Abstract:

We report here on the production of nitrogen doped carbon using the hydrothermal carbonization process of nitrogen containing carbohydrates under mild carbonization temperatures. The resulting materials contain significant amounts of nitrogen in their composition and display a high degree of aromatisation. The nitrogen contents are also maintained after further calcination at higher temperatures. All the resulting materials have been characterized using X-Ray Photoelectron Spectroscopy (XPS), solid state ^{15}N and ^{13}C-NMR, elemental chemical analysis, nitrogen adsorption, Scanning (SEM) and Transmission Electron Microscopies (TEM). Finally, the nitrogen-doped materials proved to possess superior electronic conductivity to their nitrogen free counterparts.

1. Introduction

Carbon materials have found a large number of applications in different domains ranging from environmental science [1-3], to drug delivery [4-6] and energy storage [7], according to their structural, morphological and chemical properties [8]. Nevertheless, for some specific applications, functionalization [9-13] is required.

The properties of carbon materials depend to a large extent on the raw material, surface structure and porosity, but also heteroatoms built into their structure exert large effects on physicochemical properties of carbons. Recently, nitrogen-containing carbons attracted particular interest due to their improved performance in applications such as

CO_2 sequestration [14], removals of contaminants from gas and liquid phases [15], environmental protection [16], catalysts and catalysts supports [17], or in electrochemistry as supercapacitors [13, 18], cells and batteries [19].

The methods for the production of such materials rely normally on very harsh and multistep processes, which involve high temperature production of carbon materials [20] followed by introduction of nitrogen into the structure using ammonia, amines or urea [21, 22]. Nitrogen-containing carbons have been also more readily prepared using precursors like acetonitrile, pyrrole or polyacrylonitrile [23, 24]. However, these precursors are less sustainable and available, as compared with carbohydrates or other The problem of sustainable synthesis of nanostructures carbon materials was recently revisited and implemented by several research teams [25-31], where hydrothermal treatment of biomass in water under relatively mild conditions and, in some cases, in presence of additives like metal salts yielded bulk, mesoporous, or nanostructured carbon materials [32-46]. Although this technique was already known since 1913, [47] the need of exploring cheap and sustainable ways to obtain chemicals [48] and carbons from raw materials other than crude oil or natural gas lead to a re-exploration of this field. In addition, the implementation of a low-cost pathway to recycle byproducts of farmed biomass would additionally represent a way to sequester significant amounts of CO_2 [27], and at the same time a material benefit would also be created.

Here we present a green and sustainable alternative to produce nitrogen rich carbonaceous materials which is based on the hydrothermal carbonization of nitrogen-containing carbohydrates such as chitosan or glucosamine.

2. Experimental Part

2.1 *Materials and Synthesis*

All the chemicals are purchased from Sigma-Aldrich and used without further purification. Chitosan (medium molecular weight) and D(+)-glucosamine hydrochloride (>99.0%, HPLC) are the chosen biomass-derived nitrogen-containing carbohydrates . Nitrogen-doped carbons are synthesized as follows: 2 g carbohydrate and 18g deionized water were mixed together, then the mixture was sealed into a glass vial inside a PTFE inlets autoclave followed by hydrothermal treatment at 180 °C overnight. After the reaction, the autoclave was cooled down in a cold water bath, then the obtained black solid powder was filtered and washed with distilled water for several times. Finally, the materials were placed into a vacuum oven at 80 °C overnight for drying. The hydrothermal nitrogen-containing carbons were named as HC-Chitosan (HC-CH) and HC-Glucosamine (HC-GA). Afterwards, in order to improve the level of structural order, further high temperature treatment was performed in an oven under N_2 flow at three different temperatures. The calcined samples are referred to HC-CH-750 and HC-GA-750 (where750 °C in the temperature for further calcination under a N_2 stream). To compare, non-nitrogen containing carbons from D(+)-glucose were synthesized the same way as nitrogen doped carbon. These sample were denominated as HC-Glucose (HC-G), and HC-G-750 Isotopic enrichment for sold state ^{15}N NMR was accomplished using 1 wt% of ^{15}N-labelled glucosamine (from CortecNet).

2.2 *Characterization methods*

The products were characterized by elemental analysis (EA) using a Vario El elemental analyzer. X-ray Diffraction (XRD) patterns were recorded in reflection mode (CuKa radiation) on a Bruker D8 diffractometer oven the 2θ range of 2-80 °. Scanning Electron Microscopy (SEM) images were acquired on a LEO 1550/LEO GmbH Oberkochen provided with an Everhard Thornley secondary electron and In-lens detectors. Transmission Electron Microscopy (TEM) was performed on a Zeiss EM 912 Instrument equipped with CCD camera and a filament of LaB_6 under a 120 kV tension (Carl Zeiss, Oberkochen, Germany). Nitrogen adsorption and desorption isotherms were measured at 77 K with a Quadrachrome Adsorption Instrument. The Brunaer–Emmett-Teller (BET) and DFT methods were used for the surface area determination and pore size distribution calculation. Conductivity measurements were performed by I-V method with a Gamry Ref 600 Potentiostat/Galvanostat/ZRA.

Surface charge analysis-- Zeta Potential measurements were realized on a Malvern Nano ZS instrument. Carbon powders were dispersed and stirred in 0.03M NaCl solution at different pH values (0.03M HCl and NaOH were used to adjust pH values) for two days at 25 °C to reach equilibrium. Due to the heterogeous nature of the samples, in order to avoid immediate pollution of the electrodes, all solutions were filtered by PTFE 5µm disposable filters. Disposable clear zeta cells (DTS1060c) were used to determine the zeta potential. Gas Chromatography (GC) was coupled to Mass Spectroscopy (MS) to separate and identify the main molecular species by mean of the NIST database included

in the spectrometer software package. The instrument used is an Agilent Technologies (GC= 6890N; MS= 5975) apparatus

The composition of the powder was investigated by XPS. XPS spectra were run on a Perkin-Elmer 5600ci spectrometer using standard Al radiation (1486.6 eV) working at 350 W. The working pressure was $< 5 \cdot 10^{-8}$ Pa. The spectrometer was calibrated by assuming the binding energy (BE) of the $Au4f_{7/2}$ line at 83.9 eV with respect to the Fermi level. The standard deviation for the BE values was 0.15 eV. The reported BE were corrected for the charging effects, assigning, in the outer layers where contamination carbon is still present, to the C1s line of carbon the BE value of 284.6 eV [49, 50]. Survey scans (187.85 pass energy, 1 eV/step, 25 ms per step) were obtained in the 0-1300 eV range. Detailed scans (58.7 eV pass energy, 0.1 eV/step, 100-150 ms per step) were recorded for the O1s, C1s, N1s regions. The atomic composition, after a Shirley type background subtraction [51] was evaluated using sensivity factors supplied by Perkin-Elmer [50]. Samples were introduced directly, by a fast entry lock system, into the XPS analytical chamber. The assignments of the peaks was carried out by using the values reported in the [50], in the NIST XPS Database [52] and in the references reported in the text.

^{13}C and ^{15}N solid-state MAS NMR experiments have been acquired on a Bruker Avance III 300 MHz (7.0 T), 400 MHz (9.4 T), 500 MHz (11.7 T) and 700 MHz (16.4 T) spectrometers. All ^{13}C spectra have been acquired on the 7.0 T and 9.4 T spectrometers with a 4 mm zirconia rotor as sample holder spinning at MAS rate $\nu_{MAS}= 14$ kHz. The chemical shift reference for ^{13}C was tetramethylsilane (TMS; $\delta= 0$ ppm) while the

reported ^{15}N chemical shifts are referenced to labeled glycine at -348 ppm on the nitromethane scale (CH_3NO_2 at zero ppm).

^{13}C spectra were all recorded under Cross-Polarization (CP) conditions (cross polarization time is 3 s), reycle delay is 3 s and TPPM decoupling scheme is applied during signal acquisition. Number of transient is 1200 (HC-CH, HC-CH-T, HC-GA,), 2400 (HC-GA-T), 65 (pure GA), 64 (pure CH). Proton nutation (90°) frequencies were 5.40 μs and 2.32 μs, respectively, on the 9.4 T and 7.0 T spectrometers.

One pulse ^{15}N spectrum was acquired on the 11.7 T spectrometer with a 7 mm rotor (ν_{MAS}= 5 kHz) and an antiring pulse programme (ARING) with a 90° pulse angle. ^{15}N nutation frequencies are 9.50 μs (90°) and 4.25 μs (45°) with respective recycle delays of 30 and 60 s. Number of transients is 9339 (recycle delay= 30 s) and 15000 (recycle delay= 60 s). ^{15}N CP-MAS was performed on the 16.4 T spectrometer with a 3.2 mm rotor (ν_{MAS}= 22 kHz), 3.47 μs 90° proton pulse, number of transient is 50971, recycle delay is 3s and spinal-64 decoupling pulse scheme is applied during signal acquisition.

3. Results and Discussion

3.1 *Morphology and Composition*

Hydrothermal carbonization of glucose and other carbohydrates has been previously described [29], leading to carbonaceous materials [31] with applications in fields such as catalysis [53], electrochemistry [54, 55] or adsorption [56]. This approach is extended

here to the production of nitrogen doped carbon materials with chitosan (sample code HC-CH) or glucosamine (sample code HC-GA) as starting products. As-synthesized and further calcined (T= 750°C) nitrogen containing samples were compared with the nitrogen-free ones, as discussed below.

Fig. 1 - Scanning and transmission electron micrographs of the nitrogen doped carbons obtained upon hydrothermal carbonization of a,d) chitosan (HC-CH); b,e) glucosamine (HC-GA)
G).

Fig. 1 shows the morphology of some hydrothermally carbonized samples. It is observed that the morphology of nitrogen containing samples is very different from the reference case of pure glucose, where hard spherical particles of ~400-500 nm diameter (SEM, Fig 1c) without inner texture (TEM, Fig 1f) are obtained [39]. In the case of chitosan no spherical particles but a continuous network of small intercalated spheres are found, displaying a monolithic structure with an interstitial macroporosity. This can be also observed from the TEM picture in Fig. 1d which shows some intercalated, irregularly shaped spheres with a diameter of about 50 nm. Similarly, upon hydrothermal carbonization of glucosamine (Fig 1 b), a compact network formed of agglomerated smaller particles has been obtained. This is clearer when looking at the TEM micrographs (Fig.1e) which reveal again such morphology with interstitial porosity. The morphology of the samples does not change after further heat treatment. Some electron micrographs

of the samples treated at higher temperatures are shown in Fig. S 2-supporting

information, while the pure precursors, before any heat treatment, are shown in Fig. S 1

Nitrogen adsorption-desorption experiments isotherms (Fig. S 3 in supp. mater.) for

nitrogen-containing HC show that the amount of adsorbed gas is very low (BET specific

surface areas are lower than 10 m^2/g), and no specific porosity is actually detected.

Isotherms show the typical behaviour of interparticle adsorption, suggesting that the

microstructure of the material is formed of aggregated particles, in complete agreement

with TEM analysis. Lack of developed porosity is generally associated with these

materials[57] some exceptions exist for few specific cases, in which a more developed

porosity can be achieved in the absence of an external porogen by forming monoliths

from starch [33] or by reducing to the nanoscale the size of the aggregated particles[58].

Upon further carbonization some more micropores are developing, and there is a slight

increase in the surface areas up to ~30-50 m^2/ g in all materials due to an increase in

microporosity.

Some interesting results come from the elemental analysis of pure and carbonized

samples (Table 1). It is found that, after hydrothermal carbonization, the chitosan-derived

(HC-CH) material has a carbon content of 59 w%, lower than the one obtained for HC-

GA and HC (about 65 w%). Glucosamine and glucose-derived carbons contain instead

about 65 w% C (Table 1). The amount of nitrogen is as high as 9 w% in HC-CH sample

and ~6.8 w% in HC-GA sample. Upon hydrothermal carbonization the carbon content for

all the samples obviously increases, which is mainly due to the loss of oxygen and

hydrogen in the dehydration process of the saccharides, while the amount of nitrogen is

actually maintained constant, thus evidencing that no specific mechanism leading to the elimination of nitrogen takes place. This is interesting as it implies that nitrogen is stored in stable bonds; volatile aminated compounds, if produced, react further with the carbonaceous scaffold, as previously reported [59-61]. After further high temperature carbonization, the carbon content increases up to 89%, as expected, while the nitrogen content stays virtually constant (Table 1). This suggests that indeed nitrogen is incorporated within the carbon matrix upon hydrothermal carbonization and that, upon further heat treatment, it can actually be incorporated in the graphitization process of the carbon structure.

Table 1 -Weight percentages of the carbon-based materials as obtained by elemental analysis and XPS.

Material	%C	%N	C/N	%C	%N	C/N
	From chemical analysis			From XPS		
P-Glu	40.0	0	-			
P-CH	32.8	9.4	3.5			
P-GA	33.4	6.5	5.1			
HC-G	66.6					
HC-G-750	89.6					
HC-CH	56.2	8.9	6.3	72.5	5.2	13.9
HC-CH-750	79.2	9.1	8.8	87.7	7.7	11.4
HC-GA	66.6	6.7	9.9	79.9	5.6	14.3
HC-GA-750	81.6	6.6	12.4	90.5	6.3	14.4

3.2 *Bulk analysis*

Solid state NMR revealed to be a powerful technique to study the structure of hydrothermal carbons, which was mainly resolved as a 3D cross-linked network of furan rings. Here, ^{13}C and ^{15}N NMR are used to characterize the structure of amino-derived carbons both after hydrothermally treatment and after further calcination at 750 °C. Unfortunately, the low natural isotopic abundance of ^{15}N (0.32%) and the lack of a (affordable) ^{15}N source prevents us from performing ^{15}N NMR experiments with good signal-to-noise ratios. ^{15}N CP MAS experiments at natural abundance (0.36%) did not provide any signal in a reasonable amount of time (60h), and for this reason, we were forced to apply weak isotopic enrichment using 1 w% of N15-labeled glucosamine. One-pulse experiments are much more time-consuming but have the advantage of providing a full insight of all nitrogen species while CP experiments are time-saving but only provide information on nitrogen atoms with a nearby protonated environment. According to both one pulse and CP experiments, two distinct nitrogen families of comparable amount exist in the HC-GA sample. The main peak at -243 ppm (Fig. 2) indicates the existence of protonated C-NH-C groups, either in the pyrrole-like or amide forms [63, 64]. Interestingly, the presence of free amino groups (-300 ppm $< \delta <$ -400 ppm) derived from glucosamine seems to be highly reduced or even disappeared, as suggested by the arguable low intensity peak at -350 ppm. Given the low signal-to-noise ratio, one-pulse experiments do not provide any quantitative answer; nevertheless, one can safely state that primary amines have massively reacted. Fig. 2 shows two one-pulse experiments which have been acquired at two different values of recycling delay, RD= 30s and 60s. With respect to CP-MAS, the one pulse experiment at RD= 30s (solid grey line) shows

the presence of a signal in the 200 ppm region, whose intensity is comparable with the signal at 243 ppm. The 200 ppm signal indicates the presence of additional de-protonated amide groups inside the carbonaceous scaffold. Moreover, the same one-pulse experiment at longer recycling delays (RD= 60s, black dotted line) shows a broad hump between -78 and -200 ppm [63, 64]; this is the fingerprint of conjugated, pyridine-like, C-N=C aromatic networks. Due to the probably very long spin-network relaxation times of nitrogen in all these chemical species, longer RD should be used to recover their full signal; which was however result in extremely long, difficult to realize, N15 experiments.

Several literature reports exist on the degradation mechanisms of GA in water at high temperatures [59-61], and in most cases, they agree on the fact that glucosamine dehydrates into hydroxymethyl furfural (HMF), which is also the major transformation product of glucose dehydration under the same conditions [65-68], and release of ammonia in solution. Then, NH_3 readily reacts with HMF to form several type of N-containing molecules [60, 61]. In general, pyrrole-like [60] or pyridine and pyrazine [60, 61] compounds are described but the possibility to form amide bonds exist [59]. Interestingly, in many cases, the furanic moiety is kept throughout the process, and it is substituted by nitrogen at different positions. The ^{15}N experiments presented above on the HC-GA sample indicate a large amount of protonated, substituted pyrrole-like molecules or amide bonds. Aromatic C-N=C compounds, even if their identification is a difficult task, are also formed. We believe that several mechanisms may take place to transform glucosamine into N-carbon. The preferred mechanism of formation of HC-GA should pass through the production of ammonia and its reaction with HMF or similar furanic compounds. Considered the lower amount of aromatic amines, the mechanism leading to

aromatic amines (e.g., dimerization of two glucosamine moieties, as proposed by Jun et al. [61]) does not abundantly take place here. ^{13}C NMR data shown below suggest a strong aromaticity for HC-GA with respect to HC-G, supporting the idea that aromatic amines are distributed throughout the material.

Fig. 2 – ^{15}N CP-MAS and one-pulse experiments performed on the HC-GA sample. N15 enrichment was necessary. RD= Recycle Delay.

^{13}C CP MAS NMR was performed on all amino-derived samples, and the results are as shown in Fig. 3. As a matter of comparison, we report the typical spectrum of a pure hydrothermal carbon from glucose (HC-G) in Fig. 3-B. A crude attribution can be done as follows: δ = 10-50 ppm: aliphatic CH_x groups; δ= 100-150: aromatic range, mainly dominated by the furanic ring (sp2 β-carbons resonate between 100-130 ppm while oxygenated α-carbons resonate between 130-150 ppm). Only less than 6% of total

carbons are involved in a pure graphite-like structure (peak at 130 ppm). Peaks at 175 and 210 ppm belong to the different carbonyl groups. When thermal treatment at 750 °C is applied, the corresponding spectrum (A) shows a single main peak between 125-130 ppm, with a clear loss of all aliphatic and carbonyl groups and the furanic doublet. This behaviour is rather typical for a strong graphitization of the material.

Fig. 3 – ^{13}C CP-MAS experiments performed on the pure precursors, the hydrothermally treated and carbonized (750°C) samples.

Some changes in the ^{13}C CP MAS behaviour are found when using gluosamine as the

direct nitrogen-containing source for HC, (HC-GA, Fig. 3-D). If aliphatic and carbonyl regions do not show major changes, the amount of COOH groups at 175 ppm seem to have relatively decreased or, at least, the peak seem to be broader. This behaviour is indicative for the reaction of the carboxylic species. The aromatic region (100-150 ppm), on the contrary, shows a single, main contribution between 125-130 ppm, suggesting occurrence of the graphitization already throughout the hydrothermal treatment. Secondary peaks due to furanes at 150 and 110 ppm can also be identified. These data show that the structure of the GA-derived carbons is far from being similar to the one of the glucose-derived hydrothermal carbons, with HC-GA having strong N-heterocyclic aromaticity while having only a weak contribution from furanic moieties.

Calcination at 750 °C (sample HC-GA-750) provides the general effect found for all hydrothermal carbons: loss of all aliphatic and carbonyl peaks while intensification of the peak between 125-130 ppm suggests a wide graphitization of the carbon samples. Residual presence of a shoulder peak in the 150 ppm area is still sign of oxygenated and/or aminated sp2 carbons. When comparing the ^{13}C NMR spectra of the glucosamine-based HC-GA materials (Fig. 3 spectrum D) with a pure glucosamine sample (Fig. 3 spectra E), it is quite evident that almost the whole amount of the amino-sugar has reacted, as its peaks between 50 and 75 ppm have disappeared. On the contrary, the chitosan-derived HC materials (figure 5, spectrum G) still possesses strong signals.

Therefore, the ^{13}C solid state CPMAS NMR analysis shows that the hydrothermal treatment of aminated sugars enhances the carbonization process towards more aromatic carbons with extended graphitic domains already throughout hydrothermal treatment at

180°C, while the differently aminated chitosan results in lower carbonizaiton efficiencies along the traditional reaction scheme. These data also nicely mirror the elemental analysis results.

3.3 *Surface analysis*

Surface properties of the carbonaceous materials were characterized with XPS and ζ-potential measurements. XPS analysis was performed on the pure starting precursors, on the hydrothermally treated samples and on the carbonized samples. Detailed spectra were collected for the three ??? regions of interest (N1s in Fig. 4 and C1s in Fig. S 4). from which the atomic percentages of the two elements could be calculated (reported in Table 1). As it can be evidenced by comparing the atomic percentage values obtained by XPS with those calculated from the weight percentages delivered by elemental analysis, the amounts of carbon detected by XPS is systematically higher that those calculated starting from the experimental weight percentages obtained by elemental analysis. Noooooo, this is brutally wrong. XPS is by no means a quantitative technique, as the spectra a folded with a so-calles exit work functions, means: you only see conducting, wave function localized parts of the sample, which are not representative. I hope Niki added this sentence, as I have hoped to have you educated differently. ☺

This shows that the surface of the material is rather oxygen-poor if compared to its bulk. As we previously discussed, the core structure of hydrothermal carbon powders is mainly composed of furan rings interconnected via aliphatic bridges. Zeta-potential data, showing a negative surface charge for HC-G (see Fig. 5 below), combined to quantitative ^{13}C solid-state NMR experiments [62], displaying a low amount of COOH

groups (< 10 % with respect to carbon atom), allow us to say that, most likely, the only oxygen source at the material surface is constituted by carboxylic groups. Again crude bullshit, erase…

Remarkably, atomic percentage values for nitrogen are high for all samples and, in agreement with elemental analysis, their values increase with increasing thermal treatment. On the contrary, upon heating, the discrepancy in carbon amount between chemical and XPS analysis is drastically reduced. Yes, of course, see my words above… This information, coupled to the disappearance of the carbonyl peaks with temperature as shown by ^{13}C solid state NMR experiments (Fig. 3), confirms the picture of a carboxy-rich surface.
Wipe out…

Fig. 4 – N1s signals of the pure, hydrothermally treated and calcined glucosamine (GA) and chitosan (CH) samples. The values in the abscissa are not corrected for charging effects. Refer to discussion in the text or to Table 1 for corrected values. ??

what does this mean, leftover??

The XPS spectra for the chitosan series are shown together with a deconvolution of the C1s and N1s peaks in Fig. S 4 and Fig. 4, respectively. The values for the binding energies together with their assessments are presented in

Table S 1 in the supplementary material. In the case of pure chitosan, according to references reported in literature[69], three different carbon components could be identified: the more intense one, at 286.1 eV, was ascribed to carbon bonded to –OH and/or OR groups, whereas the component at lower BE (284.6 eV) was assigned to aliphatic carbon/adventitious carbon; the one at higher BE (287.9 eV) is attributed to C-O-C moieties. After the hydrothermal carbonization, the band at 284.6 eV corresponding to the sp^3 hybridized carbon is still present meaning in this sample, as previously shown by ^{13}C-solid state NMR experiments (see Fig. 3). After further carbonization at higher temperatures, major changes in the structure are visible. First of all, a decrease in oxygen content and an increase in the C/N ratio is observed. Secondly the sample derived from chitosan treated at 750°C shows only a C1s component at 285.1 eV meaning almost all the oxygenated functionalities were removed from the sample, in agreement with elemental analysis and ^{13}C solid state NMR. The same trend could be observed also in the glucosamine-derived sample. This component at 285.1 eV corresponds to a predominantly sp^2 hybridized aromatic system (reference value 284.8-285.0 eV).

Concerning the N1s peak (Fig. 4), the pure chitosan sample shows only one component which according to the binding energy value (399.3 eV) corresponds to the

primary amine group, as expected. After hydrothermal carbonization the binding energy shifts from 399.3 to 402.1 eV, thus suggesting that the amino group has undergone a chemical reaction leading to the formation of quaternary N in aromatic graphene structure. [21, 71, 72] Upon even further heat treatment at higher temperature (750°C), the N1s region could be fitted with two components, with very different positions with respect to the untreated samples: a more intense one at 400.5 and a less intense at 398.0 eV, with an intensity ratio of about 4:1. Whereas the former component was ascribed to a tertiary N in aromatic graphene structure[21, 71], the second one has a value which is typical of that reported for pyridinic (aromatic) nitrogen [72].

A similar trend can be observed in the case of glucosamine precursor. The C1s spectra of the pure precursors show the presence of three components of C-H, of C-OH and C-O-C bonds which are also partly maintained after the hydrothermal carbonization. Clear differences between the pure precursors and the hydrothermal carbonized materials do not appear to be significant in XPS. From ^{13}C solid state NMR experiments (Fig. 3), we know that glucosamine has gone under full reaction after hydrothermal treatment; this means that the carbon species detected by XPS do not belong to the glucosamine molecule but rather to CH and C-O-C groups derived from the carbonization process and largely described in [62]. Well, a weak part of the discussion as these data contradict themselves. You clearly cannot write it like that, but Silvia will certainly correct.

Upon further calcination of the HC material under nitrogen, we again find only one component for the C1s corresponding to an aromatic system with only very little oxygenated functionality.

In both chitosan- and glucosamine-based samples, upon hydrothermal treatment, although the different components of C1s can be observed, but their intensity ratios changes, and an increase of the aromatic/aliphatic part can be observed with respect to the pure precursors. As far as pure glucosamine is concerned, the N1s region contains two components, at 399.3 and 400.2 eV, corresponding to amine and to protonated amine groups (the starting product is an acidified glucosamine). In the case of HC-GA, the N1s peak shows two components at 399.3 and 401.3 eV, respectively. The former can be ascribed to pyridinic nitrogen, the latter to quaternary N in condensed polyaromatic structure, in agreement with what observed by NMR. Upon further carbonization at 750°C, two components at 398.1 eV and 400.8 eV, ascribed to amide [73] and to a ternary N in aromatic graphene structure, respectively, could be observed. XPS data confirm ^{15}N NMR experiments (Fig. 2) showing that nitrogen is incorporated into the core of a more aromatized system.

What is this part good for, except repeating everything ?? If there is nothing new, just cross out, as you simple do not explain things twice in a line. I think this is a parallel leftover..

The structural study performed so far by electron microscopy, XPS and NMR suggest an altered growth under hydrothermal treatment of amino-group containing carbohydrates. We have shown that the mechanism of transformation of glucose into carbon-like materials under hydrothermal conditions involves the dehydration of glucose to hydroxymethyfurfural (HMF) in the first step, followed by the polymerization and aromatization of the latter to produce the carbonaceous material[29, 74]. In the case of

amino containing carbohydrates, the transformation process is much more complex, as we previously discussed. In addition, Maillard-type reactions (very well known in food chemistry [73, 75]) between HMF (containing an aldehyde group) and the amine may also take place and lead towards nitrogen-containing heterocycles. This scenario is also supported by the GS-MS spectra of the liquid phase obtained upon hydrothermal carbonization of chitosan and glucosamine (data not shown), which shows only small traces of HMF in comparison with pure glucose, but shows indeed nitrogen containing heterocycles which are not detected in the case of pure glucose. In addition, consumption of amine groups is also clear from CP-MAS ^{15}N solid state NMR spectra of HC-GA (Fig. 3). And again: what is this good for. Again a summary or conclusion within the discussion. If yes, either cross out completely or move to the Conclusion

Zeta-potential experiments as a function of pH on aqueous dispersions of the samples (Fig. 5) can help to further characterize the nitrogen functions. The as-synthesized HC-CH and HC-GA hydrothermal powders (Fig. 5 a) clearly show positive zeta-potentials below pH~ 5-6, indicating the existence of positively charged, accessible amino groups at the particle's surface with values up to 30 mV at pH 2.5. These data are coherent with XPS analysis, which have showed that roughly 6% of nitrogen sites at the material surface, and ^{15}N NMR data, which have shown the presence of protonated pyrrolic sites. On the contrary, pure hydrothermal carbon (HC) from glucose shows no positive zeta-potential value in the whole examined range, as previously described [58]. Analyzing the effects of calcination on the zeta-potential (Fig. 5b), it is found that the positive character is clearly diminished by the temperature treatment. A nearby explanation in agreement

with XPS nitrogenated functions is that the nitrogen is now incorporated into the aromatic carbon system and therefore has a much less basic in character.

Fig. 5 - Zeta- potential experiments of (a) HC-G, HC-CH and HC-GA; (b) HC-G-750, HC-CH-750 and HC-GA-750.

XRD measurements on the prepared samples show one single broad reflection for the HC-GA and HC-GA-350 while a second one at a doubled 2-theta value (arrghh, again one of those mistakes: the is not a second order reflection but the in plane organization of graphite..) **Change** starts to appear for samples treated at 550°C and above. This demonstrates that at low temperatures, the sample has an amorphous structure whose order improves towards a lamellar phase with increasing the temperature (Fig. 6). In addition, the width of the (002) and (100) reflections at, respectively, $2\theta= 24°$ and $48°$, typical for interlayer stacking, decreases with increasing the temperature, showing that long-range order improves. Thus, only a very broad peak at $2\theta= 25$ is found after hydrothermal carbonization, while the reflection at 45° corresponding to the (100) order of graphite cannot be observed in this sample

This is fucking wrong, and it was correct in the original version. I am sick of correcting always the same shit put back in the paper….

Fig. 6 - XRD profiles of the carbons obtained from glucosamine at different temperatures.

As stated above, nitrogen doped carbons are interesting materials due to their improved performance. Like other carbon nanostructures such as carbon nanotubes, hydrothermal carbon's electronic band structure was also probably significant influenced by nitrogen doping[62]. Therefore, conductivity measurements of samples after further carbonization at 750 °C were undertaken. Results shown in Table 3 that nitrogen doped hydrothermal carbon based on chitosan and glucosamine, show an improved electronic conductivity with respect to the glucose based carbon.

Table 3. Conductivities of HC-G-750, HC-CH-750 and HC-GA-750.

Sample	HC-G-750	HC-CH-750	HC-GA-750
Conductivity (S/m)	80.3 ± 10.5	100.3 ± 19.5	103.7 ± 9.7

4. Conclusion

We have demonstrated that it is possible to synthesize nitrogen containing carbonaceous materials by using hydrothermal treatment at 180 °C of amino containing carbohydrates. Besides being green, cheap and sustainable, this process has the advantage to introduce nitrogen dopants into the carbonaceous scaffold, which are known to be very favorable for catalysis, adsorption, or energy storage devices Various characterization methods (nitrogen adsorption-desorption, TEM, SEM, XPS, ^{13}C-solid state NMR, XRD, zeta potential and elemental analysis) were used to describe the resulting carbon structures. Temperature treatments showed that all materials retain the nitrogen content almost unchanged up to 750 °C. Maybe one of the most important benefit of the nitrogen dopant is the fact that we can increase spontaneous aromatization already at 180°C in a hydrothermal treatment

The beneficial properties were exemplified by the conductivity measurements where an increase of the direct current conductivity was found for the nitrogen containing materials

Last but not least, the whole synthetic process occurs in an energy and atom-saving fashion from cheap and sustainable resources, as employed temperatures in the first step remain below 200 °C, and neither metals nor surfactants have been used to catalyze and control the reaction.

We are presently investigating the performance of such nitrogen containing carbon materials in fields such CO_2 sequestration, supercapacitors as well as catalysts. The preliminary results are very promising especially in the filed of selective CO_2 sequestration showing such easy produced materials could be of major importance.
