Abstract The peccary digestive tract is characterised by an elaborate forestomach. In order to further characterise the digestive function of peccaries, we report body mass, digestive organ mass, content mass of the gastrointestinal tract compartments and their length and width, as well as liver, parotis and mandibular gland mass. Our data on eleven collared and four white-lipped peccaries suggest that peccaries have a small relative stomach volume compared to other

foregut fermenters, which implies a comparatively lower fermentative capacity and thus forage digestibility. The forestomach could enable peccaries to deal, in conjunction with their large parotis glands, with certain plant toxins (e.g. oxalic acid). The finding of sand being trapped in the forestomach blindsacs could indicate a disadvantage of the peccary forestomach design. The relevance of the forestomach to peccaries remains enigmatic.

Introduction

Peccaries are foregut fermenters. Their digestive tract is characterised by an elaborate forestomach in which the diet, mainly fruits, leaves, stems, roots and flowers, is fermented (Barreto et al. 1997; Altrichter et al. 2001). Thus, peccaries differ in the digestive anatomy from their next relatives, the monogastric suids. The peccary stomach consists of a gastric pouch, an anterior and upper blindsac and a glandular compartment (Sowls 1978; Langer 1978). The forestomach—constituting 85% of the volume of the total stomach (Langer 1988, p 169)—is the primary site of fermentation (Lochmiller et al. 1986), and effective fibre digestibility has been demonstrated in peccaries (Gallagher et al. 1984; Comizzoli et al. 1997; Nogueira-Filho 2005). However, when comparing different species, fibre and dry matter digestibility in peccaries is not higher than in monogastric wild suids (Clauss et al. 2008). Dyson (1969), cited in Sowls (1997, p77), on the other hand, concluded that “fiber digestion in the collared peccary is higher than in most nonruminants but considerably lower

than in true ruminants". This conclusion was based on volatile fatty acid concentrations in the stomach content of hay-fed captive collared peccaries being lower than in hay-fed cattle from the literature. A direct comparison to monogastric herbivores seems to be lacking. Although collared peccaries resemble grazing ruminants regarding the total concentration of volatile fatty acids in stomach contents (reviewed by Sowls 1997, p 76–80), the acetate to propionate ratio is lower in the former (1.5–2.5 vs. 3.1–3.7 on pasture only). Carl and Brown (1983) found the concentration of protozoa to be similar in peccary and ruminants. Most of the protozoa found were of the genus *Entodinia*, primarily starch digesters, typically found in browsing ruminants (compiled by Clauss and Lechner-Doll 2001). With respect to passage time, the ability of the peccary forestomach to slow down ingesta passage is less obvious than in ruminants. Average solid ingesta passage through the peccary gut is 35 h compared to 60 h in ruminants on similar dry matter intakes ($50 \text{ g}/(\text{kg}^{0.75} \text{ day})$, Schwarm et al. 2009). In comparison to other non-ruminating foregut fermenters, particle MRT in peccaries is similar to kangaroos and shorter than in hippos (Schwarm et al. 2008, 2009). Whether food passage time through the gastrointestinal tract of peccaries is longer than in the monogastric suids has, to our knowledge, not been investigated.

The anatomy of the peccary gastro-intestinal tract as well as the type of diet found in stomach contents is well reported by (Langer 1978, 1979, 1988). However, the stomach and intestine content mass were not assessed so far, whereas Lochmiller et al. (1986) measured the mass of the emptied gut in collared peccary. In order to further

characterise the digestive function of peccaries (sensu Comizzoli et al. 1997), we report body mass, digestive organ mass, content mass of the gastrointestinal tract compartments and their length and width, as well as liver, parotis and mandibular gland mass in this study. For comparison, we report parameters of the non-ruminating foregut fermenter pygmy hippo (*Hexaprotodon liberiensis*), the monogastric hindgut-fermenter wild boar (*Sus scrofa*) and the babyrousa (*Babyrousa babyrussa*) which has been described as an intermediate form between a foregut-fermenter and a monogastric hindgut fermenter due to a pronounced stomach fornix with a prominent microbial flora (Langer 1988; MacDonald et al. 2008).

Materials and methods

Eleven collared peccaries and four white-lipped peccaries were clinically healthy but culled for population control at the zoo. Up to their death, animals had displayed a normal food intake and had been fed with a mixed diet consisting of fruits, vegetables, cooked potatoes, grass or hay supplemented three times a week with chicks, eggs, grains and concentrates. Total body mass (including blood) and net body mass (excluding blood) were measured by weighing the animals with an analogue scale. In two collared peccaries, only net body mass could be assessed. In these animals, total body mass was calculated by applying a correction factor of 5% difference, i.e. the average difference between both weights determined in the other animals. Liver mass was assessed in all animals. Parotis and mandibular total gland mass were measured

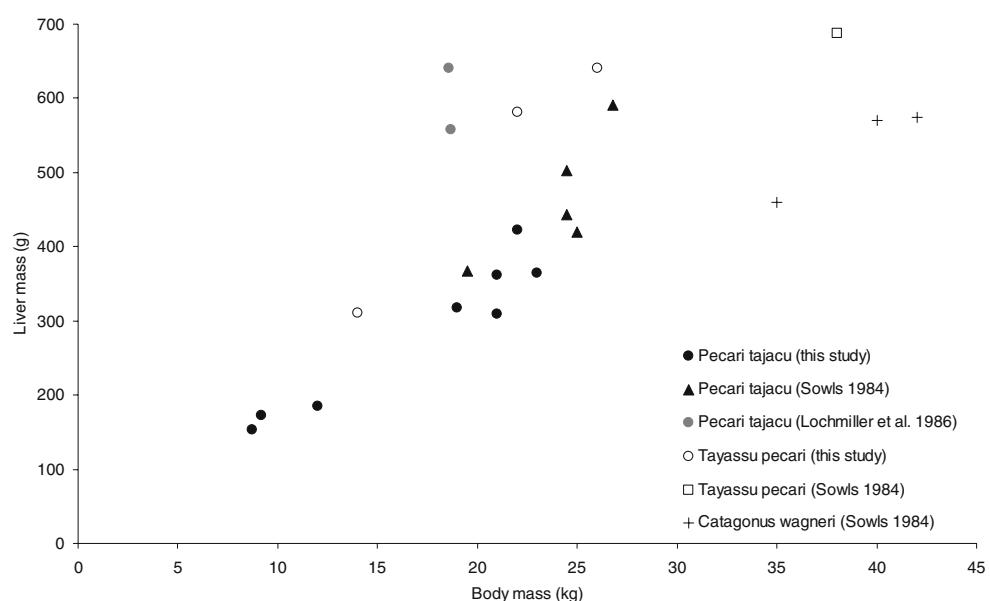

Fig. 2 Relationship between body mass (kilograms) and small intestine length (centimetres) in collared peccary (*Pecari tajacu*, this study and Lochmiller et al. 1986, mean of $n=16$), white-lipped peccary (*Tayassu pecari*, this study), wild boar (*S. scrofa*, this study), domestic pig (*S. scrofa domestica*, Pond et al. 1981, mean of $n=12$) and babirusa (*B. babyrussa*, this study). Spearman correlation coefficients (SCC): collared peccary, $n=11$, SCC=0.74, $p=0.010$

in five collared peccaries. At necropsy, all adhering mesenteries were removed from the gastrointestinal tract. The stomach, small intestine, caecum and colon were weighed individually with and without content to the nearest gramme with a portable digital scale. The length of the individual segments of the gastrointestinal tract was measured without stretching to the nearest half centimetre using a linear scale. For the measurement of the gastric pouch and the intestine segments, the shortest distance was applied. For the blindsac and the glandular stomach, two measurements are specified: the major and the minor curvature. Photographs were taken to facilitate the preparation of anatomical drawings. The Mann–Whitney U test was used for comparisons between peccaries because the sample size of 4 (white-lipped peccaries) was too small to

test for normality. Three pygmy hippos (*H. liberiensis*), one babirusa (*B. babyrussa*) and two wild boars (*S. scrofa*) were sampled opportunistically at different institutions (zoo, circus, wildlife park). These animals were either geriatric or were culled for population control. See Wings et al. (2008) for details of one pygmy hippo. Two pygmy hippos were consistently fed a diet of lucerne hay, mixed fruits and vegetables and herbivore pellets. The diet of the other pygmy hippo is not known; however, a similar feeding regime is assumed. The babirusa was fed the same diet as the peccaries, supplemented with salad. The wild boars were fed a diet of vegetables, potatoes and a compound feed. Total body mass, gastrointestinal tract content and organ mass of the mature animals were assessed as described for peccary. The length of the

Fig. 3 Relationship between body mass (kilograms) and liver mass (grams) in collared peccary (*Pecari tajacu*, Sowls 1984; Lochmiller et al. 1986 mean of $n=2 \times 8$; this study), white-lipped peccary (*Tayassu pecari*, Sowls 1984; this study) and chacoan peccary (*Catagonus wagneri*, Sowls 1984)

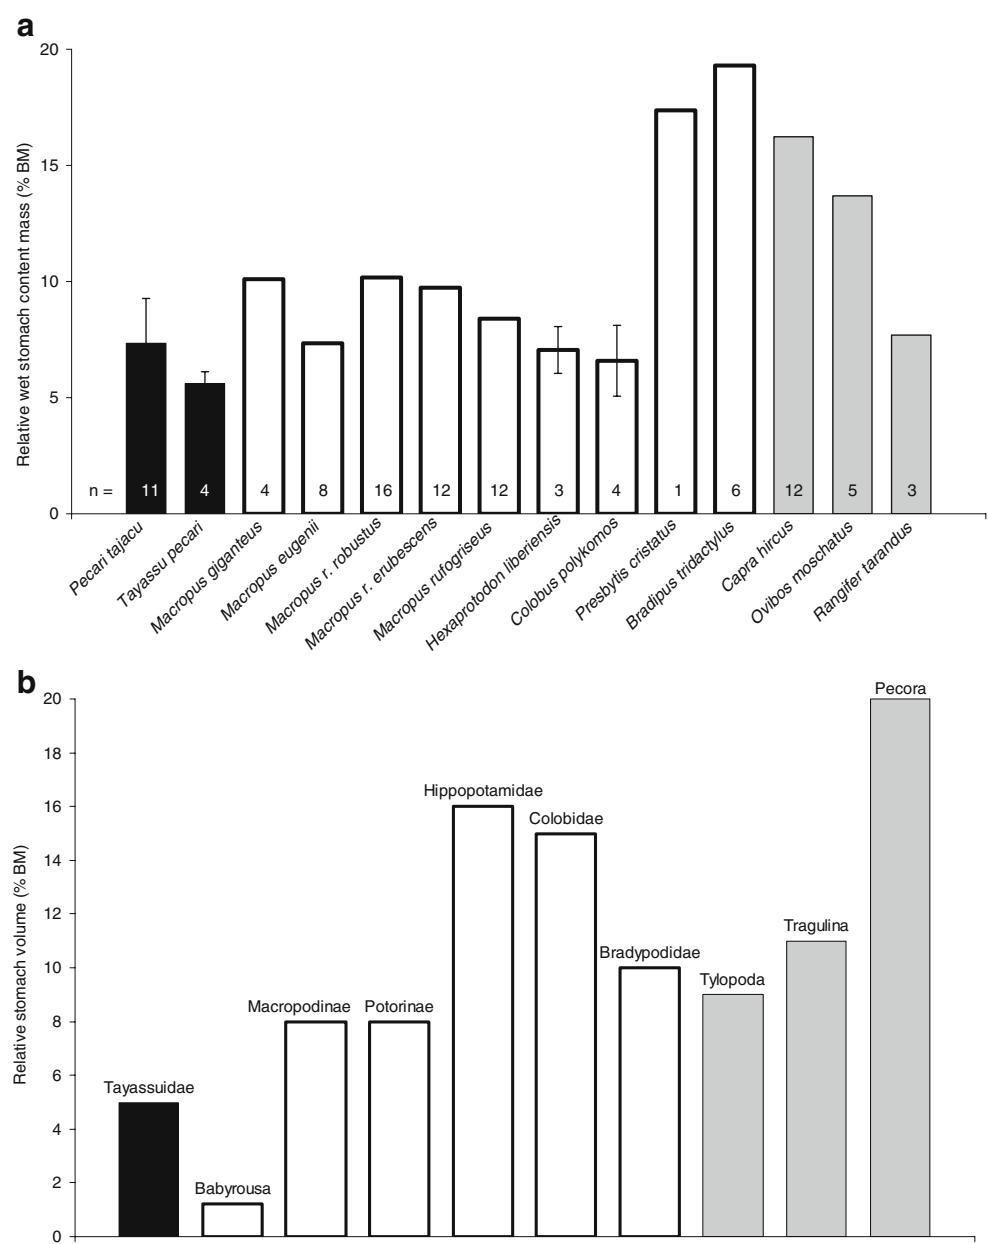

stomach compartment was measured along the central longitudinal axis.

Results

The animals were considered to be in a good body condition with no incidence of obesity (e.g. presence of mesenterial fat). The drawing of the gastrointestinal tract of a collared peccary is given in Fig. 1. The studied collared peccaries had a body mass (BM) range of 9 to 23 kg, the white-lipped peccaries of 14 to 26 kg. Body mass of collared and white-lipped peccaries did not differ significantly (Table 1); therefore, absolute parameters of the

gastro-intestinal tracts of both species could be compared. The stomach content and organ mass were of comparable size (Table 1). However, white-lipped peccaries had significantly longer large intestines than collared peccaries. And the small and large intestine organ mass was significantly higher in white-lipped than in collared peccaries. In collared peccaries, the small intestine length was related to body mass (Fig. 2). In some peccaries, a considerable amount of sand was trapped in both blindsacs of the forestomach and in the caecum (which contributes to the content mass reported in Table 1). The results for the pygmy hippo, babirusa and wild boar are also given in Table 1. The large intestine wet content mass of the monogastric hindgut-fermenting suid, the wild boar, was

not distinctively higher than that of the peccaries (4.2% of body mass, BM, $n=2$, vs. collared peccary $2.2 \pm 0.8\%$ BM and white-lipped peccary $3.1 \pm 1.5\%$ BM).

Discussion

Conclusions based on results obtained from zoo animals must be considered with caution due to differences in diet, feeding behaviour and activity between captive and free-ranging animals. Lochmiller et al. (1986) studied internal organ and gut mass and intestine length in 16 free-ranging adult collared peccaries. Although the collared peccaries of our study had a comparable average body mass (18 vs. 19 kg), we observed differences in organ mass and size. Stomach organ mass was lower in the collared peccaries of our study (349 vs. 411 g), and the small intestine was shorter (560 vs. 782 cm, Fig. 2) as well as the large intestine. Relative liver mass was also lower in the collared peccaries of our study than in the study of Lochmiller et al. (1986) (Fig. 3; on average 1.6% vs. 3.2% of total body mass). A possible explanation for the differences in relative liver mass could be a different diet: Lochmiller et al. (1986) collected the animals on the Chaparral Wildlife Management Area in Texas where they presumably fed on natural vegetation, and thus presumably on a diet with higher content of secondary plant compounds and fibre than in this zoo-based study. For browsing and grazing ruminants, it has been reported that liver size may in part reflect ability to detoxify plant secondary compounds (McArthur et al. 1991). An effect of body condition on the difference in relative liver mass is unlikely, since peccaries from both studies were lean. The peccaries in the study of Lochmiller

et al. (1986), which were shot in March in Southern Texas, showed an average absolute visceral fat depot of 110 g or about 0.6% of body mass. Although body fat was not quantified in this study, mesenteric fat was only present in one of ten collared peccaries. Indication was found that free-ranging collared peccaries ingest a diet with higher lignin content and lower digestibility than their captive counterparts (extrapolated from faecal content; Schwarm et al. 2005). A high fibre diet potentially necessitates abrasion resistance (thicker stomach walls), and it can be speculated that a longer small intestine compensates for lower digestibility. Similarly, Tyson (1683) reported the small intestine length of one individual collared peccary of unknown origin and body mass to be 822 cm and the colon length 274 cm; again, these measurements are longer than the ones from our animals.

In peccaries, the average relative wet-stomach content mass is lower compared to foregut fermenting ruminants and the majority of the kangaroos (Fig. 4a). Similarly, comparing relative stomach volumes (% BM) of different foregut fermenters collated by Langer (1988) (not explained whether stomach organ mass is included), peccaries have the smallest relative stomach of all foregut fermenters together with babyrousa (Fig. 4b). Evidently, the fermentative capacity is lower in peccaries than in other foregut fermenters. Surprisingly, the large intestine wet content mass of the monogastric, hindgut-fermenting suid, the wild boar, was not distinctively higher than that of our peccaries, suggesting that the digestive capacity of the hindgut does not vary much between these species.

The observation that a considerable amount of sand was trapped in both blindsacs of the forestomach and in the caecum of some individuals is in accord with the literature. Free-ranging peccaries have been observed to consume soil (geophagy) for postulated resources as e.g. mineral elements (Bravo et al. 2008); however, the proportion of soil to fermentable material in these animals are not known. Langer (1979) found in captive peccaries a relative increase

in sand from the gastric pouch to the pylorus and further to the caecum and rectum and stated “the increase in sand concentration relative to dry matter content is connected with a decrease in plant material, very likely because of microbial degradation of this material”. This author also observed a lot of sand in the forestomach blindsacs of peccaries in Arizona (P. Langer pers. comm.) which were wild-caught and kept in open-air enclosures some time before death. In the pygmy hippos, with access to an enclosure with natural soil, sand and gravel were also found in the forestomach blindsacs (reported in Wings et al. 2008). These findings indicate that the forestomach blindsacs of both peccaries and hippopotami will function as sedimentation traps, as suggested by Clauss et al. (2004) based on the finding that small (potentially denser) particles are sometimes—not always—retained for a longer time in the forestomach of hippos (Schwartz et al. 2008) and peccaries (Schwartz et al. 2009) than larger (potentially less dense) particles. However, such a differential excretion of particles was not observed in these species with the same consistency as, for example, the differential excretion of different-sized particles from the forestomach of ruminants (Schwartz et al. 2008; 2009), which gives rise to the suspicion that a “sedimentation trap” action might not be the primary function of the forestomach blindsacs in hippos and peccaries.

In contrast, the finding of sand being trapped in these blindsacs could, alternatively, indicate a disadvantage of the peccary (and hippopotamus) forestomach design, facilitating the accumulation of dense, indigestible material. During necropsy, we had the impression that in some animals, the sand could no longer be excreted easily because the blindsacs were stretched by the sand’s weight, causing a concomitant constriction of the blindsac opening (Fig. 5, anterior blind sac). This could be a speculative reason for the fact that this particular forestomach design is not at the base of large species radiations. Among the non-ruminant foregut fermenters, the sloth is the only other representative whose forestomach might trap dense, sedimenting material (Clauss 2004). However, due to their arboreal habits, sloths are unlikely to ingest relevant amounts of dense sand or grit, in contrast to hippos or peccaries.

The collared peccaries of this study had, with $11.3 \text{ g/kg}^{0.75}$ ($n=11$), heavier relative parotis glands than other foregut fermenters (see Table 2, e.g. in *Alces alces* $4.9 \text{ g/kg}^{0.75}$ (Hofmann et al. 2008) and in *Macropus parma* $1.1 \text{ g/kg}^{0.75}$ (Lentle et al. 2002)). Assuming that salivary gland mass, salivary flow rate and the degree of separation of the liquid and solid phase of digesta are interrelated, peccaries compared to colobine monkeys actually excrete fluids faster than particles (Schwartz et al. 2009). However, both macropods and ruminants achieve distinctively higher degrees of separation between fluid and particle passage (Schwartz et al. 2009), which suggests that, similar to the

suspicion of Hofmann et al. (2008), salivary gland size is not directly linked to saliva flow. The reason for the large size of the peccary’s parotis gland, potentially linked to the production of secondary plant compounds (e.g. oxalic acid), remains to be elucidated.

The small relative stomach and thus forestomach volume of peccaries imply a lower fermentative capacity and thus forage digestibility compared to other foregut fermenters. This, again, gives rise to the question about the relevance of a foregut to peccaries. The diet of peccaries is as diverse as the habitat they occupy—arid US southwest and dense tropical rain forests of South America. In the former habitat, peccaries consume primarily grasses and roots; in the latter habitat, they are more frugivorous (Sowls 1997). The forestomach could enable peccaries to maintain on a fibre-rich diet or deal, in conjunction with their large parotis glands, with certain plant toxins. For example, the breakdown of oxalic acid in the forestomach could be important. This toxin can be found in greater quantities in prickly pear (*Opuntia* sp.), which can constitute an “exclusive food” of peccaries in the desert areas and causes at worst renal failure (Sowls 1984, p 58 for peccaries; e.g. Allison et al. 1977, for ruminants). The relevance of the forestomach to peccaries remains enigmatic.
