Abstract

The human risk assessment of feed contaminants has often been hampered by a lack of knowledge concerning their behavior when consumed by livestock. To gain a better understanding of the transfer of contaminants from animal feed to animal products, a meta-analysis of published literature was made. Data concerning feed contaminant concentrations, feeding periods, residue levels in animal products, and other parameters, were gathered and recorded. For each case a “transfer factor”, defined as the ratio of the concentration of a chemical in an animal product to the concentration of the chemical in animal feed, was calculated. Scientifically founded transfer factors were calculated and analyzed for groups of chemicals based on their contaminant classes or physico-chemical properties. These database-derived transfer factors enable a more accurate risk assessment in the case of a feed contamination, and enable rapid risk management decision-making and/or intervention.

Keywords: Transfer factor; carry-over; contaminants; residues; risk assessment; risk management

Introduction

In recent years increasing attention has been paid to the risk to consumers posed by chemical contaminants or residues in animal feed. This was caused by various cases of milk, eggs or other animal products contaminated with environmental chemicals. The best-known examples include contamination of milk with dioxins and PCBs as a result of industrial activities (e.g. emission of dioxins and PCBs by waste incinerators). In addition, animal feed has been found adulterated with hormones, antibiotics, dioxins, and other chemicals either deliberately, or from malpractice, or from sloppy manufacturing practices. The current use of pesticides for crop protection is an example of controlled “contamination” of crops which may become available for human consumption via animal feed. Also, contamination of animal feed can occur in a more or less biological way as is the case with mycotoxins due to improper storage of feed or feed ingredients. Cases like the Belgian PCB incident, as described by Bernard *et al.* (2002), demonstrated that adequate risk management is indispensable.

As various kinetic processes determine the qualitative and quantitative transfer of contaminants from feed to edible commodities, it is noted that without detailed information on a specific contaminant, a worst case approach is the only way to perform a risk assessment. For most of the contaminants this will lead to an excessive overestimation of residue levels in animal commodities. However, for some accumulating compounds a worst case estimation may still be an underestimation of the actual residue

1
2
3
4
5 levels after prolonged exposure. This might be the case for highly lipophilic compounds
6
7 like DDT or for some (heavy) metals which are known to accumulate in edible offal. A
8
9 risk assessment of a possible feed contamination using a worst-case approach might
10
11 therefore lead to wrong decisions, costing effort and money in the case of an erroneous
12
13 overestimation, or health risk to consumers in the case of an erroneous underestimation of
14
15 the contamination levels of the edible products under evaluation. In order to respond
16
17 promptly to questions concerning risk assessment of contaminated livestock feed, the
18
19 availability of a comprehensive data set on the transfer from feed to animal products of
20
21 various classes of contaminants was considered useful. Therefore, a meta-analysis of the
22
23 literature was performed to gather data on the transfer from livestock feed to animal
24
25 products covering various classes of chemicals. This paper will enable risk assessors to
26
27 gain a better understanding on the transfer of feed contaminants to edible commodities.
28
29 Furthermore, the data presented can be used to perform a rapid and founded estimation of
30
31 feed contaminant transfer if needed.

40

41 **Methods**

42
43
44 Data on the transfer of contaminants from animal feed to animal products included in the
45
46 database were mainly collected from the open literature. The literature databases AGRIS,
47
48 AGRICOLA, Food & Human Nutrition, and Toxline, were searched covering the period
49
50 of 1970 to 2005. The data on the transfer of pesticides were also obtained from publicly
51
52 available evaluations by the FAO/JMPR, the Advisory Committee on Pesticides of the
53
54 UK-PSD, and from pesticide dossiers filed in the archives of the TNO Quality of Life.
55

60

1
2
3
4
5 Several studies were published in languages other than English, including Czech, Dutch,
6
7 German, Italian, Polish, Korean, and Japanese. Publications in other languages than
8
9 English, Dutch and German were taken into account as far as data could be derived from
10
11 English abstracts or are available in the tables provided in these publications. Only
12
13 studies were selected in which the compound was administered via the feed or by
14
15 alternative oral exposure (e.g. via capsules). Exposure via drinking water was not taken
16
17 into account. Results from radio-labeled studies were only used in case individual
18
19 residues were identified and analyzed. A database was generated using the Microsoft
20
21 Corporation Excel 2003 (SP-2) software program for Windows XP. For each study the
22
23 following data were recorded: chemical name, CAS number., molecular weight, log
24
25 Po/w, water solubility, animal species name, concentration in the feed, amount of residue
26
27 per commodity (e.g. eggs, whole milk, meat, fat, and edible offal's (e.g. kidney or liver)),
28
29 feeding period, and remarks. CAS numbers or physico-chemical properties were retrieved
30
31 online using Chemfinder.com or ChemIDplus (<http://chem.sis.nlm.nih.gov/chemidplus/>),
32
33 whereas lacking log Po/w data were retrieved online using the interactive analysis logP
34
35 predictor website: <http://www.logp.com> (Interactive analysis, Bedford, MA, USA). Not
36
37 only the transfer of the compound itself, but also transfer of possible metabolites to the
38
39 animal products were included if present. Within the remarks, information on residue
40
41 differences between kidney and liver, periods to reach plateau levels in whole milk or
42
43 egg, correction factors used, amongst other remarks, are specified.

26
27

28 29 *Establishment of transfer factors*

30
31
32 The term *transfer factor* is used throughout this paper to define the transfer of chemical
33
34 compounds from animal feed to animal products as determined in animal feeding studies.
35
36 The transfer factor is expressed as the concentration of the compound in animal products
37
38 (mg/kg) divided by the concentration of the compound in animal feed (mg/kg), in which
39
40 the concentration in animal products is on a wet weight basis, and in feed on a dry weight
41
42 basis.
43
44
45
46
47
48

49 For most of the transfer factors, the compound itself is analyzed both in the feed and in
50
51 the animal commodity. However, for (heavy) metals, most of the analytical methods used
52
53 are specific for the metal in the respective commodity (e.g. Ni), but not for the compound
54
55
56
57
58
59
60

1
2
3
4
5 as present in the feed (e.g. NiCl_2). The transfer factors calculated are therefore based on
6
7 the metal ion and included in the database as such. Furthermore, several studies are
8
9 included in the database based on sludge contaminated feed where no specific compound
10
11 is known apart from the total metal concentration. For several other compounds, the
12
13 parent compound is metabolized after becoming systemically available. An example is
14
15 the metabolism of the pesticide 2,4-D to 2,4-dichlorophenol, where the metabolite may
16
17 be present at concentrations exceeding that of the parent compound in sheep with a factor
18
19 of 35. For metabolites, the metabolite concentration in the animal commodity is divided
20
21 by the parent compound concentration in feed to calculate the respective transfer factor.
22
23
24
25
26 In case the transfer factor is based on a metabolite, its identity is indicated in the
27
28 database.
29

30
31
32
33
34 In case data are reported which are not in the appropriate format (e.g. residues in milk fat
35
36 instead of whole milk, or residue in animal products based on a dry weight basis),
37
38 standardized factors are used to convert these data accordingly. The following conversion
39
40 factors were used in order to unify the data from the various available studies. An average
41
42 multiplication factor of 4.0 was used for all matrices to convert dry animal product
43
44 weight into wet tissue weight (Boyer, 1981). Milk data were often found to be expressed
45
46 on the basis of milk fat, especially dioxin and PCB data. Since dietary risk assessment
47
48 procedures take whole milk into account, all milk data in the database are expressed on
49
50 the basis of whole milk. On the assumption that whole milk may contain up to 4.3% fat
51
52 (Bluethgen, 1995), milk fat concentrations were multiplied by 0.043 to derive values for
53
54
55
56
57
58
59
60

1
2
3
4
5 whole milk. Some egg data were expressed on the basis of egg fat or egg fatty acids. For
6
7 the same reasons as for whole milk, the various egg data were converted to the whole egg
8
9 using a conversion factor of 0.088, derived from the data of Schuler (1997). Data in egg
10
11 white and yolk are converted to whole egg assuming a ratio of 65:35 (egg white: egg
12
13 yolk). It is noted that in case actual data (e.g. percentage of milk fat) are specified in the
14
15 publication, these data are used for the conversion.
16
17
18
19
20
21

22 In studies where the daily body dose, but not the feed concentration was specified, it was
23
24 assumed that the dry weight feed consumption of dairy cattle was 20 kg/day, of pigs 3
25
26 kg/day, and of chickens 0.12 kg/day (EC working document 7031/VI/95, rev. 4).
27
28
29
30
31

32 If commodity levels are determined below the limit of determination (LOD), the LOD
33
34 value was used for the calculation of the transfer factor. Transfer factors based on LOD
35
36 values are marked in the database in case a compound specific analysis has to be
37
38 performed. As a consequence, the calculated means are an overestimation of the means
39
40 when calculated using the actual commodity concentrations (<LOD).
41
42
43
44
45
46
47

48 **Statistics**

49
50 The SAS/STAT software V8.2, 1999-2001 (Cary, NC. SAS Institute Inc.), statistical
51
52 package was used to determine the distribution pattern of the transfer factors. The
53
54
55
56
57
58
59
60

1
2
3
4
5 Microsoft Office Excel 2003-SP2, including the Analysis ToolPak add-in was used to
6
7 calculate the mean, median, 95th percentiles, and maximum values of the transfer factors.
8
9

10 11 12 13 **Results**

14
15
16 The meta-analysis of the literature evaluated up to 2005, covering about 250 references,
17
18 resulted in a total of 3624 transfer factors, most of which were found on edible offal's
19
20 (31%) and meat (25%), followed in about equal numbers by eggs (12%), whole milk
21
22 (15%) and fat (17%). Animals included are cattle, poultry, pig, sheep, goat, rabbit and
23
24 several birds like pheasant, turkey, duck and quail. An overview of the amounts of
25
26 transfer factors found in each animal commodity, as well as for each of the various
27
28 contaminant classes are given in table II.
29
30
31

32
33
34
35 **<Insert table II>**
36
37
38
39

40
41 Statistical parameters covering the geometric mean, geometric standard deviation,
42
43 median, 95th percentile and maximum transfer factors were calculated using all transfer
44
45 factors for each commodity, and are listed in table III. It appears that the highest transfer
46
47 factors are found for fat and edible offal's. The transfer factors for eggs, meat and whole
48
49 milk are generally lower compared with fat and edible offal's.
50
51

52
53
54
55 **<Insert table III>**
56
57
58
59
60

1
2
3
4
5
6
7
8 A further analysis of the values in table III was achieved for each animal product by
9
10 calculating the statistical parameters also for each contaminant class. These values are
11
12 given in table IV (meat, fat and edible offal's), and table V (eggs and whole milk).
13
14

15
16
17
18 <Insert table IV>
19

20
21
22 <Insert table V>
23
24

25
26
27 In general, the distribution of the transfer factors displayed a log-normal distribution for
28
29 each contaminant class. The main exception was the population of transfer factors for the
30
31 PCBs/PBBs in fat, for which a bimodal distribution pattern was found. Overall, it is noted
32
33 that (as was to be expected) the transfer factor is depending on the lipophilicity of the
34
35 compound (determined by the octanol-water partition coefficient; $\log P_{o/w}$), the potential
36
37 accumulation of the compound in animal matrices, and/or the feeding level and feeding
38
39 period. The highest transfer factors determined in the animal matrices were in the order
40
41 fat > edible offal's > meat > eggs > whole milk. The highest transfer factors found in
42
43 animal fat are indeed found to be related to lipophilic compounds which tend to
44
45 accumulate in the body fat ("old" pesticides, dioxins, furans, PCBs, and PBBs). It is
46
47 noted that these fat accumulating contaminants also showed a higher potential for egg
48
49 and edible offal's, but less for whole milk. Metal compounds with potential accumulation
50
51 in edible offal's are cadmium, copper, mercury, selenium, and zinc. Time related
52
53
54
55
56
57
58
59
60

1
2
3
4
5 accumulation of metals was observed in edible offal's, but not in meat, fat, whole milk or
6
7 fat, considering the concurrent P_{95} values.
8
9

10
11
12
13 The inclusion of feeding levels and feeding periods in the database are of importance to
14
15 refine the selection of relevant data within the dataset before a transfer factor is
16
17 elaborated in case of e.g. accumulating compounds. As can be seen in figure I, the
18
19 transfer factors of edible offal after intake of cadmium for ca. 50 days are rather
20
21 comparable between the different feeding levels ranging from 0.09 to 48 mg/kg. After a
22
23 further continuous exposure, the transfer factors will differentiate depending on the dose.
24
25 If tissue levels become too high, saturation will become apparent showing lower increase
26
27 of the transfer factors (see the slope of the feeding level of 48 mg/kg in figure I), although
28
29 the actual tissue concentration is still rising. At feeding levels of 300 and 600 mg/kg,
30
31 respective concentrations of 668 mg/kg (TF= 2.2) and 667 mg/kg (TF= 1.1) in edible
32
33 offal's are found at 70 days exposure (Bokori, 1995), showing a ceiling cadmium level in
34
35 edible offal at 70 days.
36
37
38
39
40
41
42
43

44 <Insert figure I>
45
46
47
48

49 The use of contaminant classes will not in each case be applicable or scientifically valid
50
51 in case a contaminant in the feed is found. Therefore, the use of transfer factors related to
52
53 the physico-chemical properties of the compound was examined. Statistical analysis was
54
55 performed using the respective molecular weight (MW) and the respective
56
57
58
59
60

1
2
3
4
5 experimentally established or estimated log Po/w. Considering the transfer factors based
6
7 on the molecular weight, no clear discrimination could be made between the groups
8
9 defined. Main reason is the non-homogeneous distribution of the compounds over the
10
11 molecular weight groups. Furthermore, the presence of accumulating metal compounds is
12
13 highly affecting the outcome of the transfer factors of meat and edible offal at a MW
14
15 below 100, as a large amount of transfer factors of metal contaminants are present
16
17 without information on the respective anion (only metal levels reported in the respective
18
19 studies). For these reasons the transfer factors based on the MW were not considered a
20
21 feasible discriminator based on the available dataset. Establishing log Po/w categories
22
23 between 0 and 8, using an increment of 1 between each category, showed a rather
24
25 homogeneous distribution of the transfer data per group. The respective transfer factors
26
27 and the amount of data available at the 95 percentile for each of the matrices are given in
28
29 table VI. As no log Po/w can be calculated for inorganic compounds, it was decided to
30
31 form separate groups for the metal compounds. P₉₅ transfer factors are calculated
32
33 covering the whole group of metals, accumulating metals (cadmium, copper, mercury,
34
35 selenium and zinc), and non-accumulating metals. These figures are also included in table
36
37
38
39
40
41
42
43 VI.

44
45
46
47
48 <Insert table VI>

49
50
51 Based on the data in table VI, relative low transfer factors are found with compounds
52
53 having a log Po/w below 3, and for whole milk. High transfer factors are found in the log
54
55 Po/w categories of 3-4 and 5-8, with highest transfer factors in fat at a log Po/w between
56
57
58
59
60

1
2
3
4
5 6 and 7. It is remarkable that the group with a log Po/w of 4-5 has much lower transfer
6
7 factors compared to the adjoining groups for all matrices. It is noted that this observation
8
9 seems not to be biased due to a small number of observations.
10

11 12 *Use of the transfer database in risk assessment*

13
14
15 Based on the current dataset, transfer factors based on the 95th percentile (P₉₅) can be
16
17 used as a first step for assessing the transfer of specific contaminants. These P₉₅ values
18
19 can be applied in a tiered approach of risk assessment. In case chemical specific transfer
20
21 data are available in the dataset, the actual data can be used in the risk assessment. If no
22
23 chemical specific transfer data are available, the P₉₅ value of the respective log Po/w
24
25 category or the respective chemical group may be used. It is noted that in case transfer
26
27 factors of a specific chemical group are considered, one should think about the surplus
28
29 value of the chemical group over the respective log Po/w data, since assigning chemical
30
31 groups is in general relatively arbitrary taken the biological processes influencing the
32
33 transfer factors into account. At last a generic approach, by using the overall transfer
34
35 factors of the respective edible commodity (see table III), might be considered for
36
37 components for which little to no information is present, e.g. unidentified components.
38
39
40
41
42
43
44
45
46

47 It is noted that without the use of database derived transfer factors, only a literature
48
49 search, which should include the fate and behavior of the contaminant, or, in case no
50
51 compound specific information could be retrieved from the public literature, a worst case
52
53 scenario can be used in the risk assessment. This approach is not only time consuming,
54
55
56
57
58
59
60

1
2
3
4
5 but also limited to the contaminant, whereas information on comparable chemicals may
6
7 be of value to estimate the transfer of the respective contaminant from the feed to the
8
9 edible commodities. The use of database derived transfer factors in risk assessment,
10
11 including a comparison using worst case assumptions, is illustrated in 3 case studies
12
13 below.
14
15

16
17
18
19
20 *Case 1: Nickel contamination.*
21

22
23 To illustrate the value of the database, we used a case of a possible metal contamination
24
25 of a raw material to be used in the production of animal feed. The question was raised
26
27 about the consumer risks upon a possible presence of nickel in dairy cattle feed. The
28
29 feed's contamination level was expected to be maximally 1.5 mg/kg feed (dry weight
30
31 basis).
32
33

34
35
36
37 In order to perform a risk assessment, the maximum transfer factors of nickel were
38
39 retrieved from the database for each commodity. As comparison, also the P₉₅ transfer
40
41 factor of the contaminant class of metals (and the subgroup of non-accumulating metals),
42
43 the maximum metal transfer factor, and the transfer factors based on the overall P₉₅
44
45 transfer factor were retrieved from the database to simulate an increasing level of
46
47 uncertainty in case insufficient information on nickel would be present in the database. A
48
49 comparison to a traditional risk assessment was made using worst case assumptions. For
50
51 this we assumed complete absorption and retention of nickel by livestock animals and
52
53 complete distribution towards (one of the) edible commodities. To bring some nuance
54
55
56
57
58
59

3
4
5 into the worst case approach, we assumed a steady state after feeding for about 1 week (>
6
7 5 times the plasma half life). This would mean that only the cumulative nickel intake for
8
9 1 week would add to the ultimate residue levels in edible commodities. The respective
10
11 transfer factors are given in table VII, in order of the assumed highest to lowest
12
13 uncertainty.
14
15

16
17
18
19 <Insert table VII>
20
21
22
23

24 We used the figures of table VII as a basis for the risk assessment. For health risk
25
26 assessment, a Tolerable Daily Intake (TDI) for nickel of 0.05 mg nickel per kg body
27
28 weight per day (or 3 mg/person/day, assuming a body weight of 60 kg) can be used, as
29
30 proposed by the Dutch National Institute of Public Health and the Environment (Baars *et*
31
32 *al.*, 2001). Furthermore, a human consumption pattern is used, as assumed in the health
33
34 risk assessment for residues of Veterinary Medicinal Products (EC, 2003) i.e. daily
35
36 consumption of 1.5 kg of milk and milk products, 100 g eggs and egg products, 300 g
37
38 meat, 50 g fat, 100 g liver, and 50 g kidney. On the basis of these figures and the
39
40 presumed worst case assumptions, consumption of the cattle commodities would lead to
41
42 intake estimates which can be compared to its respective TDI.
43
44
45
46
47
48
49

50 Based on these transfer factors, the intake by the consumption of the respective
51
52 commodities was calculated as a percentage of the TDI for each commodity (see table
53
54 VIII).

7 <Insert table VIII>
8
9
10

11
12 The results presented in table VIII indicate that in general with a growing level of
13 uncertainty, an increased consumer risk is indicated. One should keep in mind that the
14 nickel data are based upon actual (experimental) data, and as such can serve as
15 comparison for the other evaluations. Looking at the P₉₅ transfer factors for nickel it is
16 noted that not kidney or liver, as estimated by the worst case approach or the maximum
17 metal transfer factor, but meat may be the major source of nickel residue intake by
18 consumers. The nickel intake via meat is in fact rather comparable to the calculations
19 based on worst-case assumptions, the overall P₉₅, and the metal P₉₅ transfer factors. Yet,
20 it appears that the intake by whole milk and fat is expected to be much lower than
21 assumed on the basis of the worst case assessment. Although differences in the intake
22 calculations exist between the evaluations, it is noted that in case of lacking data for a
23 specific metal, the P₉₅ transfer factor of the contaminant class of (non-) accumulating
24 metals is a better alternative over the worst case approach, showing intake estimations
25 rather near the actual data.

48 *Case 2: Contamination based on physical chemical properties (log Po/w <3).*
49

50 To demonstrate the use of transfer factors based on physical chemical properties of a
51 compound, experimental transfer data of a veterinary medicinal product were compared
52 to database derived transfer factors based on the 95th-percentile of the respective log Po/w
53
54
55
56
57
58
59
60

1
2
3
4
5 class. Oikawa *et al.* (1977) exposed chicken for 5 successive days to 2000 and 4000
6
7 mg/kg of sulfamethoxazole (SMX) via feed. The log Po/w of SMX is 0.89
8
9 (chemfinder.com; experimental data of Hansch, 1995). Residue levels of free SMX in
10
11 meat, fat, kidney, and egg including their respective calculated transfer factors, and the
12
13 database derived transfer factors (P₉₅) are given in table IX. It is noted that SMX was not
14
15 included in the database.
16
17

18
19
20
21 <Insert table IX>
22
23

24
25
26 When comparing the calculated and databases derived transfer factors after exposure to
27
28 SMX, it is noted that the database derived transfer factors are about 10 times higher than
29
30 calculated using the experimental data. This might be expected considering the short (5
31
32 day) exposure period to SMX. Although the database derived transfer factors are higher
33
34 than might be expected from the experimental data, it is noted that when using worst case
35
36 assumptions, considerable higher transfer factors are indicated (e.g. egg; 3.2, meat; 1.1,
37
38 fat; 2.9, and kidney; 76). The worst case assumptions considered were a full absorption of
39
40 SMX, followed by a complete distribution towards the matrix under consideration, no
41
42 excretion of SMX, whereas an accumulation of SMX during 7 days is assumed for meat,
43
44 fat, and kidney, taking into account a bodyweight of 1.9 kg, comprised of meat, fat and
45
46 kidney, for 40%, 15%, and 0.6% of the bodyweight, respectively. An egg weight is
47
48 considered of 0.053 kg (size S) with an egg production of 0.7 eggs/day. The database
49
50

52
53
54
55
56
57
58
59
60

1
2
3
4
5 derived transfer factors is therefore considered to be of value for a more refined
6
7 estimation of transfer compared to worst case assumptions.
8
9

10
11
12 *Case 3: Contamination based on physical chemical properties ($\log P_{o/w} \geq 3$).*

13
14 Equivalent to case 2, a comparison is made based on the physical chemical properties of
15
16 compounds with a relative high $\log P_{o/w}$, for which accumulation might be suspected in
17
18 one or more edible matrices. Experimental data on the transfer of 3 dioxins and 1 furan
19
20 from feed to fat are compared to the database derived transfer factor based on the 95th-
21
22 percentile of the respective $\log P_{o/w}$ class. The compounds used for the comparison were
23
24 not (yet) included in the database when the comparison was made. Thorpe *et al.* (2001)
25
26 exposed cattle for 4 weeks to a defined mixture of PCDD/F congeners, corresponding to
27
28 feed levels of 7.5 ng/kg of each congener. After a recovery period of 1 week the animals
29
30 were slaughtered. Analysis of the individual congeners was performed in fat, and the fat
31
32 fraction of liver and meat. As no information was provided on the fat fraction of liver and
33
34 meat, only the transfer of feed to fat was considered (see table X). It is noted that because
35
36 of the one week recovery period, the highest residue reported was used for the
37
38 calculations, instead of an average.
39
40
41
42
43
44
45
46
47
48
49
50
51

<Insert table X>

52
53 When calculating the actual transfer factors of the respective compounds based on the
54
55 analytical data by dividing the concentration in fat by the concentration in feed, rather
56
57
58
59
60

1
2
3
4
5 comparable transfer factors were elaborated for fat ranging from 5.7 to 7.6. Comparing
6
7 these transfer factors to the database derived transfer factor based on the contaminant
8
9 class of dioxins/furans (9, see table IV), the elaborated transfer factor to fat is about a
10
11 factor 1.5 times higher than might be expected from the actual data. When elaborating the
12
13 transfer factor based on the log Po/w class of 6-7 (table VI), the database derived transfer
14
15 factor to fat is 30, which is about a factor 4.5 times higher than the calculated transfer
16
17 factor based on the actual data. Considering the fat accumulating potential of the
18
19 compounds present in the respective dioxins/furans class or the log Po/w class of 6-7, the
20
21 P_{95} value is highly related to long term (> 1 Year) exposure. In case a longer exposure
22
23 period is considered, it is expected that an increase in the actual transfer factor will be
24
25 apparent. It is noted that when worst case assumptions were made, a transfer factor of 20
26
27 for fat was calculated. The worst case assumptions considered were a full absorption of
28
29 each congener, followed by a complete distribution towards the fat, no excretion of the
30
31 congeners, whereas an accumulation during 7 days is assumed, taking into account a
32
33 bodyweight of 550 kg and a slaughter weight of 7 kg of fat. A limited accumulation
34
35 period was chosen taking the recovery period of 1 week into account. Again a refinement
36
37 can be made by restriction of data to be included for the calculation of the database
38
39 derived transfer factor, by selecting the respective feeding periods or exposure
40
41 concentrations. The database derived transfer factors showed an approximate 1.5 to 4.5
42
43 fold higher transfer compared to the actual data. It is however noted that for the actual
44
45 data, a one week recovery period is included, whereas the transfer database is based on a
46
47 continuous exposure until slaughter which may indicate somewhat higher levels in the
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4
5 animal matrices. As the compounds considered in this case are stable and have a high
6
7 affinity for fat, the one week recovery is not considered to have a major effect on the
8
9 decline of the compounds during the recovery period. Furthermore, the highest residue
10
11 levels reported were used for the calculation of the actual transfer which is considered to
12
13 compensate for a possible decline of the mean contamination values in fat. Taking these
14
15 data into account, the database derived transfer factors showed a somewhat higher
16
17 prediction of the actual transfer, but are regarded to give a more accurate prediction than
18
19 when considering the transfer using worst case assumptions. Therefore, also in this case
20
21 the use of database derived transfer factors is considered favorable over calculations
22
23 using worst case assumptions.
24
25
26
27
28
29
30

31 **Conclusion**

32
33 It is not feasible to generate chemical-specific information for every compound for every
34
35 situation at any moment, especially considering possible (differences in) metabolism,
36
37 feed concentrations and exposure periods for each livestock animal. In this respect, the
38
39 use of database derived transfer factors showed to be a powerful tool for the evaluation of
40
41 contaminants and enables rapid risk management decision making and/or intervention.
42
43
44
45
46
47

48 Three cases of repeated exposure showed that the use of database derived transfer factors,
49
50 based on the P_{95} values of contaminant or log Po/w classes, results in a rather accurate
51
52 prediction of the presence of the respective contaminant in the edible commodity when
53
54 compared to the actual experimental transfer factors. A slight overestimation of the
55
56
57
58
59
60

1
2
3
4
5 transfer, as observed in most of the cases, is most likely related to the limited
6
7 contaminant feeding period. Deriving transfer factors from the database restricted to
8
9 actual feeding periods, feeding levels and/or relevant animals, will provide a more
10
11 accurate prediction of the transfer than when all data in the respective group, including
12
13 long term feeding periods, are used. Future studies with the database will be aimed at this
14
15 refinement.
16
17
18
19

20
21 When the risk assessment using database derived transfer factors is compared to the risk
22
23 assessment using worst case assumptions, the database derived transfer factors provide a
24
25 far more accurate indication of the contaminant levels and its concurrent risk estimation,
26
27 than when using the traditional worst-case approach. Further studies will also be aimed at
28
29 a further validation of this approach. Great care should be taken when worst-case
30
31 assumptions are used for assumed accumulating contaminants like highly lipophilic
32
33 compounds (log Po/w of 5 to 8) or cadmium, copper, mercury, selenium or zinc
34
35 containing compounds. Especially for these compounds, database derived transfer factors
36
37 based on physical chemical properties or structural related compounds may provide a
38
39 more rapid and accurate prediction than in case of using worst case assumptions.
40
41
42
43
44
45
46
47

48 Using database derived transfer factors, an evaluation can be performed using data of the
49
50 specific compound, structural related compounds, compounds with comparable physico-
51
52 chemical properties, or contaminant classes, if needed at specified feeding levels and/or
53
54 feeding periods. Furthermore, the relative vulnerability of animal matrices to a feed
55
56
57
58
59
60

1
2
3
4
5 contaminant can be evaluated. Instead of using worst-case assumptions, a generic
6
7 approach in risk assessment, by using the overall transfer factors of the respective edible
8
9 commodity, is preferable in case limited data on the identity or properties of the
10
11 contaminant involved are available. When compared to a risk assessment using worst-
12
13 case assumptions, a better understanding of the transfer of feed contaminants and
14
15 residues to animal products resulting in a more refined risk assessment is possible using
16
17 data base derived transfer factors.
