Abstract

We report on the assembly and characterisation of a high potential, stable, mediator-less and cofactor free biocathode based on a fungal laccase, adsorbed on highly dispersed carbonaceous materials. First, the stability and activity of *Trametes hirsuta* laccase immobilised on different carbon particles were studied and compared to the solubilised enzyme. Based on the experimental results and a literature analysis, the carbonaceous material BM-4 was chosen to design efficient and stable biocatalysts for the production of a “floating” air diffusion laccase-based biocathode. Voltammetric characteristics and operational stability of the biocathode were investigated. The current density of oxygen reduction at the motionless biocathode in a quiet, air saturated citrate buffer (100 mM, pH 4.5, 23°C) reached values as high as 0.3 mA cm⁻² already at 0.7 V vs. NHE. The operational stability of the biocathode depended on the current density of the device. *E.g.* at low current density (20 μA cm⁻²), the biocathode lost only 5% of its initial power after one month of continuous operation. However, when the device was polarised at 150 mV it lost more than 32% of its initial power in just 10 min. We also found that co-immobilisation of laccase and peroxidase on highly dispersed carbon materials could protect the biocatalyst from rapid inactivation by hydrogen peroxide produced during electrocatalytic reactions at high current densities.

1 Introduction

Successful realisation of many important electrochemical processes, including development of fuel cell (FC) technology, requires generation of novel highly effective catalysts, which are active at ambient temperatures and physiological pH values. Optimal technological solutions can be achieved by using biocatalysts heterogeneously arranged in an electroconductive matrix, *e.g.* redox enzymes immobilised on properly selected highly dispersed materials. For cathodic processes occurring in FCs, blue multicopper oxidases (BMCO) have been identified as very promising bioelements. BMCO efficiently catalyse the reduction of O₂, a very common electron acceptor because of its high redox potential and its ready availability, at very low overpotentials [1-5].

At the end of the nineteen seventies, direct electron transfer (DET) based bioelectrocatalytic reduction of O₂ by a fungal laccase (Lc), an enzyme from the BMCO family, was discovered [6, 7]. Later this occurrence was identified in many other redox enzymes including different BMCO, *e.g.* ascorbate oxidase [8, 9] and bilirubin oxidase [10, 11], as well as fungal [12-15], plant [12, 16], and bacterial [17, 18] Lcs.

BMCO contain four copper ions which are historically classified into three types according to their spectroscopic characteristics, *viz.* the T1, T2, and T3 sites (Fig. 1, bottom) [19]. The detailed mechanism of DET reactions during BMCO function on electrodes was discussed in several publications, *e.g.* [14]. Briefly, electrodes, on which enzymes are appropriately adsorbed with the T1 site in close proximity to the electrode surface (Fig. 1, bottom), can serve as electron donors for the active centre of the enzyme, where molecular O₂ is reduced to H₂O without formation of highly reactive oxygen species. This

1

3
4
5
6 important feature, *i.e.* the absence of formation of H₂O₂ during bioelectrocatalytic four-electron reduction
7 of O₂, was confirmed using the rotating ring-disk electrode method already in 1979 [7]. Detailed
8 fundamental bioelectrochemical investigations of BMCO were performed using various planar electrodes
9 [14]. It was discovered that carbon was superior, providing efficient O₂ bioelectroreduction at high
10 potentials, whereas DET-based bioelectrocatalysis at metal electrodes seems to be much more
11 complicated [20-22]. Thus, regarding the very efficient and stable BMCO-based biocathodes assembled
12 and characterised so far, carbonaceous electrodes are preferred (*e.g.* [23, 24]).

13 For more than 30 years, Russian electrochemists have been studying O₂ bioelectroreduction by Lcs
14 adsorbed on different electrode materials [6, 7, 25-29]. In many cases bioelectrochemical results from the
15 Russian school are presented as polarisation curves with positive cathodic currents and potentials
16 expressed *vs.* the NHE, which causes some difficulties for other scientists to compare results thus
17 gathered with data already available.

18 In order to increase the efficiency of Lc-based cathodes different carbon-based dispersed materials,
19 some of them nowadays called carbon (nano)particles, were used, *viz.* channel carbon black (AD-100),
20 furnace butyric carbon blacks (PM-100, PM-105), and different coals (KM-2, AG-3, T-39, and BM-4).
21 The main physical-chemical and electrochemical properties of these materials can be found in [25, 26, 30,
22 31]. Usage of particulate carbonaceous materials with particle sizes varying from 4 nm up to 1000 nm and
23 above (the average size of Lc is *ca.* 5 nm) increased the concentration of electronically connected (*i.e.*
24 biocatalytically active) Lc up to 20 pmol cm⁻², resulting in the realisation of very efficient and stable
25 biocatalysts. For comparison, the maximal surface concentration of electrochemically active laccase on
26 planar carbon electrodes is estimated to be about 2 pmol cm⁻² [13]. Basic properties of biocatalysts based
27 on Lc adsorbed on dispersed carbon materials were studied and some results were published in Russian
28 journals [25-27], including the very first report on DET-derived BFCs based on carbon particles [29]. As
29 early as 2002, suggestions for exploitation of “air diffusion electrodes, which ensure high overall current
30 density in a biofuel cell” were given. However, such an electrode was produced only recently, *viz.* a
31 motionless air diffusion biocathode, which reached current densities as high as 20 mA cm⁻² at 200 mV in
32 a citrate buffer at room temperature [32]. The biocathode was designed based on BMCO from
33 *Escherichia coli* (CueO) adsorbed on carbon particle-modified electrodes [32].

34 One of the most promising applications of enzymatic FCs is their usage as a power source for
35 implantable and “semi-implantable” devices operating in blood, saliva, tears, sweat, and different fluids
36 of the digestive tract. It should be emphasised that the power density of actual implanted biofuel cells
37 will, in all likelihood, be limited by O₂ supply to the electrode surface, given the low solubility of O₂
38 (~0.25 mM in air saturated buffers) and its small diffusion coefficient (~2·10⁻⁵ cm² s⁻¹). One approach to
39 overcome the mass transfer problem in useful biodevices for semi-implantable applications is to construct
40 an air diffusion biocathode utilising O₂ directly from the air [29, 33]. Obviously, the power of a FC
41 depends on the current densities and operating voltages of both electrodes. Taking into account the
42 achieved operating voltages of potentially implantable DET-based bioanodes, which usually are not less
43 than 200 mV [3, 5, 34-36], one can speculate about the power density of an implanted BFC based on the
44 recently developed CueO Lc cathode [23, 32]; in spite of the impressive maximal current density of a
45 CueO Lc-based device, its power density will be limited because of the low redox potential bioelement
46 used, *viz.* CueO Lc (480 mV *vs.* NHE [37]). To overcome this problem, high redox potential BMCO, *e.g.*
47 fungal Lc and bilirubin oxidase, should be exploited.

48 Another significant problem of current BFCs is the limited operational stability, owing to a number of
49 factors, including insufficient stability of the bioelements used, *i.e.* adsorbed redox enzymes. In addition,
50 at high current densities the amount of H₂O₂, electrochemically produced on carbon materials due to two-
51 electron reduction of O₂, might be enough to inhibit the Lc, and thus deactivate potentially very efficient
52 biodevices. However, the stability of the fabricated air diffusion Lc-based biocathode is yet to be
53 investigated [32].

54 Below we describe the fabrication and characterisation of a very stable air diffusion “floating” (ADF)
55 biocathode based on a high redox potential fungal BMCO, *i.e.* *Trametes hirsuta* Lc, adsorbed on carbon
56 particles.

2 Experimental

2.1 Materials

Unless otherwise specified, all chemicals were purchased from “Sigma-Aldrich GmbH” (Germany). All solutions were prepared using water (18 M Ω) purified with a Milli-Q system from “Millipore” (USA). The ADF electrodes were fabricated using acetylene black (Russia), analogous to XC-72 produced by “Cabot” (Belgium). Two different carbon sorbents, *viz.* furnace butyric black PM-100 and carbon BM-4 (Russia), were used as carriers in the immobilisation of redox enzymes.

2.2 Enzymes

Trametes hirsuta Lc was obtained from the basidiomycete *Trametes hirsuta* (Wulfen) Pilát, strain T. *hirsuta* 56, provided by the laboratory collection of the Moscow State University of Engineering Ecology (Russia). The basidiomycete was grown by submerged cultivation as described in [38]. The Lc was isolated and purified from a culture medium according to [39]. The homogeneous preparation of the enzyme, as judged from SDS-PAGE, with a protein concentration of about 15 mg mL⁻¹ was stored in 100 mM phosphate buffer, pH 6.5 at -20 °C.

Amoracia rusticana peroxidase (Type VI-A, HRP) isolated from horseradish roots was obtained from “Sigma-Aldrich GmbH” and used without further purification. The lyophilised powder of the enzyme was stored at +4°C.

2.3 Catalytic assay

The specific activity of Lc and HRP measured toward 2,2'-azinobis-(3-ethylbenzthiazoline-6-sulfonate) (ABTS) was not less than 200 units mg⁻¹ and 500 units mg⁻¹, respectively. The activity of both enzymes, in homogeneous solutions and in an adsorbed state, was determined spectrophotometrically in 100 mM citrate-phosphate buffer, pH 4.5, at different ionic strengths (addition of KNO₃). 5 mM ABTS was used as the first enzyme substrate, *i.e.* electron donor. The concentrations of the second substrates of the enzymes, O₂ and H₂O₂ for Lc and HRP, were 0.25 mM (air-saturated buffer) and 1 mM, respectively. The absorbance change at 405 nm ($\epsilon=36000$ M⁻¹ cm⁻¹) was measured for 60 s using a UV-mini 1240 spectrophotometer from “Shimadzu Europe GmbH” (Germany). For both enzymes, one unit of activity was defined as the amount of enzyme oxidising 1 μ mol of ABTS per min under standard conditions. Specific activity is expressed as units of activity per mg of protein.

2.4 Preparation and investigation of biocatalysts

The immobilisation of pure Lc on two different carbon materials was performed by direct physical adsorption of the enzyme from a 100 mM citrate-phosphate buffer solution, pH 4.5, with a total protein concentration of about 0.1 mg mL⁻¹. For this purpose, 5 mg of carbon BM-4 or carbon-black PM-100 was dispersed in 5 ml of the buffer and the dispersions were sonicated for 10 min. After that the enzyme was added and incubated for 4 hours. For the Lc-peroxidase-BM-4 biocatalyst, simultaneous immobilisation of both enzymes from a citrate-phosphate buffer solution with a total protein concentration of about 0.1 mg mL⁻¹ (90% Lc/10% HRP (*w/w*)) was also performed.

2.5 Electrode fabrication

The air diffusion electrodes (disks, \varnothing 1.5 cm) were produced from dispersed acetylene black using F-4D (Russia), an aqueous suspension of a fluorocarbon polymer powder, as a binding and water-repellent agent. As a current conductor, a NP-2 nickel mesh (Russia) was pressed into the fabricated porous electrodes. Suspensions of bare BM-4 particles or particles modified with Lc or a Lc-peroxidase mixture (*i.e.*, two biocatalysts, *viz.* Lc-BM-4 and Lc-peroxidase-BM-4), were dropped onto the electrodes. After that, electrodes were dried and covered by Nafion from “Sigma-Aldrich GmbH” by immersion in 1% (*w/w*) Nafion solution for a few seconds.

2.6 Electrolyte

The main buffer was a 100 mM Na-citrate-phosphate buffer, pH 4.5. All electrochemical studies were performed at room temperature, which varied insignificantly, from 20 up to 23 °C, during the measurements.

2.7 Electrochemical measurements

Electrochemical measurements were performed using the three-electrode system presented in Fig. 1. A galvanostatic method was used, *i.e.* measurements of the potential of the working electrode at constant current between counter and working electrodes. For this purpose a dc (power) supply, a resistance set, an amperometer, and a voltmeter, Ionomer I-130.2M from “APK Energoservis” (Russia), were used. In all experiments a home-made one-compartment electrochemical cell (volume 10 ml), an Ag/AgCl/3M NaCl reference electrode from “Bioanalytical Systems” (USA), and a platinum mesh counter electrode from “Sigma-Aldrich GmbH”, were used. The potential values were registered under air and O₂ saturated conditions created by bubbling air and O₂ through (before the measurements) and above (during the measurements) the electrolyte. All potentials in the manuscript are reported *vs.* NHE.

3 Results and Discussion

A very high electroactive surface area confined to a small volume can be produced by employment of highly dispersed materials. Thus, in the case of O₂ electrocatalytic reduction, high power densities limited only by O₂ diffusion to the electrode surface can be obtained. Based on information available from previous investigations regarding enzyme stability and enzyme capacity [25-27, 29], two carbon materials were selected, coal BM-4 and carbon black PM-100.

3.1. Investigations of native and immobilised *Trametes hirsuta* laccase

The activity and stability of *T. hirsuta* Lc adsorbed on the carbon materials were studied and compared to the solubilised enzyme. The specific activities of the enzyme adsorbed on BM-4 and PM-100 were measured to be 110 and 48 units mg⁻¹, respectively, *vs.* 200 units mg⁻¹ for Lc in homogeneous solution. It should be emphasised that significant differences in specific activities regarding homogeneous and heterogeneous reactions is quite common for many enzymes, and it might reflect diffusion problems in the heterogeneous case rather than simple enzyme denaturation. Also, as protein flexibility is essential for Lc biocatalysis [40, 41], any restriction to protein movements as a consequence of its adsorption to the carbon surface, most likely will influence the catalytic values obtained.

An important factor affecting both activity and stability of Lc is the buffer composition. As was shown previously for *Polyporus versicolor* Lc, a citrate-phosphate buffer is preferred compared to acetate, sodium tetraborate-succinic acid, and hydrophthalate buffers [26]. Based on those results, a 100 mM citrate-phosphate buffer was selected as the electrolyte in our studies. Moreover, usage of this buffer allowed us to directly compare our results with recently published work concerning the air diffusion Lc-based biocathode [32].

Not only the electrolyte composition but also the overall ionic strength can affect the activity of the enzyme. To reduce Ohmic losses, a biocathode should function in a high ionic strength electrolyte, which can be achieved by adding a base electrolyte to the main buffer. Taking into account BMCO inhibition by halide ions, *viz.* F and Cl ions, NaClO₄ was usually used as base electrolyte [13, 14, 24, 28], but other base electrolytes such as KNO₃ and Na₂SO₄ can also be employed. In the present study the activity dependence of native and immobilised Lc on solution ionic strength adjusted using KNO₃ was investigated. It was found that immobilised Lc is about 10% less sensitive to variations of the ionic strength, compared to the solubilised enzyme. Moreover, in 3M solutions the native enzyme still showed more than 90% of its maximal activity. As was also suggested by Kano and co-workers, proton supply to the surface of the electrode could be the rate limiting step in the biocathode function and thus, high concentrations of the buffer might improve the proton availability [32].

Also, the long-term stability of native and immobilised Lc was investigated, the results of which for native Lc, as well as Lc-BM-4 and Lc-PM-100 biocatalysts are presented in Fig. 2. From the figure, it is evident that immobilisation of the enzyme on BM-4 improved the stability of Lc compared to the enzyme in homogeneous solution and especially compared to the Lc-PM-100 biocatalyst. Moreover, Lc-BM-4

retained 55% of its initial activity after storage in the citrate-phosphate buffer for a month. Thus, Lc-BM-4 was selected for the fabrication of “floating” air diffusion cathodes.

3.2 Electrochemical characterisation of air diffusion “floating” electrode

A schematic view of the fabricated ADF electrode is shown in Fig. 1. The electrode, which can be represented as a sandwich membrane separating the electrolyte and air, comprises two layers, the active and the hydrophobic, respectively. The layer adjacent to the electrolyte, *i.e.* the active layer, is hydrophilic and it carries the biocatalysts, *i.e.* redox enzymes adsorbed on carbonaceous materials; the air facing layer is hydrophobic. During operation of the ADF electrode, atmospheric O₂ diffuses through the hydrophobic layer and is brought into contact with the electrolyte when penetrating through the active, hydrophilic layer. Therefore, the O₂ bioelectroreduction is localised at the electrode-electrolyte-air interface. When a gaseous biooxidant, *e.g.* molecular O₂, is supplied, electrochemical processes occur in specific volume elements of porous electrodes, which are available for both oxidant and electrolyte. Thus, the efficiency of ADF electrodes depends on the distribution of biocatalyst, O₂, and electrolyte inside the pores of the electrode. Establishing proper electrochemistry conditions is essential, but to ensure real world functionality, many other parameters of this complex heterogeneous system need to be considered [32, 33]. Two of the most important factors are (i) the potential established on the electrode, and (ii) the operational stability.

The open-circuit (stationary, steady-state) potential of the ADF electrode was measured to be very high, 850 mV *vs.* NHE (Fig. 3). This value is in agreement with open-circuit potentials of carbon electrodes modified with high redox potential *Trametes* Lcs, reported to be in the range from 670 mV up to 910 mV depending on electrode material, Lc source, solution pH, and amount of enzyme on the electrode surface [3, 7, 13, 14]. We also found that potentials established were almost independent of O₂ concentrations. The redox equilibrium potential of the O₂/H₂O couple at pH 4.5 is +960 mV, *e.g.* only 110 mV higher than the starting potential of O₂ electroreduction on the ADF electrode (Fig. 3).

Polarisation curves recorded on air diffusion electrodes with and without biocatalysts are also presented in Fig. 3. As one can clearly see from the figure, Lc significantly decreases the overpotential needed for O₂ electroreduction (compare curve 3 with curves 1 and 2). In accordance with the mechanism of Lc on carbon electrodes [3, 9, 14], the half-wave potential of O₂ bioelectroreduction should coincide with the potential of the T1 site, the initial electron acceptor of the enzyme during heterogeneous electron transfer. Obviously, half-wave potentials registered in our studies (Fig. 3) coincide well with the redox potential of *Trametes hirsuta* Lc, measured to be 780 mV ± 10 mV *vs.* NHE at pH about 6 [39, 42]. We also noticed that the initial parts of both curves, 1 and 2, are almost identical, pointing to the fact that at low overpotentials, the bioelectrochemical reaction of O₂ reduction occurs in the kinetic mode, *i.e.* the process is limited by DET between carbon particles and the redox enzyme. However, at high overpotentials, the bioelectrochemical reaction has, in all likelihood, mixed kinetics as indicated by a current doubling when a +670 mV potential is applied to the electrode under O₂-saturated conditions, compared to air-saturation (*cf.* curves 1 and 2 in Fig. 4). The very high open-circuit potentials of the device (850 mV *vs.* NHE) along with fast equilibration of the ADF electrode resulted in the device delivering relatively high power, in spite of the low maximal current densities obtained, *viz.* 0.3 and 0.6 mA cm⁻² under air and O₂ saturated conditions, respectively. *E.g.* a power density of 0.21 mW cm⁻² for the air diffusion cathode can be calculated at potential as high as 0.7 V, whereas the biodevice based on low redox potential CueO Lc had zero power at this voltage [32]. The fast equilibration of the Lc-BM-4-based ADF electrode is, most likely, due to fast DET between carbon particles and the T1 site of Lc, *i.e.* the overpotential needed to achieve the current plateau under air saturated conditions was only 120 mV (Fig. 3).

The reproducibility of ADF electrodes was also addressed and mean values were used to draw the conclusions. Hence, three different electrodes were examined and showed small deviations regarding the main electrochemical parameters, *i.e.* differences in current densities and open-circuit potentials did not exceed 5%.

The ADF electrode showed excellent stability at low current densities; the biodevice lost less than 5% of its initial operating potential after one month of continuous operation in 100 mM citrate-phosphate buffer, pH 4.5. In other words, the biocathode power density degraded from 16.5 to 15.8 μW cm⁻² after 31 days of operation (Fig. 4). However, at higher currents, *i.e.* when significant overpotentials were applied to the biocathode, the bioelectrochemical activity deteriorated sharply (Fig. 5). To appreciate the possible reasons for the inactivation of the biodevices, additional voltammetric studies were performed.

1
2
3
4
5
6 It is widely accepted that when relatively low potentials are applied to carbon electrodes (450 mV vs.
7 NHE and below), H₂O₂ can be electrochemically produced in a two-electron reduction of molecular O₂ on
8 the electrode surface. We speculated that when significant overpotentials were applied to the biocathode,
9 the amount of electrochemically produced H₂O₂ might be enough to inhibit the Lc immobilised on BM-4,
10 and hence drastically deactivate the biodevice. In order to evaluate our assumption, as well as to find a
11 possible solution to the problem, two biocathodes based on different biocatalysts were prepared, as
12 described in the experimental section. Horseradish peroxidase immobilised on carbon electrodes catalyses
13 bioelectroreduction of H₂O₂ to H₂O [43, 44], and co-immobilisation of which could possibly prevent
14 deactivation of Lc immobilised on the same electrode. Indeed, it was found that the operating stability of
15 the air diffusion biocathode based on a combined Lc-peroxidase-BM-4 biocatalyst was significantly
16 improved compared to the Lc-BM-4 biocathode. *E.g.*, when polarised at 150 mV, the Lc-BM-4-based air
17 diffusion biocathode lost more than 32% of its initial power in just 10 min of continuous operation (Fig.
18 5), whereas the combined Lc-peroxidase-BM-4-based biocathode retained more than 87% of its initial
19 power under the same conditions (Fig. 6). However, co-immobilisation did reduce the maximal current
20 density of the biocathode (*cf.* curves 1 and 2 in Figs. 5 and 6) starting at 13% reduction at low
21 overpotentials, and reaching 32% and more at high overpotentials.

22 23 3.3. Short discussion and further perspectives

24 We have shown that the efficiency of a Lc-based biocathode depended on many factors, such as the
25 nature of the bioelectrocatalyst, the properties of the electroconductive matrixes for enzyme
26 immobilisation, the composition and ionic strength of electrolytes, etc. The ADF electrode is very stable
27 at low current densities. The duration of continuous operation of the device at significant overpotentials
28 depends on the biocatalysts, as well as the buffer capacity of the electrolyte used. Both efficiency and
29 operational stability of the designed device might be further improved, *e.g.* by optimising the composition
30 of Lc-peroxidase-carbon particles-based biocatalysts and by optimising the hydrophobic layer to enhance
31 O₂ supply to the biocatalysts by usage of different polymers.

32 33 4 Conclusion

34 Herein we report the fabrication and characterisation of a mediatorless and soluble cofactor free, stable,
35 high potential air diffusion biocathode, which might be useful to construct very efficient and non-toxic
36 cathodes of BFCs. The latter can be pasted or otherwise attached and operate at air-liquid interfaces, *e.g.*
37 in sweat, saliva, and tear fluids. The designed biocathode showed a maximal current density of more than
38 0.5 mA cm⁻², already at 0.7 V vs. NHE. The operational stability of the biocathode depended on the
39 current density of the device. At low current density the biocathode is stable for one month of continuous
40 operation, whereas when polarised at high overpotentials, the device loses a significant fraction of its
41 initial power in just 10 min. The most likely reason for the rapid deterioration at high overpotentials is
42 electrochemically produced H₂O₂, which deactivates Lc-based biocathodes. Thus, co-immobilisation of
43 laccase and peroxidase on carbon particles protects the biocatalyst from rapid inactivation at high current
44 densities.

A principal scheme of an electrochemical setup. Working electrode – “floating” air diffusion electrode (1 – pores filled with air, 2 – pores filled with electrolyte, 3 – biocatalysts based on *Trametes hirsuta* laccase adsorbed on dispersed carbon materials, 4 – Nafion layer, 5 – active layer, 6 – hydrophobic layer); Reference electrode – Ag|AgCl|KCl_{sat} electrode; Counter electrode – platinum mesh electrode.

Comparison of long-term stabilities of *Trametes hirsuta* laccase in homogeneous solution and in the adsorbed state (100 mM citrate-phosphate buffer, pH 4.5, 20-23 °C): 1 – native enzyme; 2 – enzyme immobilised on carbon-black PM-100; 3 – enzyme immobilised on carbon BM-4.
260x170mm (72 x 72 DPI)

Review

Polarisation curves of oxygen electroreduction on a "floating" air diffusion electrode with and without *Trametes hirsuta* laccase immobilised on carbon BM-4 (100 mM citrate-phosphate buffer, pH 4.5): 1 – in air; 2 – in oxygen; 3 – in the absence of enzyme.
259x192mm (72 x 72 DPI)

view

Changes in potential of a "floating" air diffusion electrode based on *Trametes hirsuta* Lc-BM-4 catalyst at a constant current density of $20 \mu\text{A cm}^{-2}$ (100 mM air-saturated citrate-phosphate buffer, pH 4.5).
260x191mm (72 x 72 DPI)

view

Changes in polarisation curves of a "floating" air diffusion electrode based on *Trametes hirsuta* Lc-BM-4 catalyst (100 mM O₂-saturated citrate-phosphate buffer, pH 4.5). 1 – initial polarisation curve; 2 – polarisation curve recorded after 10 min of electrode polarisation at 150 mV vs. NHE.
260x168mm (72 x 72 DPI)

Influence of peroxidase on the voltammetric characteristics of oxygen electroreduction on a "floating" air diffusion electrode (100 mM O₂-saturated citrate-phosphate buffer, pH 4.5). 1 – initial polarisation curve; 2 – polarisation curve recorded after 10 min of electrode polarisation at 150 mV vs. NHE.
260x168mm (72 x 72 DPI)
