Key Words: Chlamydia, Screening

Abstract

Background: England's National Chlamydia Screening Programme (NCSP) provides opportunistic testing for 15-24 year olds in healthcare and non-healthcare settings. We aimed to explore relationships between coverage and positivity in relation to demographic characteristics or setting, in order to inform efficient and sustainable implementation of the NCSP.

Methods: We analysed mapped NCSP testing data from the South East region of England between April 2006 and March 2007 inclusive to population characteristics. Coverage was estimated by sex, demographic characteristics and service characteristics, and variation in positivity by setting and population group.

Results: Coverage in females was lower in the least deprived areas compared to the most deprived areas (Odds Ratio (OR)-0.48; 95%CI: 0.45-0.50). Testing rates were lower in 20-24 year olds compared to 15-19 year olds (OR 0.69 95%CI: 0.67-0.72 for females and OR-0.67; 95%CI: 0.64-0.71 for males), but positivity was higher in older males.

Females were tested most often in healthcare services which also identified the most positives. The greatest proportions male tests were in university (27%) and military (19%) settings which only identified a total of 11% and 13% of total male positives respectively. More chlamydia positive males were identified through healthcare services despite fewer numbers of tests.

Conclusions: Testing of males focussed on institutional settings where there is a low yield of positives, and limited capacity for expansion. By contrast, the testing of females, especially in urban environments, was mainly through established healthcare services. Future strategies should prioritise increasing male testing in healthcare settings.

Introduction

Genital chlamydial infection (chlamydia) is the commonest sexually transmitted infection (STI) diagnosed in England. The prevalence among those accepting screening in England in 2006/2007 was over 10% in males and females aged 16-24.¹ Complications associated with Chlamydia include pelvic inflammatory disease which can lead to infertility and ectopic pregnancy.²

England began to roll out its National Chlamydia Screening Programme (NCSP) in 2003, with testing occurring throughout the country by 2007. The NCSP targets males and females aged under 25 years through opportunistic screening within both healthcare settings (excluding GUM) and non-healthcare settings.³ It differs from a national pilot programme⁴ and from the chlamydia screening studies (ClaSS)⁵ in having less reliance on primary care, and to date coverage rates regionally and nationally have not been comparable with these pilots which achieved testing of 50% of the target female population in Portsmouth and 39% in Wirral in a one year period.⁴ Modelling studies on Chlamydia screening in England also demonstrated that not only does coverage have to be high but it is also important that populations known to have higher positivity are effectively targeted.⁶

The data from the first year of the NCSP (April 2003 – March 2004) have been reported, including positivity by both behavioural and demographic variables.⁷ While females 16-19 had comparable positivity to 20-24 years olds, among males aged 16-19, positivity was lower than in those aged 20-24.⁷ Individuals of black ethnicities showed higher positivity compared to white ethnicities. Testing volumes were highest in contraceptive clinics, youth services and general practice where positivity was at least 8.3% in females and 7.6% in males. Universities contributed 3% of female tests and 25% of male tests with positivity of 5.0% and 4.7% respectively.

Prior to the NCSP, chlamydia diagnoses were shown to be higher in more deprived areas, and this was not explained by differential testing rates.⁸ Modelling studies estimate that the NCSP needs to screen at least 36% of sexually active individuals under 25 years annually to deliver its anticipated health benefits.⁶ Including males in the model results in a greater and faster reduction of prevalence, but requires considerably more testing. Inequalities in coverage, if the most at risk were less likely to be tested, may result in a less efficient and equitable outcome of the screening programme.⁸

In this study we explored coverage and positivity of tests within the NCSP within the South East region of England, in relation to demographic characteristics and settings, in order to inform equitable implementation of the programme.

Methods

Over 8.3 Million individuals are resident in the South East region of England, whom 11% belong to the 16-24 year old age group eligible for Chlamydia screening. South East England surrounds London to the South and West, and contains both rural and urban districts.⁹ We analysed NCSP anonymised testing data over a one year period (April 2006–March 2007), including all individuals under 25 years old tested through the programme within the South East region of England.

The anonymised data available to us included test result, sex, postcode of residence, ethnicity, result, age in years, and clinic type. We used the 2006 National Administrative Codes Service Postcode Directory¹⁰ to map postcodes to administrative geographies based on population size, called Lower Super Output Areas (LSOA), of which populations estimates are also available, in order to estimate coverage. Not all tests mapped to the South East and these were categorised into three groups: postcodes within the South East; postcode outside the South East; and, postcode not able to be mapped (including those where the postcode was blank or incorrect).

South East postcodes were then sub categorised into screens with postcodes identical to the clinic where they were tested and others.

Mappable South East postcodes were assigned to urban/rural areas category using the Postcode Directory. Areas were classed as urban if they were within a settlement with at least 10,000 people, and rural if under 10,000.

The 2007 English Indices of Multiple Deprivation (IMD) is derived from 37 different indicators which cover: Income, Employment, Health and Disability, Education, Skills and Training, Barriers to Housing and Services, Living Environment and Crime. These are weighted and combined to create the overall IMD 2007 rank for all LSOAs throughout the country.¹¹ LSOAs within the South East region were split into quintiles according to their national rank for both the coverage and positivity analyses. For the coverage analyses the urban/rural variable was assigned at LSOA level; where both urban and rural postcodes were represented the mode was taken and if equal, urban was assigned.

The setting of each test was assigned to healthcare or non-healthcare settings according to NCSP guidance at that time.³ Healthcare includes accident and emergency (which also includes minor injuries and walk in centres), community contraceptive services, general practice, gynaecology and obstetrics, pharmacy, prison, sexual health services, termination of pregnancy. Non-healthcare settings include Chlamydia screening offices, military, outreach, postal kits, universities (including colleges and schools) and youth services.

Ethics review and data protection

The analysis was undertaken as a service evaluation by the Health Protection Agency which manages the NCSP and holds its dataset. As such, no separate ethical review was required.

The project was approved by appropriate senior managers, and standard procedures for secure

handling of data on internal secure servers within the HPA were followed, with no identifiable, psuedoanaonymised data of postcode data being transferred outside the HPA.

Testing coverage analyses within the NCSP

The Office of National Statistics provided mid-2005 population estimates for LSOAs by sex and for the age groups 15-19 and 20-24.¹² Counts of tests within each LSOA, by age group and sex were generated. Poisson regression was then used to estimate incident rate ratios for testing coverage by age group, urban/rural location and deprivation stratified by sex. This assumes a Poisson distribution, that is all events, in this case tests, are independent. The individuals tested that had a postcode that could not be mapped or who were resident outside of the South East were excluded.

Where a postcode of residence is identical to the clinic in which the test was taken, it may not be a true residential postcode (eg university testing events). This could result in an over-representation of individuals living or attending establishments (eg university residence, military bases) on a non-permanent basis, since these individuals would not be counted within population estimates. We therefore examined coverage at LSOA level excluding tests with a postcode of residence identical to the clinic postcode, in order to determine whether these tests skewed the distribution and should therefore be removed from coverage analyses.

Positivity analyses

Positivity was defined as the proportion of tests with a positive result recorded. Logistic regression was used to identify possible explanatory variables for positivity within this dataset. Multivariate analyses for separate male and female analyses included all variables that were shown to have an association with positivity with a p-value of less than 0.15 in univariate analyses for either sex. Setting was derived from clinic types so was not included in multivariate analyses.

The multivariate models in this study were used to describe testing and positivity with respect to a number of variables, not to inform a predictive model, and investigating possible interactions or effect modification between variables was not within the scope of this study.

Results

Data on 26,146 tests were available. The demographic and geographic distribution of those tested is shown in Table 1. Twenty-five percent of all tests were in males and 75% in females. The majority of all tests were in the 16-19 year age group (58% of male tests, 53% of female tests), followed by the 20-24 year age group (37% male, 38% female) and then the under 16 year olds (5% male, 10% female). In both sexes, 12% of tests could not be mapped to the postcode directory.

The most common clinic types for testing of females were community contraception services (35%), youth services (22%) and general practice (17%). For males the most common clinic types were universities (27%), military (19%) and youth services (16%). More tests were done in healthcare than non-healthcare settings for females (59%) but the reverse was true males (28%).

Coverage of testing within the South East NCSP

As seen in Table 2 1.0% of males and 3.3% of females aged 15-24 were tested. Compared to 15-19 year olds, both males and females aged 20-24 were less likely to be tested (OR 0.67, 95%CI 0.64-0.71 for males and 0.69, 95%CI 0.67-0.72 for females).

As shown in table 1, 28.1% of tests in males had a postcode that was identical to the postcode of the clinic where the sample was taken, whereas for females this only accounted for 3.8% of tests. In some LSOAs coverage was almost 200%, and was clearly inaccurate at this low level of geography. Of these tests in males, the clinic types reporting the highest numbers were military (1,045; 57.5%), universities (326; 18.0%), general practice (295; 16.2%) and prison (76;

4.2%). These poorly documented tests therefore are most likely to bias estimates where military and universities are located and were removed for the coverage by urban/rural status and IMD (both of which are also assigned by Postcode).

Testing coverage was lower in rural areas than urban centres for males and females, with ORs 0.77 (95%CI 0.70/0.84) and 0.60 (95%CI 0.57-0.63) respectively. For females, testing coverage shows an increase a linear relationship with IMD and the adjusted odds ratio of being tested in the least deprived compared to the most deprived category was 0.48 (95%CI 0.45-0.50). For males the association between testing coverage and deprivation (IMD) is not linear but rather is U-shaped, with the middle categories of deprivation having the lowest coverage.

Positivity of tests by population sub-group

Overall positivity was 7.4% in males and 8.8% in females (Table 3). Univariate analyses showed evidence of associations between positivity and all variables of interest, except for urban/rural location in males. All variables (except urban/rural for males) were therefore included in the models of testing positivity.

For males, positivity was highest in 20-24 year olds (8.6%); while both 16-19 and <16 age groups showed lower positivity with AOR of 0.62 (95%CI 0.49-0.79) and 0.21 (95%CI 0.10-0.45) respectively after accounting for other variables. Positivity in 20-24 year old females was 7.6%, and in contrast to males was similar to 16-19 year olds (AOR 1.04, 95%CI 0.92-1.17) and similarly to males was lower in <16 year olds (AOR 0.46, 95%CI 0.36-0.60).

Positivity was higher in black males compared to positivity in white ethnicities (AOR 2.15, 95%CI 1.40-3.29) but lower in females of Asian ethnicities (AOR 0.26, 95% 0.08-0.82).

Males living in less deprived areas were less likely to test positive than males in more deprived areas (AOR 0.63 95%CI 0.43-0.92, data available in web table). Crude ORs for testing positivity in males showed greater differences between IMD categories than those observed in

the adjusted analyses suggesting that the association observed is confounded by other variable/s within the model. Positivity in females varied by deprivation in a non-linear fashion.

In males, tests with a postcode identical to the clinic had lower positivity than those with a different postcode (AOR 0.60, 95%CI 0.40-0.88). For females, differences observed in the crude analyses were no longer significant in the multivariate model which suggests that this association is confounded by other variable/s within the model.

The distribution of positive tests was analysed by clinic type. Positivity in general practice was 9.4% for males and 8.2% for females. Community contraception services and youth services had comparable or higher positivity, universities showed lower positivity than general practice for both sexes and military showed lower positivity in males. Community contraception services, youth services and general practice identified the majority of positives for both males and female. In total, 44.0% of positive males were identified through healthcare settings compared to 60.8% for females.

Discussion

In the fourth year of the NCSP in the South East 1.0% of males and 3.3% of females aged 15-24 were tested. Both testing coverage and positivity varied with demographic factors, and higher coverage therefore did not necessarily correspond with a higher yield of positives. Low positivity was observed in universities and in males aged 15-19 and males tested through military settings. Although some non-healthcare settings such as outreach and Chlamydia screening offices (data available in web tables) showed positivity comparable to general practice, it may be difficult to maintain regular screening in these settings, and regular screening is essential for sustained reductions in transmission.

This is the first study describing the associations of coverage and positivity in relation to deprivation and residential status at a sub-national level, and informs the planning of NCSP rollout in contrasting demographic settings. By focusing on the contribution of various clinic

types and their identification of positives, it adds to our understanding of the programme by clinic type and setting overall.

The limitations of this study point to improvements that need to be made in the collection of data, in order to assess the NCSP in future. We assumed that the postcode of residence should not generally be identical to the clinic where the test was done. In some areas such tests appear to be over-represented, especially for males and within military and university settings. Further work is required to ascertain of the true proportion of tests where patient postcode should correctly be identical to clinic postcode, since they render coverage analyses and thus programme evaluation inaccurate. Where postcode of residence is not complete or is incorrect such tests can not be analysed with respect to deprivation and urban/rural classification or at any geographical area (without using a proxy measure such as programme area). IMD and rural/urban classification are derived from postcode and any wrong assignment of individuals to a postcode could bias all these analyses.

We calculated testing coverage using total population estimates for the 15 to 24 age group. However, the target population of NCSP is individuals under 25 that are sexually active, so our estimates in this study are an underestimate of true testing coverage. However, the Department of Health also measures coverage of the programme using the 15 to 24 population as the denominator and so our method does allow for overall comparison with data from the Department of Health. It is also possible that some of the services classified as “youth services” might have been more appropriately described as “contraception services”, and this may have led to some misclassification of tests by service type.

We were not able to provide estimates of coverage by ethnicity, due to limitations in the public health datasets available to us at lower super output level and within settings. We also did not examine interactions or effect modification which may be occurring between variables. Because IMD and urban/rural were all derived from postcode this may confound any associations observed between each of the variables and either screening coverage or positivity.

Our data indicate that Chlamydia screening in the South East of England needs to be better targeted, especially in males, while increasing the volume of testing. Coverage, as elsewhere in England,¹ was considerably below modelling estimates of their coverage required to achieve disease control,⁶ and below the coverage achieved in the one year periods of the Department of Health⁴ and ClaSS pilots of chlamydia screening.¹³ These focussed on primary care in order to achieve high coverage. The focus we saw on large military and university settings, especially for males can generate a large number of tests, but with low positivity. These institutional settings also have a finite limit to the amount of testing they can sustain, which if targets are to be met would equate to a relatively small proportion of overall tests. In the South East they appear to be targeted at groups of young people at lower risk. A strategy that can give access to both high numbers of the target population and a wide variety of individuals needs to be developed. This will require further engagement with general practice, contraceptive services and youth clinics, all of which can deliver high numbers of tests and demonstrate relatively high positivity compared to other settings. It is often claimed that men under-utilise general practice, but consultation rates in 15-19 year old and 20-24 year old males were 2.83 and 3.40 per person year respectively in 2007¹⁴ suggesting that opportunistic testing in primary care may be more realistic than is generally assumed.

Ongoing data analyses of the kind we demonstrate here, describing the distribution of testing coverage and positivity will be required to provide continuous evaluation and highlight areas where current targeting could be improved. Such analyses can assist local and national programmes improve their strategy for the targeting of testing in order to improve equity of coverage, increase testing volumes and detect a greater proportion of Chlamydia infections.

Word Count: 2788

JC was the PI for the study; SJ conducted the analyses and was the lead author for the paper; all authors contributed to the design of the study; JC, CB, GB and IS contributed to the write up.

Key Messages:

- Coverage in the fourth year of the National Chlamydia Screening programme in the South East remains low in both males and females (1.0% and 3.3% 15-24 year olds respectively).
- Testing is higher for more deprived areas for females however not males.
- Positivity was lower in tests done through university clinics and for males military clinics compared to general practice.
- Clinics within the healthcare settings have and continue to demonstrate high volumes of testing can be achieved with corresponding high positivity.
