Abstract: Introduction: Necrotizing fasciitis is characterized by fulminant destruction of soft tissue. Patients present with signs of systemic inflammation as well as local tense edema along with bullae and subcutaneous gas.

Case presentation: A 46 year-old male was transferred to our tertiary-care center with a necrotizing fasciitis of the right forearm and acute kidney injury. To find causative pathogens/conditions of the necrotizing fasciitis microbiological, viral tests as well as immunological parameters (ANCA, ANA, cryoglobulines, anti-SM antibodies) were analyzed, but were all negative. A kidney biopsy revealed a non-putride interstitial nephritis. Despite adequate surgical therapy of the fasciitis and empiric antibiotic therapy, the patient's condition did not improve significantly. He developed fever up to 39 degrees Celsius while being under continued antibiotic therapy. A progressive increase of the white blood cell count was observed with predominance of monocytes (44%). A bone marrow biopsy showed an acute myelogenous leukaemia. With successful treatment of the leukaemia, the patient recovered from his fasciitis.

Conclusion: Necrotizing fasciitis in patients with leukemia has been occasionally reported, relating the fasciitis to an infection in the immunocompromised condition. Our case is most likely the first reported case of true paraneoplastic fasciitis in leukemia because all other potential causes including infection were negative.

Response to Reviewers: We thank the reviewer for his/her valuable comments.

The title was changed according to the suggestion of the reviewer. In addition, we shortened the manuscript by 30% as suggested by the editor.

Necrotizing fasciitis and acute kidney injury in a patient with acute myelogenous leukemia - case presentation and review of the literature

Dear Editor,

Necrotizing fasciitis is characterized by fulminant destruction of soft tissue. Associated conditions include intravenous drug use, diabetes mellitus, obesity and immunosuppression [1]. It is divided into two types: type I is a mixed aerobic and anaerobic bacterial infection. Type II refers to a mono-microbial infection caused by group A streptococci. While type I primarily occurs in immuno-compromised patients, type II can manifest in any age group and among patients who do not have complicated medical illnesses [2]. Therapy consists of early and complete surgical debridement and sufficient antibiotic therapy. Antibiotic therapy alone is associated with a mortality rate approaching 100 percent [1]. We report a patient with severe fasciitis of the right arm suggestive of paraneoplastic fasciitis and acute renal failure.

A 46 year-old male was transferred to our tertiary-care center with a necrotizing fasciitis of the right forearm and an eleveated serum creatinine value of 400 µmol/L. The patient had been healthy until four weeks prior to admission when he presented to a general practitioner with pharyngitis and fever. He received penicillin for 7 days and recovered from the pharyngitis. However, undulating fever up to 39 degrees Celsius recurred after cessation of antibiotic therapy, together with generalized joint pain and myalgias. He took nonsteroidal anti-inflammatory drugs (ibuprofen) over several days, which relieved his symptoms. Two weeks prior to admission the patient developed local pain and swelling of the right forearm. Initial laboratory parameters showed a C-reactive protein (CRP) level of 310 mg/L, a white blood cell count of 25.000 cells/uL and a creatine kinase (CK) of 602 U/L. Computed tomography showed massive edema of subcutaneous tissue of the right forearm. Several aerobic and anaerobic blood culture samples remained sterile. Tissue from repeated surgical debridements was cultured and stained for micro-organisms, but showed negative results (**Figure 1a, b**). A transthoracal and transesophageal echocardiography did not reveal signs of endocarditis. Viral tests, including hanta virus were unremarkable. ANCA, ANA,

cryoglobulines and anti-SM antibodies were all negative. A kidney biopsy was performed and showed a non-putride interstitial nephritis. No leukaemic infiltrates were present. The affected tissue of the right forearm was immediately surgically removed. A systemic antiinfectious treatment regimen including intravenous penicillin, clindamycin, meropenem, amphotericin B and fluconazole was initiated. Moreover, the interstitial nephritis was treated with prednisolone in a concentration of 1 mg/kg body weight, which was tapered over 15 weeks to 5 mg once daily. Over the next two weeks the white leukocyte count showed a transient fall to a minimum of 17.700/µL, C-reactive protein levels fell to 170 mg/L. Nevertheless, the patient's overall clinical condition improved only temporarily. He developed fever up to 39 degrees Celsius while being under continued antibiotic therapy. A progressive increase of the white blood cell count to 82.200 cells/µL was observed. The differential blood cell count revealed rising numbers of monocytes, from a minimum value of 10.200/µL on day 5 after admission to 36.000/µL on day 18 (44% of the white blood cells). A bone marrow biopsy showed a myelodysplastic-myeloproliferative disorder with an excessive proliferation of the monopoiesis (Figure 1c, d). Cytogenetics revealed a normal karyotype with a constitutional inv(9). Molecular analysis of the bone marrow cells revealed an NPM1 exon 12 mutation and thus the diagnosis of a molecular defined acute myeloblastic leukemia according to the current WHO-classification was established. Induction chemotherapy with cytarabin, daunorubicin and vesanoid was initiated resulting in a complete remission. Following chemotherapy, the inflammation of the right forearm gradually regressed and the wound was successfully skin-grafted with autologous tissue from the thigh within three weeks. Also, renal function recovered to normal values and remained stable.

At the initial presentation, the clinical symptoms and course of the patient's condition was most compatible with a bacteria-associated (e.g. group A streptococci) respiratory infection. In that context, the most likely cause of acute renal failure was post-streptococcal glomerulonephritis or tubulointerstitial nephritis due to the infection or hypersensitivity to the pharmacological therapy. We believe that the interstitial nephritis found in the biopsy is most likely associated with the pharmacological treatment. The fact that bacteria could not be isolated in multiple specimens of the resected tissue and in blood cultures does not support bacteria-associated nephritis. In light of the final diagnosis of the patient –acute myeloblastic leukemia- tubulointerstitial nephritis could have been associated with this disease as reported by Elsurer et al. in two cases of acute interstitial nephritis secondary to acute leukaemia [3]. However, we did not detect any leukemic infiltrates in the kidney.

Leukemia could only be suspected by the patient's individual clinical course. Particularly, the recurrence of fever while being on intense antibiotic therapy in combination with the dramatic increase in white blood cell count, which was predominated by monocytes, led to the suspicion of an underlying malignant disorder. The bone marrow biopsy and molecular analysis finally showed an acute myeloblastic leukemia.

The exact cause of the necrotizing fasciitis in the presented case is unclear. We believe that the fasciitis in our case is a true paraneoplastic phenomenon. To this end, we did not identify other causes like vasculitis, cryoglobulinaemia, polymyositis or viral infections. Also, druginduced fasciitis is unlikely. Type I necrotizing fasciitis would have been an attractive explanation. We did, however, not have any positive microbiological results in multiple blood cultures, swabs and tissue cultures.

We performed a literature search to find cases with necrotizing fasciitis secondary to leukaemia (**Table 1**). Necrotizing fasciitis secondary to leukaemia has been reported in few instances. Most of the reported patients had acute forms of leukaemia and were at very young or relatively old age. Half of the cases had pseudomonas aeruginosa as the putative trigger of the fasciitis. However, no patient with leukaemia was reported to develop necrotizing fasciitis without a bacterial trigger. In our patient, we were not able to identify a bacterial cause

Therefore, our case is most likely the first reported patient with paraneoplastic fasciitis secondary to leukaemia.

Figure 1:

A: (H&E, 20x):

Necrotizing fasciitis/myositis in low power magnification showing necrobiotic striated muscle fibres with adjacent and multifocal dense inflammatory infiltrate.

B: (H&E, 100x):

In higher magnification remnants of necrotic muscle fibres are encased in dense infiltrates of neutrophilic granulocytes.

C: (Giemsa, 40x):

Bone marrow biopsy showing a hypercellular marrow with prominent (non-neoplastic) megakaryocytes. Even at low power a rather monotonous mononuclear proliferation and a loss of the regular erythro- and granulopoesis can be appreciated.

D: (Giemsa, 400x):

Here the monotonous proliferation of blasts including mitotic forms is shown at higher magnification. Regular elements of hematopoesis are lacking, blasts with nuclear clearing, prominent nucleoli and sometimes rather convoluted nuclear outlines predominate.
