A Cu-Fe nanocomposite containing 50 nm thick iron filaments dispersed in a copper matrix was processed by torsion under high pressure at various strain rates and temperatures. The resulting nanostructures were characterized by transmission electron microscopy, atom probe tomography and Mössbauer spectrometry. It is shown that  $\alpha$ -Fe filaments are dissolved during severe plastic deformation leading to the formation of a homogeneous supersaturated solid solution of about 12 at.% Fe in fcc Cu. The dissolution rate is proportional to the total plastic strain but is not very sensitive to the strain rate. Similar results were found for samples processed at liquid nitrogen temperature. APT data revealed asymmetric composition gradients resulting from the deformation induced intermixing. On the basis of these experimental data, the formation of the supersaturated solid solutions is discussed.

Keywords: Severe plastic deformation, Nanocomposite, Intermixing, Copper, Iron

### 1. Introduction

The formation of metastable phases by mechanical alloying (MA) has been studied extensively during the past twenty years [1]. A large amount of experimental but also theoretical work has been done to clarify the physical mechanisms of the formation of non-equilibrium supersaturated solid solutions (ssss) in binary systems with a positive heat of mixing. The Cu-Fe system has been widely investigated by many authors for a full range of composition using numerous experimental techniques such as X-ray diffraction (XRD) [2-5], Mössbauer spectroscopy [5,6], Differential Scanning Calorimetry (DSC) [2-4], High Resolution Transmission Electron Microscopy (HRTEM) [5, 7, 8], Atom probe Tomography (APT) [9]. However, the physical mechanisms underlying the deformation induced intermixing are still under debate. This might be due to the following reasons:

1  
2  
3  
4 (i) Mechanically alloyed products are nanostructured powders that are difficult to  
5 observe directly by TEM or APT. Thus, data about composition gradients or about  
6 any atomic scale mechanism are usually not available.  
7

8  
9  
10 (ii) Mechanically alloyed products are inherently subject to contamination. Even if  
11 contamination by oxygen and oxidation problems can be avoided by careful milling in  
12 Ar atmosphere, there is always an unknown amount of material that is transferred  
13 from the steel balls and the vial to the powder.  
14

15  
16 (iii) The exact relationship between milling parameters and physical parameters like  
17 the temperature of the powder during deformation, the strain rate or the total  
18 accumulated strain is not known.  
19

20  
21 (iv) Basic deformation mechanisms leading to the high strain rate plastic deformation  
22 of powders under the impact of a steel ball are unknown.  
23

24  
25 (v) The density of crystallographic defects like dislocation or vacancy in MA powder  
26 is unknown while they should play a critical role in the intermixing mechanism.  
27

28  
29 (vi) Supersaturated solid solutions prepared by ball milling are not always fully  
30 homogeneous even for very long milling time [7, 9, 10]. This is probably an indirect  
31 consequence of the non uniform total strain sustained by powders.  
32

33  
34 Anyway, various mechanisms have been proposed in the literature to account for the  
35 deformation induced Cu-Fe intermixing. Most of them rely on thermodynamic  
36 arguments: during milling, nanoscaled domains are formed leading to an interfacial  
37 energy sufficiently high to overcome the positive heat of mixing [2, 11]. However,  
38 such an approach does not provide any atomistic mechanism to account for the  
39 kinetics of the reaction. Some authors argue that pipe diffusion in the stress field of  
40 dislocations could play a role [4], but they do not provide any experimental evidence.  
41  
42 The role of dislocations is also underlying the so-called “kinetic roughening” model  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53

55  
56  
57  
58  
59  
60

1  
2  
3 of Bellon and Averback [12]. Atoms are supposed to be shifted across interfaces by  
4  
5 the shear of atomic glide planes. The final state would be determined by the balance  
6  
7 between these forced jumps and decomposition due to thermal diffusion. Recent APT  
8  
9 measurements on the Cu-Ag system seem to validate this approach [13]. There are  
10  
11 also some models incorporating both kinetic and thermodynamic effects where the  
12  
13 ballistic events are introduced as excess entropy [3, 14] but microstructural features  
14  
15 are not taken into account. With a pure kinetic approach, some other authors proposed  
16  
17 a theory based on enhanced mobility resulting from deformation induced point defects  
18  
19 [15], but unfortunately this assumption has not been yet tested by experiments.  
20  
21

22  
23 Thus, for a better understanding of the mechanically induced intermixing as observed  
24  
25 in mechanically alloyed powders, it is necessary to design some model experiments  
26  
27 where deformation parameters are fully under control. As proposed in our earlier  
28  
29 work [16, 17], severe plastic deformation (SPD) of bulk Cu-Fe composites by High  
30  
31 Pressure Torsion (HPT) may lead to some significant intermixing. The deformation  
32  
33 mechanisms are very different comparing to mechanical alloying. During HPT the  
34  
35 strain rate is fully under control, it is constant, and much smaller than during the  
36  
37 impact of steel balls on powder grains. Since the strain rate is small, the temperature  
38  
39 does not significantly increases and remains almost constant. Last but not least, HPT  
40  
41 processing requires bulk samples that are easier to analyze or observe (TEM, APT)  
42  
43 and there is no contamination.  
44  
45

46  
47 The aim of the present study was first to optimize the process designed in [17] to  
48  
49 obtain large volume fraction of homogeneous Cu-Fe ssss in a bulk sample. The  
50  
51 second purpose was to investigate the influence of deformation parameters (strain  
52  
53 level, strain rate and temperature) on the mechanically induced intermixing of Cu and  
54  
55 Fe to get new insights into the physical mechanisms. In particular, tests were  
56  
57  
58  
59  
60

1  
2  
3 performed at low temperature where the mobility of vacancies is thought to be  
4 negligible. Mössbauer spectroscopy was used to quantify the average amount of solid  
5 solution, while local analyzing techniques like TEM and APT were used to observe  
6 microstructures and to visualize diffusion gradients at the atomic scale. On the basis  
7 of these data, the driving force and the kinetics of the intermixing are discussed.

## 18 **2. Experimental**

19  
20 The Cu-Fe composite processed by HPT was fabricated by accumulative cold  
21 drawing in a way very similar to the one used in our previous study [17]. The  
22 procedure was however modified in order to obtain a nanoscaled composite, i.e. a  
23 copper based material with iron filaments thinner than 100nm. Indeed, we have shown  
24 that the size of Fe grains is a critical parameter that directly controls the driving force  
25 of the intermixing reaction: the smaller they are the stronger the mixing [17]. To  
26 investigate the influence of deformation parameters a large volume fraction of sss is  
27 needed, therefore it is necessary to process by SPD a composite with nanoscaled  
28 grains. Pure copper (99.9%) and pure iron (99.95%) were assembled as follows: an  
29 iron rod (2mm diameter) was inserted in a copper tube (inner diameter 4mm, outer  
30 diameter 6mm) that was inserted in an iron tube (inner diameter 7mm, outer diameter  
31 10mm) that was inserted in a Cu tube (inner diameter 12mm, outer diameter 14mm).  
32 This assembly was cold drawn down to a diameter of 1mm, and then it was cut in  
33 pieces that were inserted again in a copper tube (inner diameter 12mm, outer diameter  
34 14mm). This restacking procedure was applied five times. The resulting material is a  
35 copper based composite with nanoscaled iron filaments aligned along the wire axis  
36 (Fig.1). The average thickness of iron filaments is 50 nm, but there is a large  
37 distribution ranging from 25 to 100 nm. During the drawing process, intermediate

57  
58  
59  
60

1  
2  
3 annealing treatments were performed at 650°C to recover the ductility and to allow  
4 further reduction of the composite diameter. These annealing treatments were applied  
5  
6 once the reduction of the cross section area of the wire was about 90%. In the fifth  
7  
8 step, the annealing temperature was reduced down to 550°C to avoid coarsening and  
9  
10 globularisation of nanoscaled iron filaments. The volume fraction of iron in the final  
11  
12 nanocomposite is 12%, but as shown in the Fig. 1, the filaments are not  
13  
14 homogeneously distributed within the copper matrix. This is due to the restacking in  
15  
16 copper tubes during the processing by accumulative cold drawing as described above.  
17  
18  
19 During the last drawing step of the composite, the process was stopped at a diameter  
20  
21 of 8mm. Thin discs (thickness 0.8mm) were cut with a diamond saw, sand blasted and  
22  
23 then processed by HPT with a pressure of 6.2GPa up to 25 revolutions at various  
24  
25 strain rates and temperatures. Due to the high pressure applied during the torsion  
26  
27 straining, the thickness of the discs after processing was only about 0.5mm.  
28  
29  
30 The microstructures were characterized by Scanning Electron Microscopy (SEM)  
31  
32 using a LEO FE1530 (secondary electron detector) and by TEM using a JEOL  
33  
34 2000FX microscope operating at 200kV. X-ray Energy Dispersive Spectroscopy  
35  
36 (EDS) was carried out using an Oxford Instrument detector. For SEM observations,  
37  
38 samples were mounted, mirror polished and etched using 5% HNO<sub>3</sub> diluted in  
39  
40 Ethanol. For TEM observations, samples were cut out at distance of 3±0.5mm from  
41  
42 the disc center, mechanically grinded down to 100µm, dimpled down to 20µm and  
43  
44 thinned down to electron transparency by ion milling using a GATAN PIPS 691 at  
45  
46 5keV. Atomic scale analyses were performed by APT using a CAMECA advanced  
47  
48 delay line detector [18]. Specimens were prepared by standard electropolishing  
49  
50 techniques [17] so that the tip was located at a distance of 3±0.5mm from the disc  
51  
52 centre. Samples were field evaporated in UHV conditions with femtosecond laser

### 20 3. Results

21  
22 To check that HPT could lead to the formation of a large volume fraction of  
23  
24 Cu-Fe ssss, the Cu-Fe nanocomposite was first subjected to 25 turns at room  
25  
26 temperature (293K) with a rotation speed of 0.4 rev/min. These severe plastic  
27  
28 deformation conditions correspond to a total shear strain of about 540 and a strain rate  
29  
30 of  $0.2 \text{ s}^{-1}$  where the sample was characterized (i.e. at a distance of 3mm from the HPT  
31  
32 disc centre). The microstructures of the composite before and after HPT processing  
33  
34 are compared in the Fig. 2. On the image showing the composite before deformation  
35  
36 (Fig.2(a)), the filamentary structure does not appear because this is a cross sectional  
37  
38 view and thus filaments are aligned along a direction parallel to the beam axis. The  
39  
40 morphology of these filaments is very complex (see also Fig. 1(a)). As reported in the  
41  
42 literature for other drawn composites [21, 22], this feature results from the  $\langle 110 \rangle$ -  
43  
44 fibre texture of the bcc  $\alpha$ -Fe phase that induces a plane-strain deformation of this  
45  
46 phase in the fcc Cu matrix. The selected area diffraction (SAED) pattern (Fig. 2(b))  
47  
48 shows Debye-Scherrer rings characteristic of polycrystalline structures with a very  
49  
50 small crystallite size. In the initial state, both fcc Cu and bcc  $\alpha$ -Fe phases are detected  
51  
52 within the microstructure. After 25 turns by HPT, nanoscaled grains with an equi-  
53  
54 axed structure clearly appear (Fig.2 (c)). The grain size is in a range of 10 to 50nm  
55  
56  
57  
58  
59  
60

1  
2  
3 and only Debye-Scherrer rings corresponding to the fcc Cu phase are detected on the  
4  
5 SAED pattern (Fig. 2(d)). However, using EDS measurements, the average amount of  
6  
7 Fe measured in this area was  $12\pm 2$  at.%. Thus, during the HPT deformation, the  
8  
9 original iron filaments are dissolved and a Cu-Fe ssss is formed. APT analyses were  
10  
11 carried out to image at the atomic scale the distribution of Fe atoms within this  
12  
13 nanostructure. As shown on the three-dimensional reconstruction of the analyzed  
14  
15 volume, the distribution of Fe atoms is fairly uniform (Fig. 3(a)). The average Fe  
16  
17 concentration in this volume is  $12.6\pm 0.1$ at.%, which is consistent with EDS  
18  
19 measurements. The distribution of Fe concentration measured in a  $1.2\times 1.2\times 1.2\text{nm}^3$   
20  
21 sampling volumes was plotted to statistically compare it with a random distribution  
22  
23 (Fig. 3(b)). Although there is a small deviation for the highest and the lowest  
24  
25 concentration, this distribution fits very well a random Bernouilli distribution,  
26  
27 indicating that the Cu-Fe ssss is homogeneous.  
28  
29  
30  
31  
32

33  
34 The influence of HPT processing parameters on the volume fraction of Cu-Fe ssss  
35  
36 was investigated by Mössbauer spectroscopy. This technique provides some  
37  
38 information about the local environment of Fe atoms. If Fe atoms exhibit a bcc  
39  
40 structure ( $\alpha$ -Fe phase), absorption spectra are characterized by a magnetic sextet, but  
41  
42 if Fe atoms are in solid solution in the fcc Cu phase, absorption spectra are  
43  
44 characterized by a paramagnetic doublet [5, 20]. Spectra recorded for various levels of  
45  
46 deformation up to 25 turns at room temperature (293K) and for a strain rate of  $0.2\text{s}^{-1}$   
47  
48 are displayed in the Fig.4. The paramagnetic contribution obviously increases as the  
49  
50 level of plastic deformation increases, indicating that this parameter has a strong  
51  
52 influence on the formation of the Cu-Fe ssss. One should note that before HPT  
53  
54 processing, there is already a small paramagnetic contribution. It is attributed to Fe  
55  
56 atoms that have diffused in solid solution in the Cu matrix during annealing  
57  
58  
59  
60

1  
2  
3 treatments performed during the accumulative cold drawing process. The volume  
4 fraction of Fe atoms in solid solution in the fcc Cu phase was directly computed from  
5 the fits of Mössbauer spectra, assuming that the area of each contribution is  
6 proportional to the number of absorbing Fe atoms. Figure 5, the proportion of Fe  
7 atoms in solid solution is plotted as a function of the number of HPT turns for two  
8 different processing temperatures (293 and 77K) and two different strain rates (0.2  
9 and  $0.02\text{s}^{-1}$ ). The dissolution of Fe filaments is very sensitive to the total plastic strain  
10 (number of HPT revolution) for any temperature or strain rate that were tested.  
11 Processing at low temperature (77K) slightly slows down the dissolution but at the  
12 end, there is only 15% less Fe atoms in solid solution than at 293K. It is also  
13 interesting to note that a change of the strain rate by one order of magnitude (from 0.2  
14 down to  $0.02\text{s}^{-1}$ ) does not significantly increase the dissolution rate.

The understanding of the physical mechanisms underlying the dissolution of iron  
filaments and the formation of the Cu-Fe ssss requires some investigation of the  
microstructure evolution for various levels of deformation. Some data collected in the  
sample processed by five revolutions by HPT are shown on the Fig. 6. On the bright  
field TEM micrograph two distinct regions are shown (Fig. 6(a)). In the upper part  
(labelled 1), there is a filamentary structure corresponding to a bunch of filaments  
located in the first Cu tube used for the preparation of the composite by accumulative  
cold drawing. A part of this Cu tube is imaged in the lower part of the image where  
grains are more equi-axed with a size in a range of 100 to 200 nm (labelled 2). One  
should note that under the shear strain, the thickness of the filaments was significantly  
reduced comparing to the initial material. SAED patterns taken in these filamentary  
regions always display both fcc Cu and bcc  $\alpha$ -Fe phases. Such a region was analyzed  
by APT, and the 3D reconstructed volume clearly shows an iron filament with a

1  
2  
3 thickness of only few nanometres (Fig. 6 b)). However, if it assumed that the Cu-Fe  
4 composite is homogeneously deformed during the HPT process, the thickness of Fe  
5 filaments should be theoretically less than one nanometre after 5 revolutions (see [17]  
6 for details). This indicates that the deformation is more pronounced in iron depleted  
7 zones (i.e. former Cu tubes used for restacking as described in the previous section).  
8 As exhibited on the concentration profile computed across this iron filament (Fig.  
9 6(c)) it does not contain any detectable amount of Cu, but a significant amount of Fe  
10 was detected in the Cu matrix. Due to the roughness of the interface, the gradient in a  
11 window of 1nm on each side of the interface cannot be rigorously interpreted;  
12 however on the copper rich side a long range composition gradient spreading over 5  
13 nm is clearly exhibited.

24  
25  
26  
27  
28  
29 After 14 revolutions by HPT, the original lamellar structure hardly appears on TEM  
30 bright field images (Fig. 7(a)). As shown on the 3D APT reconstructed volume (Fig.  
31 7(c)), the lamellae are very thin (down to few nanometres) and exhibit a wavy  
32 morphology. The composition profile computed across Cu/Fe interfaces (Fig. 7(b))  
33 shows that the Fe concentration gradient in the fcc Cu phase is larger than after 5  
34 revolutions (Fig. (6)). The fcc Cu phase contains up to 30 at.% Fe in solid solution  
35 while iron filaments do not seem significantly affected by Cu (excepted the thinnest  
36 filament on the right of the profile). Thus, in agreement with Mössbauer data, APT  
37 measurements confirm that the higher the level of deformation the larger the amount  
38 of Fe in solid solution in the fcc Cu phase.

52  
53 The microstructure of the composite processed by HPT at 77K (liquid nitrogen  
54 temperature), was also characterized by TEM and APT. The microstructures look  
55 very similar and no significant difference was observed on the micrographs. After 14  
56 revolutions, there are still some regions with a lamellar structure containing bcc  $\alpha$ -Fe  
57  
58  
59  
60

1  
2  
3 as shown in Fig. 8(a) (region labelled 1). This image is very interesting because a  
4 region with nanoscaled equi-axed grains is also exhibited (labelled 2). The SAED  
5 pattern from this area clearly indicates that it is fully fcc, e.g. there is no  $\alpha$ -Fe phase.

8  
9  
10 However, EDS measurements revealed that it contains  $13.4 \pm 2$  at.% Fe and thus that it  
11 is a fcc Cu-Fe ssss. The transition between these two regions and the mechanisms of  
12 the formation of the nanoscaled equi-axed ssss will be discussed in the next section.  
13  
14  
15 APT measurements were performed after 25 revolutions at 77K (Fig. 8(b)). Like in  
16 the composite deformed at room temperature, this 3D volume exhibits a homogeneous  
17 distribution of Fe atoms ( $12.2 \pm 0.1$  at.% ). Like in the sample processed at room  
18 temperature (Fig. 3), the distribution of Fe atoms was compared to a random  
19 distribution (data not shown here). No significant difference was found, confirming  
20 the homogeneity of the ssss.

#### 33 4. Discussion

34  
35 Homogeneous super saturated solid solutions (ssss) of about 12at.% Fe in fcc  
36 Cu were achieved by SPD. This is far beyond the equilibrium solubility limit at room  
37 temperature and even larger than the solubility of Fe in Cu at 1350K (about 4at.%  
38 [23]). Such ssss were already obtained in the past in the same system using ball  
39 milling of powders, however in the present study bulk samples were produced and as  
40 demonstrated by APT data the ssss is fully homogeneous which is usually not the case  
41 in ball milled powders [9, 10, 24]. It is however worth noticing that the sextet typical  
42 of  $\alpha$ -Fe still appears even in samples processed up to 25 revolutions by HPT. This can  
43 be simply explained by the deformation gradient in HPT discs: the shear deformation  
44 is a linear function of the radius, thus the cumulated strain in the disc centre is quite  
45 low and not strong enough to promote the dissolution of the  $\alpha$ -Fe phase. A lead shield  
46 (diameter 4mm) was used to mask the centre of the disc, and the recorded Mössbauer  
47  
48  
49

56  
57  
58  
59  
60

1  
2  
3 spectrum (data not shown here) did not exhibit the sextet, confirming that the  $\alpha$ -Fe  
4  
5  
6 phase is located only in the low strained region.  
7

8  
9  
10 These data raise two questions: what are the physical mechanisms of the  
11 deformation induced intermixing, and why are the present super saturated solid  
12 solutions so homogeneous? The experimental data show that the mixing is not strain  
13 rate sensitive (in the range of 0.02 to 0.2 s<sup>-1</sup>), it is reduced by about 15% if the  
14  
15  
16 temperature is decreased from 293K to 77K and it starts with asymmetric composition  
17  
18  
19 gradients. Two different approaches could be considered to understand the evolution  
20  
21  
22 of the nanostructure under severe plastic deformation: the first one involving  
23  
24  
25 thermodynamic destabilization and the second involving pure mechanical mixing.  
26  
27

#### 28 ***4.1 Thermodynamic destabilization***

29  
30  
31 The microstructure of the Cu-Fe composite investigated in the present study is  
32 characterized by a very small grain size and thus a huge proportion of interfaces. As  
33 suggested for ball milled powders, the driving force might be the high interfacial  
34 energy of the nanoscaled Cu-Fe mixture combined with the high density of crystalline  
35 defects [2, 4, 11]. It is also important to note that it was recently proposed by  
36  
37  
38 Kozeschnik that such intermixing may significantly reduce the Cu-Fe interfacial  
39 energy [25]. It is however important to note that grain growth or coarsening would  
40  
41  
42 have a similar effect, but the continuous deformation of the two phase mixture  
43 prevents such mechanism and even continuously increases the Cu/Fe interfacial area  
44  
45  
46 and thus the driving force for mixing. As suggested by Jiang and co-authors [5, 6], in  
47  
48  
49 such a highly strained and nanoscaled system, the bcc  $\alpha$ -Fe phase may also transform  
50  
51  
52 into fcc. Such a transformation may be promoted by the small grain size [26], the  
53  
54  
55 shear stress [27] or to decrease the interfacial energy like in the early stage of  
56  
57  
58 precipitation of Fe in fcc Cu where Fe precipitates exhibit the meta-stable fcc  
59  
60

1  
2  
3 crystallographic structure [28]. However, this fcc Fe phase was not detected on the  
4  
5 Mössbauer spectra (paramagnetic contribution at room temperature characterized by a  
6  
7 singlet with an isomer shift of  $0.09\text{mm s}^{-1}$  [29]) or by TEM, in the present  
8  
9 investigations.

10  
11  
12 With this scenario, the mixing rate and the composition gradients are not controlled  
13  
14 by the driving force (interfacial energy) only. Of course, the atomic mobility plays a  
15  
16 crucial role and the following condition is required: thermal diffusion should be  
17  
18 significant or an alternative media may exist.  
19  
20  
21

22  
23 *(i) Thermal diffusion*  
24

25  
26 During ball milling, the local temperature following impacts of steel balls might be  
27  
28 high enough to promote diffusion, but this is obviously not the case during HPT  
29  
30 experiments. Indeed, the temperature is directly linked to the strain rate and our data  
31  
32 clearly show that this latter parameter has little effect on the dissolution rate. Thus,  
33  
34 this feature clearly indicates that, as expected, the temperature does not significantly  
35  
36 increase during the torsion under high pressure. Since the atomic mobility of Cu in  
37  
38 bcc  $\alpha$ -Fe and of Fe in fcc Cu is not significant at room temperature or below [30, 31],  
39  
40 thermal diffusion cannot account for the enhanced atomic mobility and other  
41  
42 mechanisms have to be considered.  
43  
44  
45  
46  
47

48  
49 *(ii) Alternative diffusion media*  
50

51  
52 Nanostructured materials processed by SPD are characterized by non-equilibrium  
53  
54 grain boundaries acting as fast diffusion path [32], high dislocation densities and high  
55  
56 vacancy concentration [33-36]. However, only these two later kinds of crystalline  
57  
58 defects could promote bulk mixing leading to the formation of homogeneous ssss.  
59  
60 The role of dislocations as possible diffusion pipe has already been proposed for the

1  
2  
3 mixing of ball milled powders [4, 37]. However, in the present study, no segregation  
4 along linear defects was observed by APT, even for the lowest deformation rate. The  
5 reason might be that in such nanostructured alloys, dislocations are emitted but also  
6 annihilated along boundaries during plastic deformation. Concerning SPD induced  
7 vacancies, the formation of point defects by plastic deformation has been reported  
8 since the 60's and various models are proposed in the literature [38-40]. The role of  
9 high internal stresses [41, 42], high strain rates [43, 44] and SPD [33-36] have been  
10 investigated. In SPD processed materials the vacancy concentration is typically in a  
11 range of  $10^{-5}$  to  $10^{-4}$ . However, to enhance the atomic mobility not only a high density  
12 of vacancy is necessary, but vacancies should also exhibit a significant **mobility**.  
13 During the HPT process, the material is deformed under a pressure of 6.2GPa,  
14 corresponding to an elastic deformation of about 5% for the fcc Cu phase and 3% for  
15 the bcc Fe phase. In such conditions, as demonstrated by Sato and co-authors [42], the  
16 migration energy of vacancies may be reduced by 30%. As suggested in our earlier  
17 studies, such conditions sufficiently enhance the diffusion rate of Fe in fcc Cu to  
18 account for bulk diffusion at room temperature [17, 45]. However, the present  
19 investigations clearly show that at cryogenic temperature (77K) large amounts of  
20 homogeneous ssss can be obtained while the mobility of vacancies is not significant.  
21 Therefore, the following "pure mechanical mixing" mechanism should be considered.  
22  
23  
24  
25  
26

#### 50 ***4.2 Pure mechanical mixing***

51  
52 Following the approach proposed by Bellon and Averback based on Monte Carlo  
53 simulation [12] and recently supported by atomic scale investigation of ball-milled  
54 Ag-Cu powders [13], one may consider the so-called "kinetic roughening" model.  
55 During the course of SPD, atoms may be shifted across interfaces by dislocation  
56  
57  
58  
59  
60

1  
2  
3 induced shear of atomic planes. Such forced atomic jumps may lead to a significant  
4  
5 Cu-Fe intermixing near Cu/Fe interfaces. This mechanism is intrinsically symmetric,  
6  
7 but asymmetric concentration profiles may result from the balance between these  
8  
9 forced jumps and the decomposition due to thermal diffusion. Considering such a  
10  
11 mechanism for the Cu-Fe system of the present study, it seems that Cu atoms  
12  
13 mechanically forced to diffuse in the  $\alpha$ -Fe phase are easily swept back to the fcc Cu  
14  
15 phase while Fe atoms inserted in the fcc Cu phase do not have enough thermal  
16  
17 mobility to fully balance strain induced atomic jumps. Then, at higher strain there is  
18  
19 more and more Fe atoms in solid solution in the fcc Cu phase while  $\alpha$ -Fe grains  
20  
21 shrink and progressively disappear which gives rise to a homogeneous ssss.  
22  
23  
24  
25

26  
27 With this scenario, the mixing mechanism and composition gradients are not only  
28  
29 controlled by the strain level, but as well by the solubility limit (e.g. the driving force  
30  
31 for decomposition) and the thermal diffusion coefficients of Cu in bcc  $\alpha$ -Fe and of Fe  
32  
33 in fcc Cu. So, the following conditions are required:  
34  
35

36  
37  
38 *(i) Cu/Fe interfaces must be sheared by dislocations.*  
39

40  
41 From our TEM observations of the early stage of deformation, Cu/Fe interfaces  
42  
43 always appear continuous in all directions (cross sectional and longitudinal views). It  
44  
45 seems that the continuous deformation by HPT, contrary to ball milling, does not  
46  
47 promote significant shearing of Cu/Fe interfaces. As observed in cold drawn metal  
48  
49 matrix composite, both phases co-deform along the flow direction [21, 22]. But for  
50  
51 higher level of deformation when  $\alpha$ -Fe filaments become extremely thin and break-  
52  
53 up, the situation is probably very different. In principle, atomic scale analyses by APT  
54  
55 should be able to exhibit sheared interfaces. The reason why it was never clearly  
56  
57  
58  
59  
60

1  
2  
3 observed could be due to the subsequent decomposition induced by thermal diffusion.  
4  
5 This phenomenon may indeed strongly affect the topology of interfaces.  
6  
7

8  
9 *(ii) Cu and Fe should exhibit different thermal diffusion coefficient or/and*  
10  
11 *decomposition driving force.*  
12

13  
14 At low temperature, the Cu-Fe phase diagram is quite symmetric, and the solubility  
15  
16 extremely limited on both the Cu rich and Fe rich side. At 1100K, the solubility limit  
17  
18 is 4at.% Fe (respectively 2at.% Cu) in fcc Cu (respectively bcc Fe) [23]. So the  
19  
20 driving force for decomposition might be higher in the bcc  $\alpha$ -Fe phase. However, at  
21  
22 500K the thermal diffusion coefficient of Cu in bcc  $\alpha$ -Fe is 5 orders of magnitude  
23  
24 lower than that of Fe in fcc Cu [30, 31]. So, Cu ssss in bcc  $\alpha$ -Fe should be more  
25  
26 difficult to decompose than Fe ssss in fcc Cu, which is not consistent with APT data.  
27  
28 However, as discussed in the following, the atomic diffusivity might be affected under  
29  
30 HPT conditions.  
31  
32  
33  
34

35  
36  
37 *(iii) Thermal diffusion should be significant or an equivalent media may exist.*  
38

39  
40 As already discussed previously for the so-called “thermodynamic destabilization”  
41  
42 mechanism, thermal diffusion cannot give rise to significant atomic mobility but SPD  
43  
44 induced point defects may contribute to solute transport. It is interesting to note that  
45  
46 positron lifetime spectroscopy experiments have demonstrated that deformation  
47  
48 induced vacancies often agglomerate in bcc Fe while they are more homogeneously  
49  
50 distributed in fcc Cu [46]. This could be attributed to a lower migration energy in the  
51  
52 fcc Cu phase which in turn may promote the formation of the asymmetric  
53  
54 composition gradients revealed by APT.  
55

59  
60

Considering these two mixing mechanisms and their related arguments, one may also imagine that a combined process occurs.

#### 4.3 Mixed mechanism

Under a continuous and slow deformation process like HPT, dislocations could not simply cross Cu/Fe interphase boundaries and that is probably why we did not find any experimental evidence of this mixing mechanism (previously called mechanical mixing). However, if some Fe atoms diffuse in the fcc Cu phase to relax some interfacial energy (following the thermodynamic destabilization mechanism), concentration gradients would appear and consequently deeply modify the configuration of Cu/Fe interfaces. In such a situation, it seems reasonable to think that mechanical mixing would be more likely to occur. Dislocations stored along boundaries in the early stage of deformation and SPD induced vacancies may promote the formation of mixed interfaces. At cryogenic temperature, the lower atomic mobility would simply delay the process leading to a lower volume fraction of ssss after 25 revolutions by HPT.

Last, one should note that ssss obtained by HPT are homogeneous with equi-axed nanoscaled grains (Figs. 2, 3 and 8). Thus, the dissolution of  $\alpha$ -Fe filaments is combined with a progressive destruction of the original filamentary structure of the Cu-Fe composite. The thickness of  $\alpha$ -Fe filaments in the course of deformation is only few nm (Figs. 6 and 7). This is much smaller than the mean grain size of the ssss (in a range of 10 to 50 nm, Fig. 2), therefore as already reported in pure copper [47], one may conclude that boundary migration (i.e. dynamic recrystallisation) occurred during the HPT process. In the early stage of deformation, the huge amount of Cu-Fe interfaces prevents any grain boundary motion [28], but once the  $\alpha$ -Fe phase is dissolved, dynamic recrystallisation and grain growth may freely occur to reduce the

1  
2  
3 interfacial energy. One should note that similar features have been recently reported  
4  
5 in other nanocrystalline materials processed by SPD [47-49] and it is thought that the  
6  
7 movement of boundaries may promote the chemical homogenisation process.  
8  
9

## 10 11 12 13 **5. Conclusions**

14  
15 i) Fully homogeneous Fe ssss in fcc Cu were obtained by SPD under controlled  
16  
17 deformation parameters (plastic strain, strain rate and temperature). Up to 12 at.% Fe  
18  
19 atoms homogeneously distributed were dissolved in the fcc Cu phase. Once  $\alpha$ -Fe  
20  
21 filaments are completely dissolved, some dynamic recrystallisation occurs and equi-  
22  
23 axed nano-grains do form.  
24  
25

26  
27 ii) The dissolution rate is mostly controlled by the accumulated plastic strain while it  
28  
29 does not significantly change for a strain rate in range of 0.2 to  $0.02\text{s}^{-1}$ . SPD at liquid  
30  
31 nitrogen temperature delay the dissolution but very similar ssss also **forms**.  
32  
33

34  
35 iii) As shown by APT data, ssss results from Cu-Fe intermixing. During the early  
36  
37 stage of deformation, Cu-Fe interfaces exhibit asymmetric composition profiles.  
38

39  
40 iv) Two different models were considered to account for the formation of ssss: “pure  
41  
42 mechanical mixing” where the diffusion mechanism is controlled by shuffling of  
43  
44 atoms induced by shear of atomic planes, and “thermodynamic destabilization” where  
45  
46 the Cu/Fe interfacial energy is the driving force for  $\alpha$ -Fe dissolution in the fcc Cu  
47  
48 matrix. It is concluded that the observed ssss may result from a combination of these  
49  
50 two mechanisms.

## Figure captions

Figure1. SEM pictures of the Cu-Fe nanocomposite processed by accumulative cold drawing. Iron filaments are darkly imaged. (a) Cross sectional view of the wire showing a bunch of iron filaments stacked in the copper tube of the second step of the process (see text for details). The average thickness of iron filaments is 50 nm. (b) Longitudinal view of the wire showing the alignment of iron filaments along the wire axis.

Figure2. (a) Bright field TEM image of the Cu-Fe composite before severe plastic deformation; (b) corresponding Selected Area Electron Diffraction (SAED) patterns where both fcc Cu and bcc  $\alpha$ -Fe phases are detected. (c) Bright field TEM picture of the Cu-Fe composite after 25 revolutions by HPT at 293K with a strain rate of  $0.2 \text{ s}^{-1}$ ; (d) corresponding SAED pattern where only the fcc Cu phase is detected.

Figure3. (a) Three-dimensional reconstruction of a volume analyzed by APT in the Cu-Fe composite processed by HPT (25 revolutions at 293K with a strain rate of  $0.2 \text{ s}^{-1}$ ). Only Fe atoms are displayed to show their homogeneous distribution within the volume. The Fe concentration in this analysed volume is 12.6 at.% ( $\pm 0.1$ ). (b) Distribution of Fe concentrations computed in  $1.2 \times 1.2 \times 1.2 \text{ nm}^3$  sampling volumes compared with a Bernoulli random distribution.

Figure4. (a) Mössbauer spectra recorded on the Cu-Fe nanocomposite before HPT processing. (b) after HPT processing by 5 turns, (c) 14 turns and (d) 25 turns (at 293K and with a strain rate of  $0.2 \text{ s}^{-1}$ ). The paramagnetic contribution corresponding to the Cu-Fe ssss is fitted in red while the black line is the sum of both the ferromagnetic (corresponding to the bcc  $\alpha$ -Fe) and the paramagnetic contributions used to fit the spectra.

Figure5. Volume fraction of Cu-Fe solid solution measured by Mössbauer spectroscopy plotted as a function of the level of deformation by HPT. Measurements were carried out at two different temperatures (77 and 293K), and two different strain rates ( $0.2$  and  $0.02 \text{ s}^{-1}$ ).

Figure6. (a) TEM bright field image and corresponding SAED pattern (inset) of the Cu-Fe nanocomposite processed 5 revolutions by HPT (at 293K with a strain rate of  $0.2 \text{ s}^{-1}$ ). In the upper part of the image (labelled 1), the filamentary structure corresponds to a bunch of iron filaments where the bcc  $\alpha$ -Fe is detected. In the lower part (labelled 2), the copper tube used for the first restacking is imaged. (b) Three-dimensional reconstruction of a volume analysed by APT in the filamentary region. Iron atoms are displayed in green and copper atoms in red. This image shows that the thickness of iron filaments is below 10 nm after 5 revolutions by HPT. (c) Composition profile computed across the iron filament displayed in the 3D volume (thickness of the sampling volume  $0.5 \text{ nm}$ ). A significant Fe gradient appears in the Cu matrix.
