**ABSTRACT**

Social accounting matrices are adequate databases for the economic modelling. These matrices emphasize the role of households in the economy, and so, they usually disaggregate the household sector into several groups. This disaggregation allows social accounting matrices to be used for diverse income distribution analysis.

The objective of this work is to use the linear SAM models to study how inequality is modified by several exogenous injections of income. The set of multipliers and indicators presented is applied to the economy of Extremadura – a region situated in the southwest of Spain-. In particular, together with the accounting multipliers, two redistributed income matrices are presented to show how changes in final demand and in income transfers cause opposite effects in inequality. For contrasting these results, we also use Gini and Theil indices. Finally, a major reduction in both would result from an appropriate re-allocation of transfers.

Keywords: social accounting matrices, SAM multipliers, income distribution, inequality.

## 1. Introduction

Inequality measurement is an important topic in the economic literature. However, National Accounting and, more precisely, Social Accounting Matrices have not been widely used as instruments for inequality analysis. This question has already exposed by Atkinson and Bourguignon (2000), who argued that income distribution should be integrate into economic analysis. Some attempts for solving this lack can be found in Rubio and Vicente (2003), where SAM multipliers and inequality measurement were put in touch in a country-level analysis. On the other hand, computable general equilibrium models have been applied to analyse the relationship between economic growth and income inequality -Hanson and Rose (1997)- or the effects on income distribution of several energy taxation measures –Yang (2000).

In this sense, this paper was carried out in the framework of linear SAM modelling. The objective was to apply these models to the economy of Extremadura, in order to quantify and arrange the interdependence relationships, focusing on several results related to households and income inequality.

To attain this objective, together with a brief analysis of traditional SAM multipliers, three applications focused on income distribution analysis are presented. Firstly, two redistributed income matrices are computed. These matrices show the effects that exogenous inflows to either the different activity sectors or the households groups would have on the households' relative incomes. Secondly, Gini and Theil inequality indices are considered to how both indices change because of increases in final demand or in income transfers. Finally, since inequality decrease is an important goal of social policy, we calculated what the redistribution of initial income transfers should be to minimize both inequality indices.

Particularly worthy of note among the results was that increments in demand and increments in transfers had precisely the opposite effects. The former increased the inequality in income distribution between the different groups of households, while the latter reduced it. In addition, a major reduction in the two inequality indices would result from an appropriate re-allocation of transfers towards the low-income households.

The work is structured as follows. Section 2 presents the linear SAM multipliers in an abridged form, and shows the formulation required to obtain the redistributive multipliers. Section 3 is an overview of the SAM that was constructed for the Extremadura economy, and that will be used as the basis for the subsequent calculations. Section 4 presents the results of the four applications performed. Finally, section 5 gives the principal conclusions drawn from the analyses.

## 2. Linear SAM models and redistribution matrix

Social accounting matrices (SAM) can be conceived of as a disaggregated matrix representation of the circular flow of income, allowing one to study the processes of the generation and distribution of income. These matrices are generally presented as square matrices, with a row and a column identically arranged for each agent or economic sector incorporated in the matrix. By convention, the row entries are interpreted as income, and the column entries as payments or expenditures. An important accounting constraint is that a SAM should satisfy the necessary equality between the sum of each row and the sum of its corresponding column.

Their principal application is as a basis for the construction of economic models. A first group of such models is that of the so-called linear SAM models. These allow one to determine the changes in income levels of the different agents that may be caused by

possible exogenous shocks. Other indicators may be established based on these multipliers to determine the relative changes in endogenous incomes<sup>1</sup>.

It is important to note that, since it captures in a complete way the interrelationships between the different agents and sectors, this methodology is well suited to evaluating multiplicative effects. In addition, the level of disaggregation that SAMs normally incorporate enables the obtained multipliers to be presented with a high degree of detail.

To construct a SAM multiplier model, one must begin by classifying the SAM accounts into endogenous and exogenous. Traditionally, public administrations, the capital or savings/investment account, and the external sector accounts are usually considered exogenous. The accounts for the productive factors, the remaining institutional sectors, and the activity sectors are therefore considered endogenous<sup>2</sup>.

In the formulation of these models, one basically transforms and rewrites the SAM's accounting identities. Assume that the total number of accounts in the SAM,  $m$ , is apportioned between  $n$  endogenous and  $k$  exogenous accounts, and that the column vectors  $\mathbf{y}_n$  and  $\mathbf{y}_k$  represent their levels of production or income. Using  $\mathbf{A}_{ij}$  to denote submatrices of column-normalized coefficients -expenditure share-, the partitioned matrix structure of the SAM can be expressed in the following manner:

$$\begin{pmatrix} \mathbf{y}_n \\ \mathbf{y}_k \end{pmatrix} = \begin{pmatrix} \mathbf{A}_{nn} & \mathbf{A}_{nk} \\ \mathbf{A}_{kn} & \mathbf{A}_{kk} \end{pmatrix} \begin{pmatrix} \mathbf{y}_n \\ \mathbf{y}_k \end{pmatrix} \quad (1)$$

Computing this matrix product:

$$y_n = A_{nn}y_n + A_{nk}y_k = (I - A_{nn})^{-1}A_{nk}y_k = (I - A_{nn})^{-1}x = Ma \cdot x \quad (2)$$

The column vector  $x$  shows the sum of exogenous injections received by each endogenous account. The matrix  $\mathbf{Ma}$  allows one to relate exogenous injections of income with the incomes of the endogenous accounts, providing the termed accounting multipliers<sup>3</sup>.

The SAM multipliers analysis has traditionally focused on determining changes in absolute income levels. It is also important, however, to determine what changes the possible exogenous shocks would cause to the relative position of a given economic agent. The accounting multipliers can be used as the basis to define other measures that capture these relative effects. A good example is found in the redistributive multipliers set forth by Roland-Holst and Sancho (1992)<sup>4</sup>. Following these authors, one defines the relative income vector  $z_n$ :

$$z_n = \frac{y_n}{e' y_n} \quad (3),$$

where  $e'$  is a unitary row vector. Substituting the expression for  $y_n$ , equation (2), and with matrix differentiation, one has:

$$\begin{aligned} dz_n &= (e' Ma x)^{-1} \left[ I - (e' Ma x)^{-1} (Ma x) e' \right] Ma dx = \\ &= \frac{1}{e' y_n} \left[ I - \frac{y_n}{e' y_n} e' \right] Ma dx = R dx \end{aligned} \quad (4)$$

The matrix  $\mathbf{R}$ , termed redistribution matrix, determines the ultimate distribution of relative incomes resulting from different exogenous shocks.<sup>5</sup> To show and interpret the redistributive effects more closely, a generic element  $R_{ij}$  can be expressed in the following manner:

$$R_{ij} = \frac{1}{e'y_n} \left[ Ma_{ij} - \frac{y_{ni}}{e'y_n} (e'Ma_{.j}) \right] \quad (5),$$

where  $y_{ni}$  is the  $i$ -th component of vector  $y_n$ , and  $Ma_{.j}$  is the  $j$ -th column of the matrix  $\mathbf{Ma}$ . One observes that the sign of  $R_{ij}$  depends, therefore, on the terms in brackets, i.e., it depends on the relationship between  $Ma_{ij}/(e'Ma_{.j})$  and  $y_{ni}/(e'y_n)$ .

An exogenous injection received by  $j$  account will improve the relative position of agent  $i$  if  $i$ 's share of the multiplier gains ( $Ma_{ij}/(e'Ma_{.j})$ ) exceeds its initial share of nominal income, ( $y_{ni}/(e'y_n)$ ), determining, therefore, a positive value of  $R_{ij}$ . On the opposite, a negative value of  $R_{ij}$  shows a worsening in its relative position.

### 3. Social accounting matrix for the Extremadura economy

To carry out the subsequent applications, we took as the basis the only SAM built for the Extremadura economy, corresponding to the year 1990<sup>6</sup>. The set of accounts conforming this matrix (henceforth, SAMEXT90) is presented in figure 1.

The main statistical sources used have been a table of intersectoral flows (input-output table), the corresponding Regional Accounts, and a household's income and expenditure survey. Other more specific sources were also used to complete certain transactions of

1  
2  
3 the matrix.  
4

5  
6 With respect to its disaggregation, firstly, there are two accounts for the labour and  
7  
8 capital production factors, that reflect the value added generated in production and its  
9  
10 distribution among the eleven household groups. These ones have disaggregated  
11  
12 according to different criteria as age, activity sector or income level. Although the  
13  
14 households' incomes basically come from the labour and capital factors, they also  
15  
16 receive transfers from the government and the external sectors. With these incomes, the  
17  
18 households consume, save, and make various payments to the government.  
19

20  
21 Regarding the activity sectors, their accounting structure is analogous to an input-output  
22  
23 table structure. In particular, their cost structure (columns) reflects payments to the  
24  
25 labour and capital factors, intermediate inputs, imports, and payments to the government  
26  
27 (production and import taxes). Their rows reflect intermediate outputs, private  
28  
29 consumption, public consumption, investment, and exports.  
30  
31

32  
33 Finally, SAMEXT90 also includes an aggregate capital account, reflecting the overall  
34  
35 equilibrium between savings and investment; a government account; and three accounts  
36  
37 reflecting the relationships between the Extremadura economy and the three  
38  
39 differentiated external sectors – rest of Spain, European Community, and rest of the  
40  
41 world.  
42  
43  
44

#### 45 46 47 48 **4. Analysis of the results** 49

50  
51 The presented applications are clearly aimed at an income distribution and inequality  
52  
53 analysis. We first calculated the accounting multiplier matrix as an application for  
54  
55 showing the capacity that the different endogenous agents have to generate increments  
56  
57 in income. The following three applications represent the main body of the study,  
58  
59  
60

1  
2  
3 analysing the incomes of the different household groups and on their relationships with  
4 the production sectors. In this sense, the second application deals with two redistributive  
5 effects matrices related to households' relative incomes. The third application  
6 emphasizes these results, by simulating increases in final demand and income transfers  
7 and assessing the changes in some inequality indices. Finally, the fourth application, in  
8 calculating the redistribution of the initial transfers required to minimize two standard  
9 inequality indices, shows the importance of transfers as a redistributive instrument.  
10  
11  
12  
13  
14  
15

17  
18  
19  
20  
21

#### 22 **4.1 The accounting multipliers matrix**

23  
24 In our case, the usual closure assumption for SAM multipliers model is used, that is, the  
25 accounts for production factors, household groups, and activity sectors are considered as  
26 endogenous. Therefore, the corresponding accounting multipliers matrix - **Ma (Ext)** - is  
27 of order  $30 \times 30$ .  
28  
29  
30  
31  
32

33  
34 Although one could differentiate various submatrices that carry relevant information, in  
35 this section we shall restrict ourselves to analyzing the multipliers calculated as column  
36 sums of the matrix **Ma(Ext)**, that we term diffusion effects (backward linkages in input-  
37 output terms). These multipliers show the overall effects of a unitary exogenous  
38 injection received by the endogenous account under consideration on all endogenous  
39 account incomes. Thus, agents or sectors with large diffusion effects generate significant  
40 knock-on effects, and they could hence be considered as priorities with respect to  
41 receiving exogenous impulses from public administrations.  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52

53 These diffusion effects are given in table 1. It is clear that the greatest effects correspond  
54 to the service sectors, especially credit and insurance (account 28) and other sales-  
55 oriented services (account 29), with a multiplier of approximately five m.u. per received  
56  
57  
58  
59  
60

1  
2  
3 exogenous m.u. The farming (account 14) and construction (account 25) sectors also  
4  
5 give rise to major income expansion effects. The higher multipliers computed for these  
6  
7 activity sectors correspond to a higher interdependence with the rest of endogenous  
8  
9 agents. On the other hand, the industrial sector stands out for its small relative weight in  
10  
11 the Extremadura economy, and its poor capacity for generating relevant knock-on  
12  
13 effects as well (see accounts 18-24).  
14  
15

16  
17 With respect to the household groups, it is interesting to note that the multipliers for the  
18  
19 low-income households are greater than those multipliers of the equivalent high-income  
20  
21 groups. This result is due to the lower savings and payments for direct taxation, in  
22  
23 relative terms, of low-income households. Consequently, there are also less income  
24  
25 leakages to the exogenous part of the model, and so, producing a higher boost to the  
26  
27 economic activity by consumption.  
28  
29  
30  
31  
32

#### 33 34 **4.2 Redistributed income matrices: activity sectors - households, and households -** 35 36 **households**

37  
38 In this second application, a more detailed analysis was made for two sets of multipliers  
39  
40 related to households' incomes. One can define the activities-households multipliers as  
41  
42 those that reflect how exogenous injections into the activity sectors affect household  
43  
44 incomes. Moreover, the households-households multipliers as those that reflect how  
45  
46 those incomes are affected when households receive exogenous inflow income transfers.  
47  
48 Using the formalism of section 2, in the following, we use both sets of multipliers to  
49  
50 present their corresponding redistributive matrices<sup>7</sup>. The aim is to determine in relative  
51  
52 terms for which household groups increments in final exogenous demand or in income  
53  
54 transfers are beneficial, and for which they are detrimental. Nevertheless, to facilitate the  
55  
56  
57  
58  
59  
60

1  
2  
3 interpretation of the results, instead of the redistribution matrix  $R$ , we shall present a  
4 transformation of  $R$  consisting in pre-multiplying it by the term  $(e' y_n)$ . The elements of  
5 this new matrix reflect the value of the redistributed income, assuming the value of the  
6 endogenous accounts' initial incomes to remain constant<sup>8</sup>.  
7  
8

9  
10 Specifically, starting from the activities-households submatrix of **Ma (Ext)**, one  
11 calculates its corresponding redistributed income matrix (table 2). The last row indicates  
12 the redistribution of household income over each sector of activity when there is an  
13 increase in its corresponding demand of one m.u. For example, if there is an exogenous  
14 increase in the demand for farming goods, 0.091 m.u. of household income would be  
15 redistributed: 0.001 m.u. corresponding to the first households group, 0.026 m.u. to the  
16 second, 0.004 m.u. to the sixth, and 0.06 m.u. to the seventh, while the rest of the  
17 households' incomes would undergo a relative worsening. One observes that these  
18 overall redistributive effects clearly reproduce the diffusion effects presented in table 1,  
19 because the sectors with more significant effects –in our case, a higher redistribution of  
20 household income- are again the service sectors (accounts 26-30), followed by farming  
21 and construction. The remaining activities, especially the industrial activities, present far  
22 smaller total redistributive effects.  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42

43 It is more interesting to consider the values in the last column. This column represents  
44 the mean redistributive effects of a unitary increment in demand. These values are  
45 computed as a weighted mean of the row elements, using the shares of exogenous  
46 injections of each sector as weights.  
47  
48  
49  
50  
51

52 One observes that the pattern of relative improvement or worsening showed by the mean  
53 effect remains, almost independently of which activity sector receives the exogenous  
54 injection. In particular, the results show a worsening in the relative position of the retiree  
55  
56  
57  
58  
59  
60

1  
2  
3 household groups (accounts 10-13). That is why their main source of income is  
4 government-paid pensions, so the effects that correspond to the distribution of factors  
5 incomes among households lack in their chain of interdependence. Similar reasons,  
6 namely, a relatively small share of incomes from labour and capital factors, determine a  
7 relative worsening for the active low-income households (accounts 3, 5, and 6).

8  
9 In fact, the only household groups that benefit in relative terms are those of high income.  
10  
11 In particular, considering this last column, approximately 66% of the redistributed  
12 income corresponds to account nine (the fifth quintile of active non-farming  
13 households), 16% to account eight (the fourth quintile), 8% to account seven (third  
14 quintile), and 10% to account four (high-income active farming households). The results  
15 thus seem to show that exogenous increases in demand tend to widen even more the  
16 differences between low-income and high-income household groups.

17  
18 Secondly, and to conclude this subsection, we shall consider the households-households  
19 multipliers and its corresponding redistributed income matrix (see table 3). The aim is to  
20 determine how the relative incomes of households are affected by transfers received by  
21 the households themselves.

22  
23 In contrast to the previous table, one observes a clear predominance of negative signs.  
24 The exogenous income transfers only improve the relative position of the household  
25 group that received them, so that there are no mutually beneficial linkages (symmetric  
26 pairs of positive elements).

27  
28 Likewise, except for the elements in the main diagonal, for each household group the  
29 elements in its corresponding row are very similar, that is, irrespective of the household  
30 group that receives the exogenous injection, changes in its relative position are almost  
31 the same. On the other hand, although the results show certain homogeneity in the total

1  
2  
3 redistribution effects on household incomes, the previous diffusion effects are  
4 reproduced again, since the high-income households again show less capacity to  
5 generate significant effects than their low-income equivalents.  
6  
7  
8  
9

10 It is important to note that the results given in the last column (mean redistributive  
11 effects) are in the opposite sense to those presented in table 2<sup>9</sup>. Specifically, the results  
12 logically show that a transfers increase reduce the differences between low and high  
13 incomes. Indeed, the lowest income groups are almost the only ones that benefit in their  
14 relative positions, especially some of the retiree household groups. The four household  
15 groups that previously benefited in relative terms (accounts 4, 7, 8, and 9 in table 2) now  
16 show a clear worsening in their relative position.

### 29 **4.3 Measuring inequality after final demand and transfers changes**

30 In this third application, we carried out two sets of simulations that were directly related  
31 to the previous redistributed income matrices. The objective of these applications is to  
32 confirm the results of the redistributed income matrices, by using the traditional income  
33 inequality analysis. Given these matrices, it is expected that, on one hand, increments in  
34 final demand increases the inequality level and, on the other one, increments in transfers  
35 reduce it. Apart from these qualitative aspects, the inequality indices we employed  
36 provide us quantitative information about the effects of growth and transfers on  
37 inequality.  
38

50 Therefore, a first set of simulations was aimed at determining to what degree the levels  
51 of inequality are altered by increments in exogenous final demand, and the other the  
52 same, but by increments in exogenous income transfers received by households. The  
53 trials in both sets of simulations consisted of 10%, 20%, and 30% injections on each  
54  
55  
56  
57  
58  
59  
60

activity sector and each household group.

In this application, we considered two indices widely used in the literature: the Gini index, and the Theil index. The advantage of using this type of measure is that, since they are functions that assign a real number to each income distribution, they summarize all the information contained in the distribution in a single scalar. The two indices have quite different aggregation procedures, however, and therefore provide numerically distinct results.

The Gini index is probably the most commonly used inequality measure, due to its geometric interpretation and its relationship with the Lorenz curve. It is defined by the following expression:

$$G = \frac{1}{2\mu} \left( \frac{1}{n^2} \right) \sum_{i=1}^n \sum_{j=1}^n |y_i - y_j| \quad (6)$$

The Theil index is based on the concept of entropy, and indeed forms part of the general class of entropy measures (Cowell, 1995). It is defined by the following expressions:

$$T_c = \frac{1}{n} \frac{1}{c(c-1)} \sum_{i=1}^n \left[ \left( \frac{y_i}{\mu} \right)^c - 1 \right], \quad c \neq 0, 1 \quad (7.a)$$

$$T_0 = \frac{1}{n} \sum_{i=1}^n \ln \left( \frac{\mu}{y_i} \right), \quad c = 0 \quad (7.b)$$

We set the parameter  $c$  to zero, to facilitate the optimization programming that will be presented in the next section.

1  
2  
3 The simulations results for both indices are presented in tables four and five<sup>10</sup>.  
4  
5 Beginning with the changes in demand (table 4), the results clearly show that stimulating  
6  
7 the demand without making any other adjustment to the Extremadura economy leads to  
8  
9 increased inequality<sup>11</sup>. Also, the changes in the two indices become greater, the larger  
10  
11 the increment in the demand. It is important to note that these demand increases  
12  
13 determine greater income increments for the high-income households. In this sense, due  
14  
15 to the different sensitivity of both indices respect to changes in the distribution<sup>12</sup>, one  
16  
17 observes that the changes in the Theil index become progressively greater than the  
18  
19 corresponding changes in the Gini index.  
20  
21  
22  
23

24  
25 The results for changes in transfers (table 5) are in the opposite sense to the preceding  
26  
27 case: the transfers increments led to reductions in the inequality indices<sup>13</sup>. This was an  
28  
29 expected result since the transfers are mainly received by the low-income household  
30  
31 groups, thereby narrowing the gap between the values of their nominal income. As in the  
32  
33 previous simulations, the different sensitivities of the two indices cause that the changes  
34  
35 in the Theil index become progressively greater than the corresponding changes in the  
36  
37 Gini index.  
38  
39

40  
41 To conclude this subsection, it is important to note that the results of these simulations  
42  
43 confirm the conclusions drawn from the redistributive effects. In particular, although the  
44  
45 techniques of analysis are different, in both cases one observes that increments in final  
46  
47 demand or income transfers have contrary effects on the evolution of inequality.  
48  
49

#### 50 51 52 53 **4.4 Transfers redistribution and inequality minimization**

54  
55 The importance of income transfers as a redistribution tool has been made clear by the  
56  
57 preceding applications. Because of this importance, we propose a re-allocation of  
58  
59  
60

1  
2  
3 transfers in order to reduce income inequality. Exogenous transfers are very significant  
4 in the Extremadura economy and, besides, social and anti-poverty policies are much  
5 decentralized in Spain. Therefore, it is worth to explore the available actions for the  
6 regional government.  
7  
8  
9

10  
11 In particular, instead of increments in transfers, we propose a re-allocation of transfers,  
12 remaining constant its overall value<sup>14</sup>. We again used the linear SAM modelling  
13 framework showed in equation 2, since transfers redistribution modifies the exogenous  
14 inflows that the households receive, and consequently the endogenous incomes vary<sup>15</sup>.  
15  
16  
17

18  
19 Table 6 gives the two patterns of transfers redistribution that minimize the Gini and the  
20 Theil indices. In both cases, the only groups that should receive greater transfers than in  
21 the initial situation are the low initial incomes households (accounts 3, 5, 10, and 12), as  
22 well as the retiree urban high-income group (account 13). These would therefore be the  
23 only beneficiaries of this process of redistribution.  
24  
25  
26

27  
28 There are slight differences, though, according as to whether the Gini or the Theil index  
29 is used. In the former case, the reduction in inequality is smaller; also, other household  
30 groups – the second quintile of active non-farming households (account 6) and the  
31 higher-income rural retirees (account 11) would receive certain transfers, although less  
32 in quantity than the initial values. In the latter case, the sensitivity of the Theil index to  
33 changes in the low tail of the distribution leads to greater changes being proposed for the  
34 lower-income groups, which in turn leads to a greater reduction of the inequality.

## 51 52 53 **5. Conclusions**

54  
55 A set of applications based on the methodological framework of SAM multipliers has  
56 been presented for Extremadura. In particular, following the computation of the  
57  
58  
59  
60

1  
2  
3 accounting multipliers, the three subsequent applications were focused on income  
4 distribution analysis – the fundamental objective of the work. The first of these  
5 applications presented the activities-households and households-households  
6 redistributive matrices. In the next, straightforward simulations were made to determine  
7 how changes in demand or in transfers alter the levels of inequality. In addition, the last  
8 application quantified the redistribution of the initial transfers that minimizes the  
9 inequality.

10  
11 The results showed that low-income households have a greater capacity to generate  
12 increments in income than their high-income equivalents, although the greatest diffusion  
13 effects correspond to the service sectors. In addition, the accounts with the greatest  
14 diffusion effects are also those that present the greatest total redistributive effects in the  
15 activities-households and households-households redistributed income matrices.

16  
17 These last two matrices allow one to determine which household groups undergo a  
18 relative improvement and which a relative worsening in response to changes in demand  
19 or in transfers. The results showed increasing demand or increasing transfers to have  
20 opposite effects. In the former, increases in demand led to a relative improvement in  
21 high-income households at the cost of those of low income, thus widening the initial gap  
22 between the two. In the latter, however, the household groups that improved in relative  
23 terms in response to increases in transfers were clearly those of low income.

24  
25 The simulations reported in the third application again investigated the effects on  
26 income distribution of changes in demand or in transfers. The results for the two indices  
27 used were coherent with the preceding case.

28  
29 The last application showed how an appropriate redistribution of the transfers over the  
30 household groups allows the initial inequality indices to be significantly reduced. Given

1  
2  
3 that the practical entirety of these transfers comes from the public sector, the  
4  
5 methodological framework used in the present work could be a valid referent in  
6  
7 establishing social policy measures aimed at reducing inequality.  
8  
9

10 To conclude, we would make two final observations. First, we wish to call the attention  
11  
12 of national and regional statistical bodies to the necessity of providing adequate  
13  
14 statistical sources. These constitute the numerical support needed for any minimally  
15  
16 updated economic analysis to be feasible. Second, we wish to stress the methodological  
17  
18 potential of the analysis that has been described in the present work. SAM multipliers  
19  
20 have allowed us to obtain important results related to the processes of income  
21  
22 distribution and redistribution – results that would previously have been difficult to  
23  
24 anticipate and quantify intuitively.  
25

<sup>1</sup> Social accounting matrices are also typically used to calibrate the parameters of computable general equilibrium models.

<sup>2</sup> There nevertheless exist alternative closure assumptions. See Reinert *et al.* (1993).

<sup>3</sup> A generic element  $Ma_{ij}$  of the said matrix reflects the increment that will accrue in the income of endogenous account  $i$  if endogenous account  $j$  receives an additional monetary unit of income from the exogenous accounts. For a more detailed analysis of this model, see Pyatt and Round (1979). These authors also present a procedure for the decomposition of the multipliers, giving the necessary existence

---

conditions of the resulting matrices.

<sup>4</sup> See also Roland-Holst (1990), Polo *et al.* (1990) and Llop and Manresa (2004). Moreover, Cohen and Tuyl (1991) proposed a different approach for income redistribution analysis, presenting various relative distributive measures. See also, De Miguel and Manresa (2004).

<sup>5</sup> A generic element  $R_{ij}$  of the said matrix indicates the direction and magnitude of the change in relative income of account  $i$  resulting from a unitary exogenous injection received by account  $j$ . It can be demonstrated that the different columns of this matrix  $R$  sum to zero, independently of how the distribution is made between endogenous and exogenous accounts. The process of income redistribution could therefore be regarded as a zero-sum game.

<sup>6</sup> Due to the absence of a Regional Statistical Institute, the lack of statistical information is especially serious in Extremadura. These statistical limitations have determined the degree of detail of the SAMEXT90 matrix -it would have been appropriate to disaggregate the labour factor- and have prevented the construction of a SAM referred to a more recent period. For example, it is important to note that there is only one input-output table for the Extremadura economy, also referred to the year 1990. For more detailed information on the Extremadura matrix, see De Miguel, Manresa and Ramajo (1998) and De Miguel (2003).

<sup>7</sup> "Elements of the matrix  $\mathbf{R}$  are in a one-to-one correspondence with those of the original  $\mathbf{M}$  [ $\mathbf{Ma}$ ], and the normalization of incomes can be chosen for the subgroup of endogenous institutions under study." Roland-Holst (1990, pp. 129).

<sup>8</sup> It can be shown that the columns of this redistributed income matrix also sum to zero.

<sup>9</sup> The weights used in this case are those of the exogenous injections received by the different households groups.

<sup>10</sup> Although not presented here for the sake of clarity, these indices can also be calculated by differentiating between active workers (accounts 3-9 in the matrix) and retirees (accounts 10-13). It is also possible to differentiate between high and low incomes directly, i.e., applying the distinction to the active farming-linked households (accounts 1 and 2), the households of active workers in other sectors (accounts 3-7), of rural retirees (groups 8 and 9), and of urban retirees (groups 10 and 11). The results that we obtained in these cases showed the same tendency as described in the text.

<sup>11</sup> By using a different methodological approach, Assane and Grammy (2003) analyze the causal relationship between growth and inequality.

<sup>12</sup> The Gini index is more sensitive to the changes in the centre of the distribution (Sen, 1997), while the Theil index, with the parameter  $c$  set to zero, is more sensitive to changes in the extremes (Shorrocks, 1980).

<sup>13</sup> Indeed, in the initial situation reflected by SAMEXT90, the incorporation of transfers leads to a major reduction in inequality. In particular, the initial Gini and Theil indices for primary incomes are 0.5837 and 0.9456, respectively, both clearly greater than the final income indices (0.4902 and 0.5131). The reduction in the Theil index is far greater because the transfers fundamentally affect the household groups situated at the lower tail of the distribution.

<sup>14</sup> Isla, Moniche and Trujillo (2002) present a similar analysis for Andalusian economy.

<sup>15</sup> The inequality indices were minimized by solving the corresponding optimization problem, using GAMS (General Algebraic Modelling System) software.
