Abstract

For high amplitudes of vibrations, loudspeakers are subject to nonlinear phenomena that are responsible for audible distortions. In order to describe the complex dynamics of the system, the displacement field as well as the radiated sound pressure must be expressed in the time-domain. Thus the present study proposes a transient model of the acoustic radiation of axisymmetric structures. The pressure field is approximated by the Rayleigh integral corresponding to a monopole source distribution over the non-planar vibrating surface. The displacement field is expanded on the linear modes of the structure and a change of variables in the Rayleigh integral is then proposed in the case of a monotonic profile function to compute the Spatial Impulse Response associated to each mode of vibration efficiently. The results are compared to the formulation obtained in the case of planar and spherical sources. The method of calculation is then derived in the case of a typical loudspeaker profile (association of a truncated cone with a spherical cap). Finally, the present approach is used to estimate the nonlinear radiation pattern of a prototype loudspeaker and predictions are compared to measurements in anechoic room.

Key words: loudspeaker, nonlinear vibrations, transient, radiation, Rayleigh

1 INTRODUCTION

1 The aim of an electrodynamic loudspeaker is to transform an electrical sig-
2 nal into sound. Such a transduction is expected to be linear. However, for
3 high levels of vibrations, nonlinear phenomena appear and are responsible
4 for audible distortions. The various sources of nonlinearities can be separated
5 into two parts [1,2]: “electrical” nonlinearities due to the large displacement
6 of the coil in the permanent magnet, and “mechanical” nonlinearities due to
7 large displacements of the moving parts of the system (geometrical nonlineari-
8 ties). In order to describe the complex dynamics of the system subjected to
9 large amplitude motion, the displacement field must be expressed in the time-
10 domain. In that case, a common way to compute the transient displacement
11 field is to expand the transverse displacement of the structure onto the linear
12 modes. This method has received much attention in the literature in the case
13 of circular sources [3], axisymmetric sources [4] and recently in the case of
14 loudspeaker like-structure [5] but none of the cited studies include the acous-
15 tic radiation of the structure. In order to compute the acoustic field radiated
16 by thin structures subjected to large amplitude motion, the present article
17 proposes a transient model of acoustic radiation that takes advantage of the
18 modal expansion.

19 Transient acoustic radiation of planar sources vibrating in an infinite planar
20 baffle has received much attention in the literature. The Rayleigh surface in-
21 tegral is in that case an exact expression for predicting the acoustic pressure
22 produced by such sources at any observation point. An extensive review of the
23 various approaches which have been used to evaluate this radiation integral
24 has been given by Harris[6]. The most common way to compute the transient

25 radiation from such sources is to evaluate the so-called Spatial Impulse Re-
26 sponse (S.I.R.) as described by Stepanishen [7]. This formulation has been
27 developed initially in the case of an uniform velocity for a circular source, and
28 has then been extended to handle the case of nonuniform velocity patterns
29 [8,9] using a modal expansion of the displacement field.

30 For nonplanar sources, the Rayleigh surface integral is no longer valid, since
31 diffraction effects appear. An analytical formulation of the transient radiation
32 of a body of arbitrary shape has been derived by Hu and Wu [10,11], who
33 expressed the acoustic pressure as a sum of integrations of simple and doublet
34 source distributions and their couplings induced by the normal and tangential
35 components of the particle velocity. Under that consideration, the Rayleigh
36 integral represents the first term of this decomposition. This approximation is
37 commonly used to compute transient radiation of spherical radiators [12–16],
38 but the range of validity (in terms of geometrical configuration and wavenum-
39 ber) is rarely specified.

40 Only the case of spherical sources has been treated and only few studies con-
41 cern the acoustic radiation of axisymmetric sources. Farn [17] proposed a
42 numerical method based on source-density method (approximation of the ra-
43 diating surface by triangular surface elements) and Guyomar [18] used series
44 expansion of the source velocity spatial distribution. More recently, Stepan-
45 ishien [19] adapted a mean-square error method to predict harmonic radiation
46 of bodies of arbitrary shape but the radiation of transients remains a problem.

47 Other numerical approaches using retarded potentials combined to boundary
48 elements in the time domain have can also be found in the literature [20,21]
49 and give appropriate results but calculation costs remain a problem.

50 In the present study, a time-domain formulation is adopted to predict the
51 modal sound radiation from axisymmetric sources with a nonuniform vibra-

52 tory distribution. The pressure field is approximated by the Rayleigh integral
 53 corresponding to a monopole source distribution over the nonplanar vibrating
 54 surface. The diffraction effects are neglected in the present approach and let for
 55 future work. The displacement field is expanded onto the linear modes of the
 56 structure and a change of variables in the Rayleigh integral is proposed in the
 57 case of a monotonic profile function to compute the Spatial Impulse Response
 58 associated to each mode of vibration efficiently. The results are compared to
 59 the exact formulation obtained in the case of planar sources [6] and to numer-
 60 ical results obtained by Suzuki and Tichy [22,23] with the spherical harmonics
 61 method in the case of spherical radiators. The method of calculation is then
 62 derived in the case of a typical loudspeaker profile (association of a truncated
 63 cone with a spherical cap). Finally, the present approach is used to estimate
 64 the nonlinear radiation pattern of a prototype loudspeaker and predictions are
 65 compared to measurements in anechoic room.

66 2 TIME-DOMAIN RADIATION

67 2.1 Geometry of the problem

68 In the present study, attention is paid to the acoustic radiation of a baffled
 69 axisymmetric body S as represented in Fig. 1. Let a denote the external radius,
 70 $h_0(r)$ the axisymmetric profile function of the considered structure and h_{max}
 71 its depth (defined as the maximum of the profile function). The profile function
 72 only depends on the radial coordinate r since S is assumed axisymmetric. For
 73 the same reason, the observation point \mathbf{x} depends on two coordinates (y, z) in
 74 the Cartesian space only. The profile function $h_0(r)$ is called monotonic if its

Fig. 1. Geometry of the considered structure. The points \mathbf{x} and \mathbf{x}_s represent the receiver and an integration point on the structure respectively. The profile function is denoted by $h_0(r)$ and corresponds to the projection in the plane $z = 0$ of the u_z coordinate of the point \mathbf{x}_s .

75 derivative $\dot{h}_0(r)$ has a constant sign and called non-monotonic otherwise. A
 76 concave structure refers to a negative profile function $h_0(r) < 0$ while a convex
 77 structure relates to a positive profile function. In the following equations, \mathbf{x}_s
 78 denotes a point of the structure with cylindrical coordinates $(r, \theta, h_0(r))$.

79 2.2 Nonlinear vibration of loudspeaker-like structures

Previous studies [2,5] mention that the nonlinear vibrations of loudspeaker-like structure can be modeled using a nonlinear lumped parameters model coupled with a nonlinear model of the diaphragm vibrations. This formulation allows to include typical electrical nonlinearities that appear in the low frequencies domain but also geometrical nonlinearities that appear around mechanical resonances of the structure. The approach is based on an axisymmetric modal decomposition of the displacement field of the structure:

$$w(r, t) = \sum_{p=0}^{\infty} \Phi_p(r) q_p(t). \quad (1)$$

where the functions $\Phi_p(r)$ in Eq. (1) represent the modal shapes (that can be either measured or calculated) and the functions $q_p(t)$ represent the time function associated to mode p . Using a state-space formulation of the nonlinear electromechanical problem[2], one obtains:

$$\dot{Y} = \mathbf{A}Y + B(Y)u(t) + NL_e(Y) + NL_g(Y) \quad (2)$$

80 where Y is the state vector (time functions $q_p(t)$ and their first derivative
81 $\dot{q}_p(t)$), A denotes the linear dynamics of the problem, B the excitation vec-
82 tor, $u(t)$ the input signal, $NL_e(Y)$ and $NL_g(Y)$ contain respectively all the
83 electrical, mechanical and geometrical nonlinear terms of the electromechan-
84 ical transduction. Eq. (2) is solved numerically using the fixed point method
85 and Runge-Kutta algorithms, so that the global displacement field is obtained
86 from the calculation of the state vector Y using modal reconstruction Eq. (1).
87 This global nonlinear formulation describing the complex dynamics of a typ-
88 ical loudspeakers needs to be directly solved in the time-domain. In order to
89 compute the associated radiated sound pressure field for high amplitudes of
90 vibration, a time-domain formulation of sound radiation from axisymmetric
91 sources with a nonuniform vibratory distribution has to be adopted, as pre-
92 sented below.

93 2.3 Integral formulation

The sound pressure field $P(\mathbf{x}, t)$ is solution of the well known Kirchhoff-Helmholtz integral [24], that can be reduced to the Rayleigh's integral when considering weakly curved structures, i.e. for $h_0(r) \ll a$:

$$P(\mathbf{x}, t) = \rho \int_0^t \iint_S G(\mathbf{x}, \mathbf{x}_S, t, t') \frac{\partial V_n(\mathbf{x}_S, t')}{\partial t'} d\mathbf{x}_S dt' \quad (3)$$

Using the axisymmetric modal decomposition Eq. (1), the Rayleigh's integral is directly computed in the time-domain by separating the space and the time integration using the Spatial Impulse Response principle[19]:

$$P(\mathbf{x}, t) = \rho \int_0^t \sum_{p=0}^{\infty} \mathcal{H}_p(\mathbf{x}, t, t') \ddot{q}_p(t') dt', \quad (4)$$

where the Spatial Impulse Response (S.I.R.) \mathcal{H}_p associated to mode p is introduced as follow:

$$\mathcal{H}_p(\mathbf{x}, t, t') = \iint_S G(\mathbf{x}, \mathbf{x}_S, t, t') \Phi_p(\mathbf{x}_S) \vec{u}_z \cdot \overrightarrow{d\mathbf{x}_S}. \quad (5)$$

94 where $\vec{u}_z \cdot \overrightarrow{d\mathbf{x}_S}$ denotes the dot product between these 2 vectors. The analytical
 95 formulation of those functions can be obtained through an appropriate change
 96 of coordinates in the case of planar [19] or spherical structures [13]. However, in
 97 the general case, the direct calculation in the time-domain is not obvious due
 98 to the presence of the Dirac delta function. The following section proposes an
 99 appropriate change of variable in order to compute directly the S.I.R. functions
 100 for an axisymmetric source.

101 3 CALCULATION OF THE RAYLEIGH INTEGRAL IN THE 102 TIME-DOMAIN

103 3.1 Geometrical considerations

104 The aim of the following section is to simplify the calculation of the impulse
 105 response defined in Eq. (5). Geometrical considerations are firstly made in
 106 order to separate 3 areas of calculations where the properties of the sound
 107 pressure field differ. Then, a new local basis is proposed using those geomet-

115 $\mathbf{x}_o = (0, r_o)$ are solutions of:

116

$$|\mathbf{x} - \mathbf{x}_i| = \min_{(r, \theta)} (|\mathbf{x} - \mathbf{x}_S|), \quad (6a)$$

$$|\mathbf{x} - \mathbf{x}_o| = \max_{(r, \theta)} (|\mathbf{x} - \mathbf{x}_S|). \quad (6b)$$

117 Let \mathbf{x}_h and \mathbf{x}_b denote the points located respectively at the top and at the
 118 bottom of the structure, as shown in Fig. 2. Depending on the structure and
 119 on the location of the receiver \mathbf{x} , one can define 3 different zones defined in
 120 Tab. 1, where the radiation properties differ.

zone	Conditions on \mathbf{x}_i and \mathbf{x}_o
zone I	$\mathbf{x}_i \neq \{\mathbf{x}_h, \mathbf{x}_b\}$ and $\mathbf{x}_o = \{\mathbf{x}_h, \mathbf{x}_b\}$
zone II	$\mathbf{x}_i = \{\mathbf{x}_h, \mathbf{x}_b\}$ and $\mathbf{x}_o = \{\mathbf{x}_h, \mathbf{x}_b\}$
zone III	$\mathbf{x}_i = \{\mathbf{x}_h, \mathbf{x}_b\}$ and $\mathbf{x}_o \neq \{\mathbf{x}_h, \mathbf{x}_b\}$

Table 1

Definition of the 3 calculation zones.

121 3.2 Change of coordinates

122 If the present section, the aim is to transform the integration variables of
 123 Eq. (5) by 2 variables $|\mathbf{x} - \mathbf{x}_S|$ and an angle ϕ that correspond to the geometry
 124 of the problem.

Let θ_i denote the angle between axis u_z and the line $(\mathbf{x}\mathbf{x}_i)$. A new local orthonormal basis $\mathcal{B}_i = (t_{ix}^{\vec{}}, t_{iy}^{\vec{}}, \vec{n}_i)$ centered on point \mathbf{x}_i is introduced, as pre-

Fig. 2. Definition of the 3 different areas of calculation. For each position of the receiver, the associated points \mathbf{x}_i (dotted lines) and \mathbf{x}_o (dashed lines) are represented. The zones I and III only are defined in front and in back of a convex structure respectively. The intersection point F of the 3 zones is called the sweet spot (or geometrical focal point).

Fig. 3. Definition of the new local basis $\mathcal{B}_i = (\vec{t}_{ix}, \vec{t}_{iy}, \vec{n}_i)$ and the new coordinates (r_2, ϕ) . The points \mathbf{x} , \mathbf{x}_i and \mathbf{x}_S denote the observation point (located in the zone I for the present example), the projection point and an integration point located on the surface S , respectively.

sented in Fig. 3. It is defined in the Cartesian basis $\mathcal{B}_c = (\vec{u}_x, \vec{u}_y, \vec{u}_z)$ as follows:

$$\begin{cases} \vec{n}_i = & -\sin \theta_i \vec{u}_y - \cos \theta_i \vec{u}_z, \\ \vec{t}_{iy} = & \cos \theta_i \vec{u}_y - \sin \theta_i \vec{u}_z, \\ \vec{t}_{ix} = & \vec{u}_x. \end{cases} \quad (7)$$

In this basis, a set of cylindrical coordinates is introduced for any point located on the surface $\mathbf{x}_S = (r_2, \phi)$ and the coordinates in the new local basis are defined in appendix A. Introducing the tangent vectors to the surface $\overrightarrow{T}_{|\mathbf{x}-\mathbf{x}_S|}$ and \overrightarrow{T}_ϕ with respect to the variables $|\mathbf{x} - \mathbf{x}_S|$ and ϕ (detailed in Appendix A), the integration vector of Eq. (5) becomes in the new local basis[26]:

$$d\mathbf{x}_S = \left(\overrightarrow{T}_\phi \times \overrightarrow{T}_{|\mathbf{x}-\mathbf{x}_S|} \right) d|\mathbf{x} - \mathbf{x}_S| d\phi. \quad (8)$$

where $(.) \times (.)$ denotes the cross product between 2 vectors. The expression of tangent vectors and integration vector can be found in Appendix A. The principle is to replace the integration vector in Eq.(5) by the new one defined in Eq. (8) and to integrate over $|\mathbf{x} - \mathbf{x}_S|$ in order to eliminate the Dirac delta function contained in the Green's function (using the convolution theorem [27]). Introducing the time delay $\tau = t - t'$, one obtains the final formulation of the Rayleigh integral:

$$P(\mathbf{x}, t) = -\frac{\rho c}{2\pi} \int_0^t \sum_p \mathcal{H}_p(\mathbf{x}, \tau) \ddot{q}_p(t - \tau) d\tau \quad (9)$$

where:

$$\mathcal{H}_p(\mathbf{x}, \tau) = \int_\phi \frac{\Phi_p(r)}{FA + B \cos \phi - C \sin^2 \phi} \Big|_{|\mathbf{x}-\mathbf{x}_S|=c\tau} d\phi \quad (10)$$

and:

$$\left\{ \begin{array}{l} F = 1 + \frac{dh_0}{dr} \left(\frac{h_0(r) - z}{r} \right), \\ A = \left(\frac{1 - (\sin \theta_i \sin \phi)^2}{\cos \theta_i} \right), \\ B = \left(\frac{Fr_i - y}{r_2} \right), \\ C = \left(\frac{dh_0}{dr} \left(\frac{y}{r} \right) \sin \theta_i \right). \end{array} \right. \quad (11)$$

125 In this expression, the Spatial Impulse Response explicitly depends on the
 126 profile function $h_0(r)$, the modal shape $\Phi_p(r)$ (also dependent on the shape
 127 of the source), the position of the receiver \mathbf{x} and the integration time τ . The
 128 notation $|\mathbf{x} - \mathbf{x}_S| = c\tau$ means that for each time τ , a distance $|\mathbf{x} - \mathbf{x}_S|/c$
 129 is associated for computing the integrand of Eq. (10). In that case, for each
 130 time step τ , the intersection between the structure and the sphere centered
 131 on observation point \mathbf{x} and of radius $c\tau$ is sought.

132 This path (determined by the boundary values of integration path over ϕ)
 133 is unique in the case of a monotonic profile function (when the sign of $\dot{h}_0(r)$
 134 is constant) and can be closed if $\phi = [0 : 2\pi]$ or open if $\phi = [\phi_{min} : \phi_{max}]$
 135 depending on the location of the receiver, the shape of the structure and the
 136 integration time τ . The calculation of those boundaries and the application
 137 in the case of a spherical cap are expressed in Appendix B for each zone of
 138 calculation.

139 The formulation of Eq. (10) allows to reduce the order of integration compared
 140 to Eq. (5): only one spatial coordinate on variable ϕ is required and since
 141 spatial and time-domain integration are separated, the spatial discretization
 142 is independent on the time step (and thus the maximal simulated frequency).

143 In Fig. 4, the Spatial Impulse Response is computed for a hemispherical shell

Fig. 4. Spatial Impulse Responses in the case of a hemispherical transducer and for a receiver located at $(y, z) = (a, a)$. The exact solution of the Rayleigh's integral in the time-domaine derived from [13] is represented by points ($\circ \circ \circ$) and the results obtained using Eq. (10) in the case of different discretizations of the integral over ϕ are represented by lines : 3 points (dashed light grey line), 6 points (dashed dark grey line), 9 points (dashed black line) and 12 points (solid black line). The convergence is ensured in any case with at less 20 points.

144 and a receiver located at $(y, z) = (a, a)$ i.e. in the near-field region and for
 145 different discretization steps on variable ϕ in Eq. (10). The solutions in each
 146 case is compared to the solution of the Rayleigh integral [13] represented by
 147 points. It appears that less than 20 points for ϕ are required to attain a
 148 convergence error below 1% of the integral defined by Eq. (10).

150 4.1 Planar sources

In the case of a planar structure, the profile function is equal to zero: $h_0(r) = 0$.

In that case, Eq. (10) becomes [7]:

$$\mathcal{H}_p(\mathbf{x}, \tau) = \int_{\phi} \Phi_p(r)|_{|\mathbf{x}-\mathbf{x}_S|=c\tau} d\phi \quad (12)$$

151 with the boundaries derived from Eq. (C.1) in Appendix B in accordance
 152 with the results of Harris [6] and Jensen[8]. The classical example [6] of Spa-
 153 tial Impulse Responses obtained for a planar piston with a uniform velocity
 154 distribution is shown in Fig. 5. In this figure, S.I.R. functions are calculated
 155 using an integral discretization of 20 points. The in-axis impulse response is
 156 equal to 1 in a compact support which means that the effect of radiation fil-
 157 ter is equivalent to a low pass filter whose cut-off frequency is determined by
 158 the size of the support of the Spatial Impulse Response. The off-axis response
 159 decreases with respect to the off-axis position y while its compact support in-
 160 creases. In that case, the radiation filter is also equivalent to a low pass filter
 161 whose cut-off frequency is below the the in-axis cut-off frequency. This result
 162 is general for axisymmetric structures : the radiation filter is equivalent to a
 163 low-pass filters whose cut-off frequency decreases with respect to the off-axis
 164 position y .

Fig. 5. Spatial Impulse Responses obtained in the case of a plane piston with an uniform velocity distribution. The solutions are computed for a receiver located in $z = a$ and an off-axis position y from 0 to $5a$ and for 30 points of discretization in Eq. (12).

165 4.2 Spherical sources

In the present section, the approximated formulation of Eq. (9) is compared to the numerical results obtained by Suzuki [22] using 40 spherical harmonics in the wavenumbers domain, taking into account the diffraction effects. In the case of spherical sources, the profile function $h_0(r)$ equals:

$$\begin{cases} h_0(r) = \sqrt{R^2 - r^2} - \sqrt{R^2 - a^2} & \text{for } r < a, \\ h_0(r) = 0 & \text{for } r > a, \end{cases} \quad (13)$$

166 where R denotes the radius of curvature of the spherical shell and a the ex-
 167 ternal radius of the structure. In order to compare equivalent results in the
 168 frequency domain, one needs to take the Fourier transform of the Spatial Im-
 169 pulse Response computed using Eq. (10) in the case of a rigid body motion

170 (one mode of vibration: $p = 1$ and uniform displacement of the structure:
171 $\Phi_p(r) = 1$ for $r < 1$). In the work of Suzuki, the calculations are limited by
172 the order of the spherical harmonics (40 for his study), so that his model is
173 restricted to wavenumbers up to $ka = 10$. In the present formulation, only
174 the time discretization of Spatial Impulse Responses influences the upper ka
175 limit, so that no limitation of frequency range is observed. In practical cases,
176 the Spatial Impulse Responses are computed using 20 nondimensionnalized
177 time steps $\tau = tc/a$ and then completing with zeros, the precision in the
178 wavenumbers domain is adaptable.

179 The results are presented for 3 different structures: a planar piston, a spher-
180 ical cap defined by a radius of curvature $R = 1.5a$ and an hemispherical cap
181 defined by a radius of curvature $R = a$. The Fourier Transform of the Spatial
182 Impulse Responses computed for an on-axis receiver located in the far-field
183 $(y, z) = (0, 100a)$ are presented in Figs. 6 and 7 for concave and convex caps
184 and a good agreement between the present approach and the results of Suzuki
185 is obtained for low wavenumbers ($ka < 1$) and high wavenumbers ($ka > 3$).

186

187 For low wavenumbers ($ka < 1$), the monopole approximation is valid and the
188 equivalent radiation filter has a flat response. For high wavenumbers ($ka > 3$),
189 the local curvature induces a decrease of the on-axis sound pressure level and
190 the radiation filter is thus equivalent to a low-pass filter with a slope of -
191 20 dB/decade above a cut-off wavelength depending on the curvature R of
192 the profile and its radius a . In Figs. 6 and 7 the cut-off frequency of the
193 equivalent low-pass filter decreases when the curvature radius R increases. This
194 is explained by interferences phenomena that appears when the wavelength
195 $\lambda = 1/k$ is below the path difference between the nearest and the farther

Fig. 6. On-axis acoustic pressure (up: magnitude in dB, down: phase in degrees) in far-field versus nondimensionalized wavenumber ka computed by Suzuki[22] (points) and using Eq. (9) (lines). The results are presented for 3 different concave structures: planar piston (black), medium spherical cap (dark grey) and hemispherical cap (light grey). The wavenumbers domain results are obtained by taking the Fourier transform of the Spatial Impulse Response computed in the time domain.

Fig. 7. On-axis acoustic pressure (up: magnitude in dB, down: phase in degrees) in far-field versus wavenumber ka computed by Suzuki[22] (points) and using Eq. (9) (lines). The results are presented for 3 different convex structures: planar piston (black), medium spherical cap (dark grey) and hemispherical cap (light gray).

196 point seen from the observer point as presented in Fig. 8. Thus the more the

197 structure radius R is important, the more the difference path increases and

198 the more the cut-off frequency of the equivalent low-pass filter decreases.

199 Around $ka = 1$, the diffraction taken into account in the calculations of Suzuki

Fig. 8. Explanation of the interference phenomenon that appears when the wavelength k is above the path difference between the nearest and the farther point seen from the observer point. In the frequency domain, this effect is responsible for a slope of the on-axis sound pressure level of -20 dB/decade and an extension of the directivity compared to planar radiators.

200 [22] induces an increase of on-axis sound pressure level up to +6 dB in the
 201 case of concave caps (a decrease in the case of convex structures) that is not
 202 taken into account in the present model. The effect of diffraction appears in
 203 the non-dimensionnalized wavenumbers domain $1 < ka < 3$ i.e. when the
 204 wavelength approaches the maximal depth of the structure. The influence of
 205 the diffraction is hardly dependent on the shape and the validity of the present
 206 approach is thus no longer viable in the wavelength range $1 < ka < 3$.

207

208 Figs. 9 and 10 represent the directivity patterns in linear scale computed for
 209 the considered spherical caps in the far-field ($z = 100a$) for wavenumbers such
 210 as $ka = 1$, $ka = 3$ and $ka = 10$. Again, the results obtained by taking the
 211 Fourier Transform of Eq. (10) are compared to results obtained by Suzuki
 212 [22]. For low wavenumbers ($ka = 1$) the radiation patterns are almost omni-
 213 directional and become more directive for high wavenumbers ($ka > 3$). The
 214 curvature extends the directivity in both convex and concave cases and in the

215 concave case, the maximum of sound pressure is obtained for a precise obser-
216 vation angle depending on the curvature of the considered shell.

217

218 In a general manner, the curvature (not necessarily in the case of a spherical
219 shell) induces a decrease of on-axis sound pressure field due to interference for
220 high wavenumbers. The effects of diffraction, not taken into account in the
221 present model, are responsible for an increase of on-axis sound pressure level
222 around $1 < ka < 3$ in the case of concave sources (a decrease in the case of
223 convex structures). The on-axis high wavenumbers losses due to interferences
224 are compensated by an extent of directivity related to the local curvature of the
225 source. This result is general for monotonic profile functions and is extended
226 in the following section in the case of non-monotonic profile function and in
227 the case of a typical loudspeaker shape.

228 4.3 *Complex sources*

229 The previous formulation is only valid for a monotonic profile function $h_0(r)$. In
230 the case of a nonmonotonic profile, i.e. when the sign of $\dot{h}_0(r)$ is not constant,
231 the integration path (intersection between the sphere centered on observation
232 point \mathbf{x} and of radius $c\tau$ used in the calculation of Eq. (10)) is made of mul-
233 tiple paths corresponding to each monotonic part of the global profile.

234

Neglecting the multiple reflections over the emissive surface, the global radia-
tion can be expanded as the sum of contributions of each monotonic portion
of the profile. For example, for a global structure composed by 2 monotonic

Fig. 9. Directivity functions (using a linear scale) for the 3 different concave caps: plane piston (black), medium spherical cap (dark grey) and hemispherical cap (light gray). The results obtained by the present model (right) are compared to the results obtained by Suzuki [22] (left) for 3 wavenumbers: $ka = 1$ (up), $ka = 3$ (middle) and $ka = 10$ (bottom).

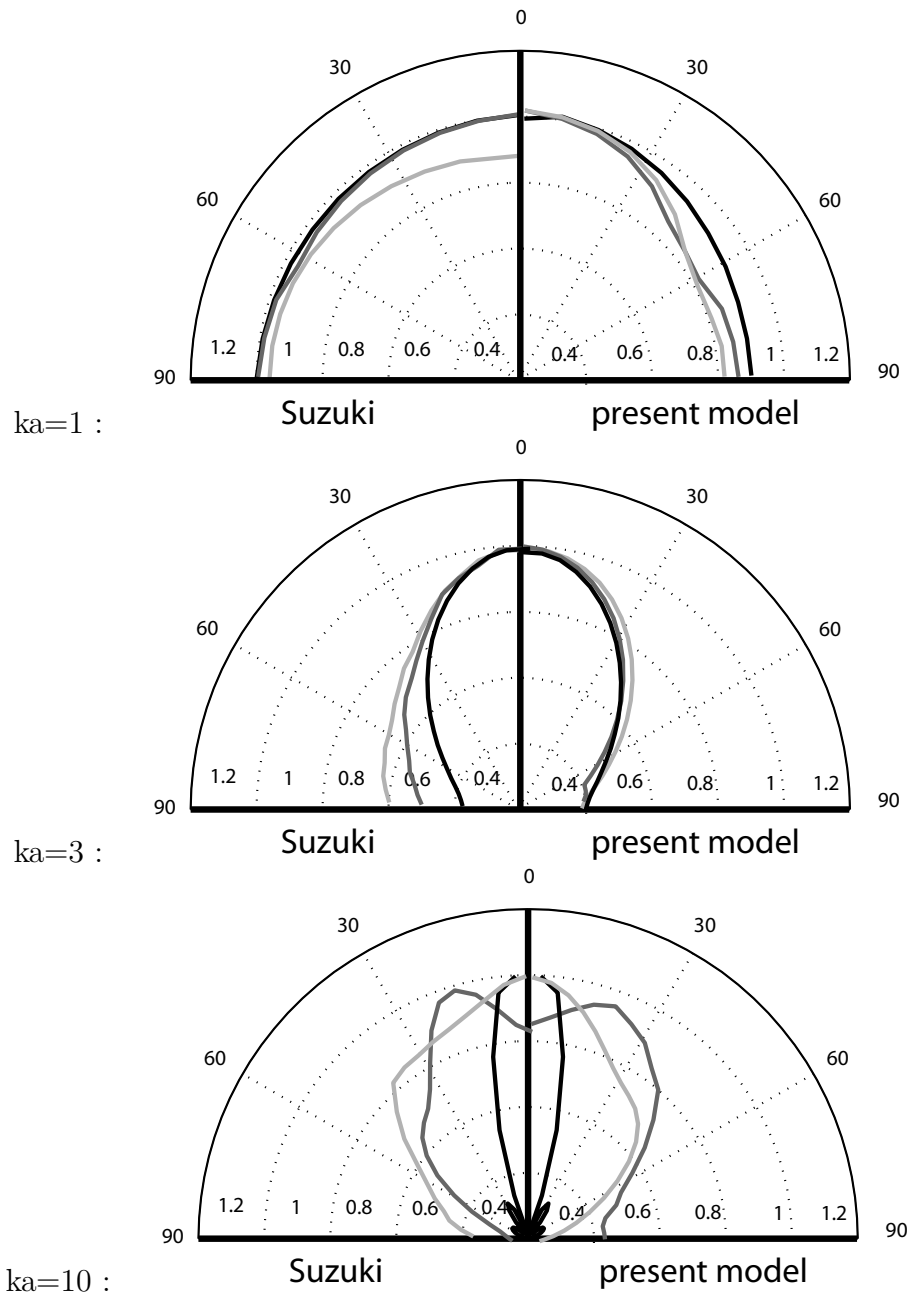

Fig. 10. Directivity functions (using a linear scale) for the 3 different convex caps: plane piston (black), medium spherical cap (dark grey) and hemispherical cap (light gray). The results obtained by the present model (right) are compared to the results obtained by Suzuki [22] (left) for 3 wavenumbers: $ka = 1$ (up), $ka = 3$ (middle) and $ka = 10$ (bottom).

profiles $S = S_1 \cup S_2$, we have:

$$P(\mathbf{x}, t) = -\frac{\rho c}{2\pi} \sum_p \left(\int_0^t \mathcal{H}_p^1(\mathbf{x}, \tau_1) \ddot{q}_p(t - \tau_1) d\tau_1 + \int_0^t \mathcal{H}_p^2(\mathbf{x}, \tau_2) \ddot{q}_p(t - \tau_2) d\tau_2 \right) \quad (14)$$

where $\mathcal{H}_p^i(\mathbf{x}, \tau_i)$ corresponds to the Spatial Impulse Response of mode p associated to the i^{th} monotone part of the profile. This procedure is applied in the case of a typical loudspeaker shape composed as the junction of a truncated cone with a spherical cap. The profile function is then described by:

$$\begin{cases} h_0(r) = \alpha(b - a) + \sqrt{R^2 - r^2} - \sqrt{R^2 - b^2} & \text{for } r < b, \\ h_0(r) = \alpha(r - a) & \text{for } r > b, \\ h_0(r) = 0 & \text{for } r > a, \end{cases} \quad (15)$$

235 where R denotes the curvature of the inner spherical shell, b the radius of the
 236 junction between both sub-structures and α the depth of the truncated conical
 237 shell. The following results are obtained for a typical loudspeaker $\alpha = 1$,
 238 $b = 0.5a$ and $R = 1.5b$. The profile function and the principle of calculation
 239 of the on-axis Spatial Impulse Response are presented in Fig. 11 and the on-
 240 axis result in the nondimensionalized wavenumbers domain ka is displayed in
 241 Fig. 12 taking the Fourier Transform of computed time function.

242

243 In Fig. 11, the respective contribution of each sub-structure in the time-domain
 244 for an on-axis receiver is represented. In the frequency domain, the global ra-
 245 diation filter is as previously equivalent to a low-pass filter whose cut-off fre-
 246 quency is not only related to the depth of the truncated conical shell. Indeed,
 247 between $ka = 1$ and $ka = 10$ in Fig. 12, the comparison between the response

Fig. 11. Calculation procedure of the Spatial Impulse Response of a typical loudspeaker (junction of a cone and a spherical cap) for an uniform velocity distribution and for a on-axis receiver located in $z = a$. The S.I.R. corresponding to the spherical cap $\mathcal{H}^1(\mathbf{x}, \tau)$ is represented by a dashed black line, the S.I.R. corresponding to the truncated cone $\mathcal{H}^2(\mathbf{x}, \tau)$ is represented by a dashed grey line and the global S.I.R. corresponds to the solid black line.

248 of the truncated conical shell only and the global structure shows that the cut-
 249 off frequency is increased when the inner spherical cap is present. The effect of
 250 the convex spherical cap compensate the interference effect around $ka = 1$ and
 251 an extension of the flat acoustic response is achieved and a global increase of
 252 +3dB with respect to the conical source is observed in the interference regime.
 253

254 The contribution of the inner cap appears in the tail of the Impulse Response
 255 and is also responsible for high wavenumber comb-filtering (for $ka > 10$) that
 256 is not present in absence of the inner spherical cap (see Fig. 12). Around
 257 $ka = 25$, a decrease of 10dB with respect to the conical source is observed

Fig. 12. On-axis acoustic pressure level (magnitude in dB versus wavenumber ka) obtained in the case of a loudspeaker (junction of a truncated cone and an hemispherical cap). The solution (solid black line) is compared to the truncated cone radiation only (dashed grey line). The use of a typical loudspeaker profile increases the low-pass filter cut-off frequency and induces oscillations in the on-axis acoustic pressure level, due to complex interference phenomena.

258 and can be interpreted as interferences between the conical and the spherical
 259 cap because this phenomenon is not present in the case of a spherical shell
 260 only neither a conical shell only as presented on Fig. 12. This effect is then
 261 amplified above $ka = 25$ and is responsible for comb filtering at multiples of
 262 that nondimensionalized wavenumber $ka = 25$, $ka = 50$ and $ka = 75$.

263 5 APPLICATION TO A PROTOTYPE OF LOUDSPEAKER

264 5.1 Presentation

265 In order to illustrate the influence of the diaphragm shape of a loudspeaker on
266 its acoustical response for high amplitudes of vibration, a prototype of loud-
267 speaker has been developed by G. Lemarquand in the LAUM [25] as presented
268 on Fig. 13. Its moving part is an aluminium convex spherical shell of 50 mm of
269 diameter. Experiments have been done with a curvature equals to $a/R = 0.3$
270 which is defined as the ratio between the external radius and the radius of
271 curvature of the shell. For the prototype, the moving part is not made in one
272 piece, since the emissive surface is glued on the supporting cylinder.

273

Fig. 13. Photography of the studied prototype in anechoic room.

274 In the studied prototype, attention is paid to the motor and suspensions, in
275 order to minimize the "electrical" nonlinear phenomena. The sources of non-
276 linearities in the motor are the variations of the fore factor (Bl), and the
277 Eddy currents. As a remedy to these defects, an ironless motor was used,

278 which is made only out of neodymium iron boron permanent magnets. The
279 classical suspensions of loudspeakers are mostly made of rubber, impregnated
280 fabric or molded plastic. They act as a spring, but have a nonlinear behavior.
281 This means that their compliance depends on the movements amplitude and,
282 above all, that the induced damping depends greatly on both amplitude and
283 frequency. These phenomena are the sources of the classical nonlinear behavior
284 of the loudspeakers suspensions at low frequencies. In the studied prototype,
285 the almost perfect compressibility properties of the air were used to create a
286 pneumatic stiffness. Indeed, the air is compressed in the closed box, whose
287 volume tunes the stiffness value. The cabinet is thus a cylindrical pipe which
288 is closed and filled up with an absorbing material. Classical electrical nonlin-
289 earities are thus not observed in the present prototype and only geometrical
290 nonlinearities remain and are due to large amplitudes of vibration of the mov-
291 ing part. This kind of nonlinearities has been pointed out mechanically but the
292 influence on the radiated sound pressure field had not been cleared explained.
293

294 *5.2 Electromechanical characterization*

295 The first step of the experimental analysis consist in understanding and mod-
296 eling the electromechanical behavior of the prototype. Fig. 14 represents the
297 impedance curves in both magnitude. Below 1 kHz , the behavior is mostly re-
298 sistive and become inductive above 2 kHz . As mentioned above, the inductive
299 part is not modified by eddy currents, due to the ironless conception of the
300 motor, and then a linear dependency of impedance magnitude with respect
301 to frequency is observed (not observable on Fig.14 because of the logarithmic

302 scale for the frequencies).

303

Fig. 14. Electrical impedance of the loudspeaker in magnitude (up) and phase (down).

304 However, the impedance curves are affected by resonances (amplification of
305 certain frequencies and perturbation in the phase curve) of different parts of

306 the prototype. Two tendencies are easily identified on Fig. 14 :

307

308 • for frequencies below 5 kHz , the resonances are due to stationary waves in
309 the rear cavity : the first resonance is around 70 Hz . Under this assumption,
310 the vibration pattern is then assimilated to a plane piston (rigid body mode).

311

312 • for frequencies above 9 kHz , the resonances correspond to mechanical reso-
313 nances of the spherical cap, as described in the following part. The properties
314 of those resonances (eigenfrequencies, modal damping, excitation and shapes)
315 have been analyzed using Laser Doppler Velocity and a linear modal analysis
316 software (IDEAS[©]) and are presented on Tab. 2.

317

318 *5.3 Nonlinear radiation : on-axis response*

319 For high amplitudes of vibration, nonlinearities appear and give rise to har-
320 monic distortion in the velocity and sound pressure signals. Due to the ironless
321 conception of the motor, the electrical nonlinearities classically observed in
322 electrodynamic loudspeakers vanish and only geometrical nonlinearities (due
323 to large deformations of the moving part) remain.

324

325 This type of nonlinearities can be modeled using the modal formulation pro-
326 posed in [5]. This approach is absolutely suitable in the present case, since
327 few modes radiate in the audible range. The principle is to model the proto-
328 type as a 4 degrees of freedom system (since 4 modes radiate in the audible

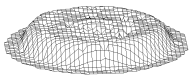

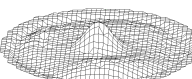

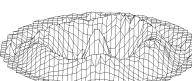

Mode	Resonance	Modal	Excitation	Modal
p	Frequency(Hz)	Damping(%)	Vector	Shape Φ_p
1	73	100	1	
2	9650	3.2	20	
3	17290	0.6	2	
4	18550	0.6	0.8	

Table 2

Axisymmetric modal parameters (eigenfrequency f_p , modal damping μ_p and excitation T_p associated to mode p) measured for the spherical dome. The first mode corresponds to a piston mode (rear cavity resonance) and is very damped compared to the structural modes (above 9 kHz).

329 range, as presented in Tab. 2) and to include geometrical nonlinearities in
 330 the modal equations through cubic and quadratic nonlinearities [2]. In order
 331 to illustrate the typical effects of geometrical nonlinearities on radiation of
 332 the prototype, only quadratic and cubic nonlinearity terms have been added
 333 for the second mode of vibration (at 9650 Hz). The displacement field is cal-
 334 culated for high amplitudes of vibrations using the State-Space formulation
 335 described by Eq. (2), and the radiation problem is solved using the Spatial
 336 Impulse Response (S.I.R.) approach developed in the present study. In this
 337 practical case, the measured modal shapes $\Phi_p(r')$ and profile function $h_0(r')$
 338 are introduced in Eq. (10) and convolutions are performed at the sampling
 339 frequency of 48 kHz. It is important to notice that the calculations of the
 340 displacement field and radiated sound pressure are computed directly in the
 341 time-domain and the results are presented in the frequency domain for clarity
 342 (taking the Fourier transform of the transient responses).

343

344 Fig. 15 represent the on-axis sound pressure measurement and prediction at
 345 1 m of the fundamental and of the harmonics 2 and 3 in the case of the
 346 convex spherical dome. Measurements have been performed in anechoic room
 347 (approximate size 1000m³) using sinusoidal input signals. A good agreement
 348 is observed in the audible bandwidth and the geometrical nonlinearities are
 349 correctly predicted around discrete frequencies such as :

350

- 351 • $f = f_a$: around a mechanical resonance frequency, the amplitude of vi-
- 352 bration increases and harmonics are generated. For example, on figure 15,
- 353 harmonics 2 and 3 are generated for an excitation frequency around 9.6kHz
- 354 (first mechanical resonance).

Fig. 15. Measurement (points) and prediction (solid lines) of on-axis sound pressure level for a 10 W input. For each frequency, the energy of fundamental (black) and harmonics 2 (dark grey) and 3 (light grey) are measured and predicted.

355

356 • $f = f_a/p$ with p integer : for the submultiple p of a resonance frequency, the
 357 frequency of harmonic p corresponds to an eigenfrequency and this harmonic
 358 is then amplified. For example, on Fig. 15, an increase of harmonic 3 at 3.2
 359 kHz which corresponds to a third of the first mechanical resonance is observed
 360 (the same effect appears with harmonic 2 at 4.8 kHz).

361

362 The Spatial Impulse Response appear to model efficiently the complex radia-
 363 tion pattern for high amplitudes of vibration. The influence of the geometrical
 364 nonlinearities on the acoustic response of the prototype has been observed ex-
 365 perimentally and modeled properly using the present approach. Other sources
 366 of nonlinearities could also be taken into account in order to predict the non-
 367 linear acoustic response of classical loudspeakers.

369 In order to compute acoustic radiation from axisymmetric structures sub-
370 jected to large amplitude motion, an explicit integral formulation is derived
371 for predicting the modal time-domain radiation. The radiated acoustic pres-
372 sure is assumed to be expressed as an integration of a simple source distri-
373 bution (Rayleigh integral), which is valid except in the nondimensionalized
374 wavenumber range $1 < ka < 3$ because the diffraction effects are neglected
375 in the present study and will be detailed in a future work. The displacement
376 is expanded onto the linear modes of the structure and the acoustic pressure
377 is expressed as a sum of modal contributions, by introducing the Spatial Im-
378 pulse Responses depending on the shape of the source, the position of the
379 receiver and the modal shapes (also dependent of the shape of the source).
380 The solution is compared to the literature in the cases of a piston and of spher-
381 ical caps and gives quite good results and low calculation costs compared to
382 frequency-domain formulations. In a general way, the radiation induces a low-
383 pass filtering whose cut-off frequency is related to the radius of the source
384 and the local curvature. The method is extended for predicting the radiation
385 of an axisymmetric source whose profile function is complex and corresponds
386 to a typical loudspeaker shape. Finally, predictions and experimental mea-
387 surements of on-axis radiation of a prototype loudspeaker subjected to large
388 amplitudes motion are compared and a good agreement is achieved on the
389 audible bandwidth.

391 **A Definition of the new local basis**

In the new local basis $\mathcal{B}_i = (\vec{t}_{ix}, \vec{t}_{iy}, \vec{n}_i)$, the coordinates of point \mathbf{x}_S are defined by:

$$\begin{aligned} \overrightarrow{\mathbf{x}_i \mathbf{x}_S} &= \left(\frac{h_0(r_i) - h_0(r)}{\cos \theta_i} - r_2 \cos \phi \tan \theta_i \right) \vec{n}_i \\ &\quad + r_2 \cos \phi \vec{t}_{iy} + r_2 \sin \phi \vec{t}_{ix}. \end{aligned} \quad (\text{A.1})$$

where r_2 is defined by the Cartesian coordinates of integration point $\mathbf{x}_S = (x, y)$:

$$r_2^2 = x^2 + \cos^2 \theta_i [y - r_i - (h_0(r) - h_0(r_i)) \tan \theta_i]^2. \quad (\text{A.2})$$

Under those considerations, the tangent vectors to the surface $\overrightarrow{T}_{|\mathbf{x} - \mathbf{x}_S|}$ and \overrightarrow{T}_ϕ with respect to the variables $|\mathbf{x} - \mathbf{x}_S|$ and ϕ are described by:

$$\left\{ \begin{aligned} \overrightarrow{T}_{|\mathbf{x} - \mathbf{x}_S|} &= \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_x}{\partial |\mathbf{x} - \mathbf{x}_S|} \vec{u}_x + \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_y}{\partial |\mathbf{x} - \mathbf{x}_S|} \vec{u}_y + \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_z}{\partial |\mathbf{x} - \mathbf{x}_S|} \vec{u}_z, \\ \overrightarrow{T}_\phi &= \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_x}{\partial \phi} \vec{u}_x + \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_y}{\partial \phi} \vec{u}_y + \frac{\partial \overrightarrow{\mathbf{x}_S} \cdot \vec{u}_z}{\partial \phi} \vec{u}_z, \end{aligned} \right. \quad (\text{A.3})$$

392 **B Change of variable**

One point located in the integration surface S is parameterized in the Cartesian basis by its 3 coordinates $\mathbf{x}_S = (x, y, h_0(\sqrt{x^2 + y^2}))$. In order to compute the tangent vectors expressed in Eq. (A.3), one needs to express the depen-

dependency of $|\mathbf{x} - \mathbf{x}_S|$ and ϕ with respect to those 3 coordinates:

$$\begin{cases} \frac{\partial x}{\partial |\mathbf{x} - \mathbf{x}_S|} = \frac{|\mathbf{x} - \mathbf{x}_S|}{Fx} \\ \frac{\partial y}{\partial |\mathbf{x} - \mathbf{x}_S|} = \frac{|\mathbf{x} - \mathbf{x}_S|}{Fy - r}, \end{cases} \quad (\text{B.1})$$

$$\begin{cases} \frac{\partial x}{\partial \phi} = r_2 \left(\cos \phi + \sin \phi \frac{Fx}{Fy - r} (\cos \theta_i - C) \right. \\ \quad \left. + \frac{dh_0}{dr} \sin \phi \sin \theta_i \frac{x}{r} \right)^{-1} \\ \frac{\partial y}{\partial \phi} = \frac{-Fx}{Fy - r} \left(\frac{\partial x}{\partial \phi} \right), \end{cases} \quad (\text{B.2})$$

and:

$$\frac{\partial h_0(r)}{\partial \star} = \frac{dh_0(r)}{dr} \left(\frac{x}{r} \left(\frac{\partial x}{\partial \star} \right) + \frac{y}{r} \left(\frac{\partial y}{\partial \star} \right) \right), \quad (\text{B.3})$$

so that the change of variables in Eq.(8) leads to:

$$\vec{u}_z \cdot \overrightarrow{d\mathbf{x}_S} = \left(\frac{2|\mathbf{x} - \mathbf{x}_S|}{FA + B \cos \phi - C \sin^2 \phi} \right) d|\mathbf{x} - \mathbf{x}_S| d\phi, \quad (\text{B.4})$$

393 where F , A , B and C are defined in Eq. (11).

394 C Boundary values of integration

Depending on the zone of calculation, the boundaries of integration in Eq. (10) differ and the integration has to be computed on a closed or an open path (an example of the two cases is represented on Fig. C.1. Tab. C.1 describes the different integration paths depending on the integration time τ and receiver position \mathbf{x} .

In the case of open contours, the boundaries are defined by the value of ϕ_m

zone	Conditions on \mathbf{x} and τ	Contour	Integration over ϕ
I	$ \mathbf{x} - \mathbf{x}_i < c\tau < \mathbf{x} - \mathbf{x}_h $	Closed	$[0 : 2\pi]$
	$ \mathbf{x} - \mathbf{x}_h < c\tau < \mathbf{x} - \mathbf{x}_b $	Open	$[\phi_m : 2\pi - \phi_m]$
II	$ \mathbf{x} - \mathbf{x}_h < c\tau < \mathbf{x} - \mathbf{x}_b $	Open	$[\phi_m : 2\pi - \phi_m]$
III	$ \mathbf{x} - \mathbf{x}_h < c\tau < \mathbf{x} - \mathbf{x}_b $	Open	$[-\phi_m : \phi_m]$
	$ \mathbf{x} - \mathbf{x}_b < c\tau < \mathbf{x} - \mathbf{x}_i $	Closed	$[0 : 2\pi]$

Table C.1

Definition of the integration contours depending on the zone, receiver location \mathbf{x} and integration time $\tau = |\mathbf{x} - \mathbf{x}_S|/c$. For open contours, the boundary are determined by ϕ_m defined in Eq. (C.1).

determined in Eq. (C.1) which corresponds to the angle of intersection of the outer edge of the structure with a sphere centered on \mathbf{x} and of radius $c\tau$:

$$\phi_m = \arccos \left(\left(1 + \frac{((c\tau)^2 - z^2 - (y - a)^2)((c\tau)^2 - z^2 - (y + a)^2)}{\cos^2 \theta_i ((c\tau)^2 - z^2 - y^2 - a^2 + 2yr_i + 2r(h_0(r_i)) \tan \theta_i)^2} \right)^{-1/2} \right). \quad (\text{C.1})$$

395 In the case of an observation point located in the zone I, the intersection start
396 by impact point \mathbf{x}_i when $c\tau = |\mathbf{x} - \mathbf{x}_i|$ then the contour is closed (integration
397 over $\phi = [0 : 2\pi]$) as presented in Fig. C.1 (up) until $c\tau = |\mathbf{x} - \mathbf{x}_h|$ then the
398 integration path is open (integration over $\phi = [\phi_m : 2\pi - \phi_m]$) as presented in
399 Fig. C.1 (down) until $c\tau = |\mathbf{x} - \mathbf{x}_b|$.

Fig. C.1. Example of a closed contour (left) and an open contour (right) of integration in the case of a spherical cap and a receiver \mathbf{x} located in the zone I. The integration path corresponds to the intersection of the structure with a sphere of radius $c\tau$ centered on \mathbf{x} .

471 **List of Figures**

- 472 1 Geometry of the considered structure. The points \mathbf{x} and
473 \mathbf{x}_s represent the receiver and an integration point on the
474 structure respectively. The profile function is denoted by $h_0(r)$
475 and corresponds to the projection in the plane $z = 0$ of the u_z
476 coordinate of the point \mathbf{x}_s . 7
- 477 2 Definition of the 3 different areas of calculation. For each
478 position of the receiver, the associated points \mathbf{x}_i (dotted lines)
479 and \mathbf{x}_o (dashed lines) are represented . The zones I and III
480 only are defined in front and in back of a convex structure
481 respectively. The intersection point F of the 3 zones is called
482 the sweet spot (or geometrical focal point). 11
- 483 3 Definition of the new local basis $\mathcal{B}_i = (t_{ix}^{\vec{}}, t_{iy}^{\vec{}}, n_i^{\vec{}})$ and the
484 new coordinates (r_2, ϕ) . The points \mathbf{x} , \mathbf{x}_i and \mathbf{x}_s denote
485 the observation point (located in the zone I for the present
486 example), the projection point and an integration point
487 located on the surface S , respectively. 11

488 4 Spatial Impulse Responses in the case of a hemispherical
489 transducer and for a receiver located at $(y, z) = (a, a)$. The
490 exact solution of the Rayleigh's integral in the time-domaine
491 derived from [13] is represented by points ($\circ \circ \circ$) and the results
492 obtained using Eq. (10) in the case of different discretizations
493 of the integral over ϕ are represented by lines : 3 points
494 (dashed light grey line), 6 points (dashed dark grey line), 9
495 points (dashed black line) and 12 points (solid black line). The
496 convergence is ensured in any case with at less 20 points. 14

497 5 Spatial Impulse Responses obtained in the case of a plane
498 piston with an uniform velocity distribution. The solutions
499 are computed for a receiver located in $z = a$ and an off-axis
500 position y from 0 to $5a$ and for 30 points of discretization in
501 Eq. (12). 16

502 6 On-axis acoustic pressure (up: magnitude in dB, down: phase
503 in degrees) in far-field versus nondimensionalized wavenumber
504 ka computed by Suzuki[22] (points) and using Eq. (9) (lines).
505 The results are presented for 3 different concave structures:
506 planar piston (black), medium spherical cap (dark grey) and
507 hemispherical cap (light gray). The wavenumbers domain
508 results are obtained by taking the Fourier transform of the
509 Spatial Impulse Response computed in the time domain. 18

- 510 7 On-axis acoustic pressure (up: magnitude in dB, down: phase
511 in degrees) in far-field versus wavenumber ka computed by
512 Suzuki[22] (points) and using Eq. (9) (lines). The results
513 are presented for 3 different convex structures: planar piston
514 (black), medium spherical cap (dark grey) and hemispherical
515 cap (light gray). 19
- 516 8 Explanation of the interference phenomenon that appears
517 when the wavelength k is above the path difference between
518 the nearest and the farther point seen from the observer point.
519 In the frequency domain, this effect is responsible for a slope
520 of the on-axis sound pressure level of -20 dB/decade and an
521 extension of the directivity compared to planar radiators. 20
- 522 9 Directivity functions (using a linear scale) for the 3 different
523 concave caps: plane piston (black), medium spherical cap
524 (dark grey) and hemispherical cap (light gray). The results
525 obtained by the present model (right) are compared to the
526 results obtained by Suzuki [22] (left) for 3 wavenumbers:
527 $ka = 1$ (up), $ka = 3$ (middle) and $ka = 10$ (bottom). 22
- 528 10 Directivity functions (using a linear scale) for the 3 different
529 convex caps: plane piston (black), medium spherical cap (dark
530 grey) and hemispherical cap (light gray). The results obtained
531 by the present model (right) are compared to the results
532 obtained by Suzuki [22] (left) for 3 wavenumbers: $ka = 1$ (up),
533 $ka = 3$ (middle) and $ka = 10$ (bottom). 23

534	11	Calculation procedure of the Spatial Impulse Response of a	
535		typical loudspeaker (junction of a cone and a spherical cap)	
536		for an uniform velocity distribution and for a on-axis receiver	
537		located in $z = a$. The S.I.R. corresponding to the spherical	
538		cap $\mathcal{H}^1(\mathbf{x}, \tau)$ is represented by a dashed black line, the S.I.R.	
539		corresponding to the truncated cone $\mathcal{H}^2(\mathbf{x}, \tau)$ is represented	
540		by a dashed grey line and the global S.I.R. corresponds to the	
541		solid black line.	25
542	12	On-axis acoustic pressure level (magnitude in dB versus	
543		wavenumber ka) obtained in the case of a loudspeaker	
544		(junction of a truncated cone and an hemispherical cap).	
545		The solution (solid black line) is compared to the truncated	
546		cone radiation only (dashed grey line). The use of a typical	
547		loudspeaker profile increases the low-pass filter cut-off	
548		frequency and induces oscillations in the on-axis acoustic	
549		pressure level, due to complex interference phenomena.	26
550	13	Photography of the studied prototype in anechoic room.	27
551	14	Electrical impedance of the loudspeaker in magnitude (up)	
552		and phase (down).	29
553	15	Measurement (points) and prediction (solid lines) of on-axis	
554		sound pressure level for a 10 W input. For each frequency, the	
555		energy of fundamental (black) and harmonics 2 (dark grey)	
556		and 3 (light grey) are measured and predicted.	33

557 C.1 Example of a closed contour (left) and an open contour (right)
558 of integration in the case of a spherical cap and a receiver \mathbf{x}
559 located in the zone I. The integration path corresponds to
560 the intersection of the structure with a sphere of radius $c\tau$
561 centered on \mathbf{x} .

38

562 **List of Tables**

563	1	Definition of the 3 calculation zones.	10
564	2	Axisymmetric modal parameters (eigenfrequency f_p , modal	
565		damping μ_p and excitation T_p associated to mode p) measured	
566		for the spherical dome. The first mode corresponds to a piston	
567		mode (rear cavity resonance) and is very damped compared to	
568		the structural modes (above 9 kHz).	31
569	C.1	Definition of the integration contours depending on the zone,	
570		receiver location \mathbf{x} and integration time $\tau = \mathbf{x} - \mathbf{x}_S /c$. For	
571		open contours, the boundary are determined by ϕ_m defined in	
572		Eq. (C.1).	37
