characteristics found elsewhere in the decomposition literature. Nevertheless the non-demographic component is appropriately described as residual or unobservable.

In addition to the decomposition, we follow Even and Macpherson’s (1993) method to estimate the contribution made by changes in the mean value of each explanatory variable, thus unpacking the compositional component. The contribution made by the  $k^{\text{th}}$  characteristic is given by:

$$C_{jk} = [\bar{P}_j^r (X_i^r \hat{\beta}^*) - \bar{P}_j^{N_r} (X_i^R \hat{\beta}^*)] \left[ \frac{(\bar{X}_k^r - \bar{X}_k^R) \hat{\beta}_{jk}^*}{(\bar{X}^r - \bar{X}^R) \hat{\beta}_j^*} \right] \text{ for } j=0,1,2,\dots,J \quad (4)$$

where  $\bar{X}^r$  denotes a vector of mean values of the covariates for the sample in region  $r$ , and  $\bar{X}_k^r$  gives the mean for the  $k^{\text{th}}$  variable.  $\bar{X}^R$  and  $\bar{X}_k^R$  are similarly defined for the rest of Britain. Estimates of  $C_{jk}$  are only reported for the employment state ( $j = 0$ ), which summarises the total contribution of each variable across all three non-employment states ( $j = 1,2,3$ ).

## V RESULTS

### *The determinants of individual non-employment risk*

Table 4 reports the estimated coefficients, based on the multinomial model in equation (1). These coefficients are based on the pooled British sample, and correspond to the baseline structure ( $\hat{\beta}^*$ ) used in the decomposition for each NUTS2 area. The model was re-run on 36 sub-samples for each NUTS2 area ( $n^r$ ), in order to produce estimates of  $\hat{\beta}^r$ , and 36 sub-samples referring to the rest of Britain (to estimate  $\hat{\beta}^R$ ). The coefficients on these sub-samples are not reported for reasons of space. The coefficients for the rest of Britain are insensitive to changes in the sample, as each NUTS2 area is excluded. Marginal effects are reported in Table 4, evaluated at the mean values of the explanatory variables.<sup>viii</sup>

TABLE 4

The estimated coefficients on the risk of unemployment ( $j = 1$ ) are all reasonable and in line with the received literature (see, for example, Pissarides and Wadsworth, 1992; Fieldhouse, 1996; and Brown and Sessions, 1997). For males, the risk of

unemployment exhibits a U-shaped relationship with age, such that younger and older workers are at greatest risk. For females, the risk of unemployment is insignificantly different between prime age (35 to 49) and older workers (over 50). The probability of being inactive ( $j = 2, 3$ ) increases monotonically with age. For example, males (females) aged over 50 are 3.6 (2.8) percentage points more likely to be recorded sick/disabled ( $j = 2$ ) than equivalent individuals aged 35 to 49. This may be because of an increasing likelihood of developing health problems in older age, but could reflect a greater discouraged worker effect among older non-employed workers, if Incapacity Benefits are used as a stopgap prior to retirement.

The risk of belonging to each non-employment state ( $j = 1,2,3$ ) is higher for those with low or no qualifications and for social housing tenants. In the case of recorded sickness, this could reflect a correlation between low income and ill health. Alternatively, less qualified individuals, with poorer employment prospects may be more likely to drop out of the labour market, some onto Incapacity Benefits. The risk of non-employment is also higher for non-white workers. Being born outside of the UK is correlated with a higher risk of female inactivity for other reasons ( $j = 3$ ), but is associated with a slight reduction in the probability of being recorded sick ( $j = 2$ ) for both males and females. Marriage and dependent children are negatively correlated with the risk of recorded sickness/disability, for both males and females. In the male case, this is reflected in a higher probability of being employed, and may point to a pro-supply effect associated with familial responsibility. For females, on the other hand, the lower probability of sickness is mirrored by the greater likelihood of being out of the labour force for 'other' reasons (i.e. to look after the family and home).

*Decomposition analysis*

The results of the decomposition for each NUTS2 area are reported in the Tables 5 and 6, for males and females respectively. Estimates of the structural and compositional effects are given in terms of percentage points, the sum of which is the raw differential in the incidence of state  $j$ . To illustrate, consider the results in the first row of Table 5, relating to the male decomposition for Tees Valley and Durham. The raw differential in the male rate of employment between this area and the rest of Britain is  $-9.0$  percentage points. According to our decomposition,  $-1.6$  percentage points is accounted for by differences in the sample means across the vector of explanatory variables (the 'compositional' component). The remaining  $-7.5$  percentage points of the differential are therefore attributed to differences in the coefficients; that is, unobservable differences between Tees Valley and Durham and the rest of Britain. The rate of long-term sickness or disability ( $j = 2$ ) is  $5.4$  percentage points higher in this area, the majority of which remains unexplained ( $4.3$  percentage points). Similar results are reported for females in Table 6. One might infer that poorer demographic characteristics help to explain labour market outcomes in Tees Valley and Durham, but other factors predominate.

## TABLE 5 AND 6

Although we will return to some of the more striking results for specific areas, we first provide a summary analysis of all 36 decompositions. In Table 7, we report the standard deviations and the minimum and maximum values for each component of the decompositions. Table 7 suggests that, across all 36 decompositions, we can explain approximately half of the variation in NUTS2 unemployment rates by differences in

the characteristics of the population. In contrast, the compositional component accounts for just less than one third of the dispersion of recorded sickness. Observable characteristics are more prevalent in accounting for spatial variation in female employment than male employment, primarily because there is greater variation in the compositional component of the 'other inactive' sub-state. This is because observable characteristics - such as marital status, dependent children and educational attainment - are more likely to determine withdrawal from the labour market to look after the family or home. In the far right-hand column in Table 7, we report the standard deviations from the decomposition analysis using the cross-sectional sample, where only the first observation for each individual is included. This confirms that the summary result across all 36 decompositions is almost identical for the pooled and cross-sectional samples.

TABLE 7

Figures 3 and 4 illustrate the relative weight of the compositional and residual components of the employment and recorded sickness differentials by representing these two components on the x-axis and y-axis respectively. Figure 3 exposes one distinct outlier - namely Inner London - where the compositional component is large. This case is discussed further below. We take some comfort in this result because it suggests that our model is capable of capturing a strong compositional component, at least where one exists. If one of the key limitations of the methodology is that the interpretation of the decomposition is tempered by the potential for omitted variable biases, this outlier suggests that our observables do a reasonably good job of controlling for key demographics.

## FIGURES 3 AND 4

It is also important to note that most NUTS2 areas are located in either the top right, or bottom left quadrants in Figures 3 and 4, implying that areas with (un)favourable structural factors also have (un)favourable compositional effects. One explanation could relate to the adjustment process following job losses. Low employment areas are subject to selective out-migration, such that workers with more favourable personal characteristics (e.g. highly educated workers) are more likely gravitate away from under-performing labour markets. Differences in population structure could therefore emerge, partly as a consequence of local labour market performance. Whilst we consider the decomposition to be an informative technique, it is beyond the scope of this type of analysis to add to our understanding of the dynamics of the relationship between regional structure and demographic changes.

Figure 4 shows that, across Britain as a whole, spatial imbalances in recorded sickness cannot simply be explained by spatial concentrations of poorly performing demographic groups - a structural explanation may be pertinent. The argument put forward in the literature (e.g. Beatty and Fothergill, 2005), that high rates of sickness are largely a consequence industrial restructuring, fits not only with the geography of male sickness, but also the strength of the residual component in explaining these regional differences. In this respect, it is interesting to compare this residual components, with Beatty *et al.*'s (2007) estimates the spatial pattern of the 'real level unemployment'. They estimate the extent to which the JSA claimant count understates additional ILO unemployment and hidden unemployment on IB. The

1  
2 mapping of hidden unemployment in their paper is in keeping with the pattern of the  
3 residual components in the decomposition, with the highest rates of hidden  
4 unemployment amongst IB claims being found in the Welsh Valleys, Clydeside,  
5 Merseyside and the industrial North East. Whereas the present paper controls for  
6 demographic composition, Beatty *et al.* (2007) control for the level of IB considered  
7 plausible in each district, benchmarked against districts that are close to full  
8 employment, and also accounting for differences in underlying health between these  
9 districts. When evidence from these two analytical approaches is taken together, this  
10 might suggest that the high rates of recorded sickness in these areas predominantly  
11 reflect a higher incidence of hidden unemployment, which cannot be attributed to  
12 demographic composition.  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23

24  
25  
26 Unobservable variation in female sickness is less easily explained by the diversion of  
27 ex-industrial workers onto IB, given that job losses in the heavy industries fell  
28 predominantly on males. However, save for a few occupations, both male and female  
29 workers compete for the same jobs, and an increase in the stock of non-employed men  
30 implies that females also face tighter local labour markets. Male and female labour  
31 markets may have become less segmented with the rising concentration of  
32 employment in the service sector, and the declining share in manufacturing and  
33 skilled, manual employment. Some descriptive evidence in support of this view is  
34 provided by significant correlation coefficients between the rate of *female* sickness  
35 and the rates of *male* unemployment and inactivity. For instance, the correlation  
36 coefficient between female recorded sickness and male unemployment is 0.5 in our  
37 data.

The strength of the structural component also sits comfortably with the view that recorded sickness is highest in regions with the greatest demand deficiency. Turok and Edge (1999) reported that the 'jobs gap' was greatest in Merseyside, Manchester and Clydeside, which may underpin the unobservable components of sickness in these areas. In contrast, some areas of the North of England, Scotland and Wales fair well compared with the rest of Britain. For example, although West Wales and the Valleys suffer from the highest rate of sickness in Britain (due to unobservable factors), the sickness rate in East Wales is below the British average (due to a favourable demographic composition). Whereas West Wales provide a classic example of a region that suffered disproportionately from job losses during the 1980s and 1990s, due to a greater reliance on heavy industry, Turok and Edge (1999) found that Cardiff experienced the steadiest economic growth relative to most other British cities. This also demonstrates the advantage of an analysis at the NUTS2 level, compared to the standard regional level where Wales is treated as a single region.

As illustrated in Figure 3, the demographic component is strongest in Inner London, accounting for a 6.4 percentage point reduction in the rate of employment for males, and 10.4 percentage point reduction for females (Tables 5 and 6). This broadly supports the decompositions performed on London's employment rate reported elsewhere in the literature (e.g. Prime Minister's Strategy Unit, 2004; Meadows, 2006; and HM Treasury, 2006). Indeed, for males in Inner London, the 'London effect' may well be positive, given that the results suggest that the employment rate in Inner London would be 1.07 percentage points *higher* than the rest of Britain, if the observable characteristics were equivalent in both areas. In contrast to previous decomposition analyses of the capital, we specifically investigate the rate of recorded

1  
2 sickness and disability ( $j=2$ ) amongst the working age population. Although the rate  
3 of sickness in Inner London is roughly average for Britain, this masks that the  
4 predicted rate of sickness, on the basis observable demographic differences, is in  
5 excess of the rest of Britain by 2.1 percentage points for males and 1.5 for females. It  
6  
7  
8  
9  
10 is to these demographic influences to which our attention now turns.

11  
12  
13  
14  
15 *Unpacking the compositional component*

Formatted: Font: Not Bold

16 The contribution of each explanatory variable to the compositional component is  
17 reported in Table 8, based on estimates of equation (4). These are reported for the four  
18 NUTS2 areas where the compositional component has the strongest negative effect on  
19 the rate of employment - i.e. areas with the poorest demographic profile.  
20  
21  
22  
23  
24

25  
26 TABLES 8  
27  
28  
29

30 The proportion of non-white male workers in Inner London is 25.8 percent higher  
31 than the rest of Britain, and this alone is estimated to account for 1.8 percentage  
32 points of the male employment differential. Similarly, the proportion of non-white  
33 females in the sample is 31.8 percent higher in Inner London accounting for a  
34 reduction in the rate of employment by 3.5 percentage points. Note that the proportion  
35 of workers born outside of the UK is also much higher in Inner London, and accounts  
36 for 1.6 percentage points of the lower rate of female employment, but the effect on  
37 male employment rate is negligible.  
38  
39  
40  
41  
42  
43  
44  
45  
46

47  
48 A higher percentage of non-whites in the West Midlands (by 11.4 percent for males  
49 and 11.8 percent for females) also accounts for a significant part of the low  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2 employment rate in this area - a reduction in the rate of employment of 0.8 percentage  
3  
4 points for males and 1.2 percentage points for females. With the exception of Inner  
5  
6 London, the areas reported in Table 8 all have poor educational attainment relative to  
7  
8 the national average.  
9

10  
11  
12 Social housing emerges as a key compositional factor in Table 8. For example, the  
13  
14 proportion of male tenants in council or other association housing is 17.4 percentage  
15  
16 points higher in Inner London, and 6.3 percentage points higher in Northumberland  
17  
18 and Tyne and Wear, accounting respectively for an additional 3.1 and 1.1 percentage  
19  
20 points on the male non-employment rate.  
21

22  
23  
24 The housing system segregates the most disadvantaged members of society into small  
25  
26 pockets (Lee, 1994). Although our other variables control for differences in these  
27  
28 disadvantageous characteristics, a high proportion of residents in social housing may  
29  
30 therefore capture additional effects arising from social dislocation in Britain's inner  
31  
32 cities and deprived estates.  
33

34  
35  
36 The nature of the housing benefit system may play a role. Housing benefit and council  
37  
38 tax benefit is based on earnings and household circumstances, such that the amount  
39  
40 received is significantly lower when individuals move into (even low-wage)  
41  
42 employment. HM Treasury (2006) has noted that national policies, intended to raise  
43  
44 the financial gain to work, may have been less effective in London because housing  
45  
46 costs and the costs of working are higher. Hills (2007) report that the rationing system  
47  
48 for social housing 'screens in' those with greatest need and, moreover, those in social  
49  
50 housing suffer an additional employment disadvantage, over and above what might be

expected given their other characteristics. Amongst other explanations put forward by Hills (2007), he highlights (1) the disincentive to work resulting from subsidised rents; (2) residential immobility; and (3) local ‘neighbourhood effects’ such as amenities, transport infrastructure and peer effects. However, it is not possible in our regression to identify the causality of the relationship. This makes it difficult to interpret the reasons why the proportion of working-age population in social housing is important, beyond suggesting that it is a carrier of some additional labour market vulnerability.

## VI DISCUSSION AND POLICY IMPLICATIONS

Formatted: Font: Not Bold

The aim of the empirical analysis is to assess the extent to which the current policy approach is likely to be effective in tackling the substantial geographical imbalances in both recorded and ‘hidden’ unemployment. The limitations of our analysis – particularly that the unobservable component of spatial dispersion in labour market outcomes remains a black box – mean that the potential policy implications are discussed tentatively.

In delivering ‘full employment in every region’, the Government has explicitly stated that, “a lack of jobs is not the problem” (p.22; HM Treasury and Department of Work and Pensions, 2003). The rationale underpinning this statement is the notion that promoting greater labour demand is fruitless, if local residents are unable to successfully compete for new vacancies. In London, where the demographic component of our decomposition is strong, this may well be the case. HM Treasury (2006) have expressed the view that, although London has a high ratio of jobs to

1  
2 residents, the economic benefits of the capital's resurgence may not have been shared  
3  
4 evenly by some groups of the resident population. London excels in high-value added,  
5  
6 largely service sector activities, but there is a mismatch between the demand for high-  
7  
8 skilled workers and the skills possessed by inner-city residents.  
9

10  
11  
12 The decomposition of London's employment rate is treated in greater detail elsewhere  
13  
14 (*London Project Report*, 2004; Meadows, 2006; and HMT, 2006), whereas the main  
15  
16 contribution of the present analysis is in decomposing the pattern of long-term  
17  
18 sickness and disability across British sub-regions. The decompositions identified that  
19  
20 demographic differences accounted for only a small fraction of spatial variation in  
21  
22 recorded sickness. The strength of the residual component may point to either a  
23  
24 shortfall or mismatch between demand and supply as the root cause of uneven spatial  
25  
26 patterns in recorded sickness.  
27

28  
29  
30 This view finds some support in more descriptive survey evidence. Goldstone and  
31  
32 Douglas (2003), for instance, reported that 63 per cent of the IB claimants who were  
33  
34 interviewed in their study stated that an insufficient number of suitable local job  
35  
36 opportunities were a barrier to gaining employment. This figure outweighed the  
37  
38 number who stated that their main barrier was that they would not be able to work  
39  
40 regularly (50 per cent of the sample).  
41

42  
43  
44 A lack of suitable employment opportunities in under-performing areas could  
45  
46 therefore inhibit the success of the Government's supply-side initiatives. This being  
47  
48 the case, increasing labour supply among individuals with health problems may only  
49  
50 serve to shift the balance back from Incapacity Benefit to Jobseekers Allowance,  
51  
52  
53  
54

rather than increasing the rate of employment. The effect could be a re-emergence of regional unemployment differentials or, more accurately, these differentials would become more overt and less 'hidden'. Given the ambitious aspiration to reduce the Incapacity Benefit caseload by one million by 2016, perhaps greater consideration should be paid to the constraints imposed on this target by the concentration of recorded sickness in less buoyant labour markets.

	<u>Unexplained</u>	<u>1.6</u>	<u>0.1</u>	<u>-4.3</u>	<u>3.4</u>	<u>1.6</u>

Note: Figures show the standard deviation, minimum and maximum values for the unobservable and composition components, based on all 36 decompositions at the NUTS2 level.

' $\sigma$  (c-s data)' refers to the standard deviation from the decompositions using purely cross-sectional data, and is shown for comparison. It is based on the first observation in the survey for each individual. See Appendix for details of the cross-sectional decomposition results on each NUTS2 area.

Note: The contribution of cohort variables is negligible and these figure have been suppressed.  $X^f - X^R$  refers to the difference in the sample proportions between region  $r$  and the rest of Britain.  $C_{jk}$  is an estimate of the contribution of variable  $k$  to the raw difference in the incidence of outcome  $j$ .

<sup>i</sup> The author would like to thank the ESRC for financial support (award no. R42200134309) and gratefully acknowledges helpful comments made by Professor Geraint Johnes, Professor Steve Bradley, Professor Jim Taylor and Professor David Blackaby. The LFS data were kindly made available through the UK Data Archive.

<sup>ii</sup> Reflected in the Report of the Employment Taskforce (chaired by Wim Kok, 2003), and the Integrated Guidelines for Growth and Jobs (2005-2008).

<sup>iii</sup> Both Pissarides and Wadsworth (1992) and Brown and Sessions (1997) performed a logistic regression to individual risk of unemployment, and decompose differences between region  $j$  and the South East of England. The differentials attributable to regional effects are found by assuming that individuals are identical across regions.

<sup>iv</sup> For instance, Amable, Demmou and Gatti (2006) considered the impact of institutions on inactivity across 18 OECD countries. Clasen *et al.* (2006) compares the impact of changes in welfare institutions in the UK and Germany. Brandolini, Cipollone, and Viviano (2004) used the European Community Household Panel to identify a spectrum of labour market attachment by estimating transition probabilities across inactive sub-states.

<sup>v</sup> A correlation between unemployment and inactivity at the NUTS2 level has also been reported across the EU-25 (European Commission, 2005b), with an R-square of 0.27 for the group of countries with an unemployment rate below 15%.

<sup>vi</sup> Social housing refers to tenants in council accommodation or who rent from other housing associations.

<sup>vii</sup> Controls for occupational skill are omitted because information on previous occupation is not available for individuals who have either never worked, or not worked in the last eight years. Educational attainment is likely to act as a proxy for the effects of occupational skill.

<sup>viii</sup> Raw coefficients are not available for the reference state,  $j = 0$  (employment). The base group in the regression refers to individuals who are aged 35 to 49, white, born in the UK, with no qualifications, single, homeowners, and were interviewed in Summer 2005.
