We demonstrate the active wavefront control of a 19-core ytterbium-doped fiber amplifier by the digital holography technique. The output wavefront is corrected even in the presence of large externally induced perturbations, with a measured output Strehl ratio of 0.6 in all cases. The wavefront-controlled multicore fiber is used to amplify 800 ps pulses at 1064 nm at a repetition rate of 40 kHz, and a gain of 23 dB is obtained.   © 2010 Optical Society of America

Fiber lasers have attracted significant interest because of their advantages in terms of efficiency, compactness, reliability, and thermal behavior. However, in the pulsed regime, the output power of such devices is limited by nonlinear effects and material damage. Increasing the effective area of the beam propagating inside the fiber is desirable, but this technique is limited because of multimode issues and beam degradation for large transverse dimensions. A widely studied alternative is the coherent combination of fiber lasers or amplifiers [1,2]. To increase considerably the effective area, a large number of emitters is needed, but the system becomes more complex and more sensitive to misalignments between the emitters, and a high fill-factor is difficult to maintain, resulting in a decrease of the energy in the central lobe of the far field. An interesting alternative is to apply this concept to an integrated architecture, such as multimode or multicore fibers.

In multimode fibers, the technique consists in locking the modes propagating inside the fiber in phase at the output of the fiber. Wavefront control by digital holography [3] has been recently demonstrated in a passive fiber supporting few modes [4]. However, the use of a multimode fiber with this technique is limited for two reasons. First, it is difficult to fabricate highly multimode polarization-maintaining (PM) structures. Second, the gain in the fiber and the velocity group dispersion are mode dependent, and the phase-conjugation system cannot compensate for this. For these reasons, it is interesting to study another structure that is less gain dependent and that can be PM with a high effective area.

In this sense, multicore fibers (MCFs) are very promising in terms of effective area, and can be PM. Another advantage is that the emitters are all mechanically and thermally strongly coupled, which make the system less sensitive to global phase variations [5]. The use of Yb-doped MCFs has been demonstrated in several laser configurations [6]. Fundamental mode operation of a 19-core MCF amplifier has also been demonstrated [7] without wavefront control. However, this operating regime depends strongly on the injection conditions. It is therefore in-

teresting to investigate alternative methods using wavefront control.

In this Letter, we demonstrate the wavefront control of a 19-core Yb-doped MCF amplifier using a digital holography technique. This technique relies on the use of the phase-conjugated −1-order of diffraction of a dynamic holographic diffraction pattern recorded on a liquid-crystal-on-silicon spatial light modulator (SLM) (resolution 1920 × 1080 and frame rate 60 Hz). The architecture, along with technical details of the experimental setup, have been described in our previous work in the context of large-mode-area (LMA) fibers [4]. The cores of the fiber used in this work have a diameter of 7 μm and a pitch of 11 μm, which makes them evanescently coupled. As a consequence, the global fiber structure supports several modes, called supermodes. Although the fiber is not PM, the depolarization measured over 5 m is very low: a linear polarization can be experimentally recovered at the output of the fiber with a quarter-wave plate. A polarization extinction ratio of 93% is measured, even when the fiber is pumped. The experimental setup is shown in Fig. 1. A laser source at 1064 nm is separated into probe and reference beams. The probe beam is coupled to the MCF. The fiber is pumped by a 26 W fiber coupled laser diode emitting at 976 nm. The CCD 1 images the distorted beam at the output MCF facet and makes it interfere with the reference beam. The pattern is displayed continuously on the SLM at a frame rate of 12 Hz

(limited by our camera), creating a dynamic holographic diffraction pattern. A fraction of the reference beam with an intensity lower than the damage threshold of the SLM (2 W/cm^2) is sent to the modulator via the PBS and is diffracted to create the phase conjugate of the object beam, the seed pulse. The diffraction efficiency (in the -1-order) is about 10%. The seed is coupled into the fiber, and while it propagates back through it, the spatial phase distortion due to the propagation in the fiber is compensated by the SLM-induced phase conjugation. At the output of the fiber, a corrected beam (in dotted lines) with a plane wavefront is obtained and analyzed on CCD 2.

The hologram recorded on CCD 1 gives access to the spatial phase of the object beam. We recorded three holograms with no pump power, 12 W, and 26 W pump power (Fig. 2). Two phase vortices can be seen on the holograms. This shows that the wavefront of the object beam is not flat, and consequently that it differs from the fundamental supermode of the MCF: the probe beam at the output is composed of several supermodes that interfere, leading to this complex phase profile. In addition, it can be seen that the three holograms are identical, which indicates that there is no self-organization of the object beam due to the presence of gain. This shows that an external control of the wavefront of the beam exiting the fiber is necessary.

To verify that we were able to generate a corrected beam with a plane wavefront, we first used a longitudinally single-mode Nd:YAG cw laser. Its narrow spectral linewidth (<1 kHz) allows interference between the output corrected beam and the reference beam with a plane wavefront on CCD 2 without delay line. Figure 3(a) shows the interference pattern when the active wavefront correction is working. The interference fringes are all parallel and equally spaced, indicating that the output beam has a plane wavefront. The spatial phase of the output beam can be degraded by turning off the active correction and applying a pressure on the fiber. This modifies the relative phase between the cores inside the fiber and the beam is no longer corrected. The effect is shown on Fig. 3(b). A strong phase distortion appears on the corrected beam, leading to the creation of phase vortices. When the active correction is turned on again, the interference pattern switches back to its original profile [Fig. 3(c)] without phase vortex. An advantage of digital holography is that no wavefront reconstruction is needed, since it is automatically performed by the holographic diffraction pattern. This allows the correction of complex phase distortion such as phase

vortices.

As the limitations of fiber amplifiers mainly arise with high peak powers, it is important to demonstrate the feasibility of digital holography in the pulsed regime. This experiment was performed with 800 ps pulses at a repetition rate of 40 kHz at 1064 nm. In this temporal regime, the group-delay dispersion between supermodes is low compared to the pulse duration and does not affect the phase correction. We checked the efficiency of the wavefront correction by observing simultaneously the near field and the far field of the corrected beam, and by evaluating the Strehl ratio (SR). The SR is evaluated on the far field. A theoretical far field is evaluated by calculating the Fourier transform of the square root of the near-field intensity, therefore assuming that all the cores are in phase. This theoretical far field is compared to the measured far field and the SR is deduced (Fig. 4). With active correction, we measured an SR of 65%. Without applying a pressure to the fiber, the SR drops down to 29%, and when the correction is turned on again, SR increases up to 59%. The measured gain inside the fiber is shown in Fig. 5. We obtain a gain of 23 dB at maximum pump power, corresponding to an average output power of 170 mW. The far-field and near-field intensity profiles are shown versus different pump power: it is clear that the phase correction works over the whole pump

range. The near field shows that the corrected beam is slightly off center compared to the central core of the fiber and differs from the fundamental supermode of the fiber. Indeed, the corrected beam exits the fiber with the same characteristics as the probe beam, which means that in our case, the probe beam was not perfectly centered on the central core. However, this is not important for the quality of the corrected beam, as it can be seen on the far field that the beam remains Gaussian.

Like all phase-conjugation methods, the digital holography technique cannot compensate for mode-dependent gain or loss inside the fiber. For multimode fibers, it is well known that the gain depends on the mode structure propagating inside the fiber [8]. This makes the digital holography technique difficult for multimode fiber amplifiers. Since we demonstrated that this technique works in MCF even with high gain (23 dB), this indicates the low dependence of the gain with respect to the supermode structure and also the absence of self-organization in MCF amplifiers. This can be understood by noting that, unlike in multimode fibers, both the gain and the supermodes are strongly located in the single-mode doped core areas that have very similar profiles and gain. Therefore, the overlap integral between modes and gain-providing areas does not vary much

from supermode to supermode.

In conclusion, we demonstrated wavefront control by digital holography in a 19-core ytterbium doped fiber amplifier in cw and pulsed regimes. Self-organization in the fundamental supermode was not observed, and wavefront correction was demonstrated with a gain up to 23 dB. Our system shows efficient correction of complex phase defects such as phase vortices: the SR was increased by a factor of 2. The effective area of the MCF is directly proportional to the number of cores and can be scaled easily. Our technique can be used for noncoupled MCF, which can be PM, and thus provides an alternative way to scale the energy of pulsed fiber systems.
