Simultaneous Estimation of Income and Price Elasticities of Export Demand, Scale Economies and Total Factor Productivity Growth for Brazil¹

Simultaneous Estimation of Export Elasticities and Productivity

Abstract

This paper focuses on a model in which low (high) export demand elasticities and the fact that developing countries are importers of capital goods help explaining the slow (high) growth of these countries. The question arises whether export demand elasticities are low or high. For answering this question, export demand elasticities for the case of Brazil are estimated using a growth model. As a by-product of estimating the model, we obtain estimates for total-factor productivity growth and for scale economies. Based on the results from estimation we calculate steady-state growth rates, engine and handmaiden effects of growth as well as dynamic steady-state gains from trade. The model and the results are discussed in regard to several strands of literature.

Keywords: Development, international linkages, open economy growth models, time-series.

1. Introduction

Income and price elasticities of export demand are important for several reasons. When real devaluations occur, the value of exports increases (decreases) if export demand is price-(in)elastic. Therefore, more (less) imports can be bought from abroad. If imports are investment goods, this increases (decreases) investment. In particular, if technical progress yields lower terms of trade, this transmits more or less strongly into growth rates of exports and investment; and if booming exports drive up the terms of trade, it depends on price elasticities how strongly this boom is curtailing itself by boosting the terms of trade. Income elasticities of export demand determine how strongly growth abroad is translated into growth in exports. Again, if investment goods are paid for by these exports, the income elasticities of export demand have an impact on growth and on dynamic gains from trade.

In this paper, we estimate income and price elasticities of export demand from a slightly modified version of a two-gap growth model with imported inputs, introduced by Bardhan and Lewis (1970). In doing so, we hope to contribute to several strands of literature. First, the literature on exports and growth has benefited much from the insight that imported inputs paid by exports are the major mechanism in the relation between exports and growth in the short run (see Khan and Knight, 1988) and in the long run (see Esfahani, 1991). Similarly, Levine and Renelt (1992), and Wacziarg (2001) found that the major channel for trade and growth is investment. In line with that idea, recent time-series literature found that the causality going from exports to output growth is stronger than that going vice versa (see Riezman et al., 1996; Islam, 1998; Asafu-Adjaye and Chakraborty, 1999; Krishna et al., 2003).² Riezman et al. (1996) pointed out that this

‘may serve as a guide to theorists who are currently working to develop better theories of economic growth’. We would like to recall that such a theory already exists since long: in the widely ignored model by Bardhan and Lewis (1970), exports are a second driving force for growth besides technical change because investment goods are imported. We use that model but go one step further: we estimate a full-fledged growth model rather than extended production functions or ad hoc specifications in order to get estimates of the export elasticities, total factor productivity growth and scale economies.

Second, growth and dynamic gains from trade are closely related since the question is whether trade increases the growth rate of the economy (see Lewer and van den Berg, 2003, for a recent survey). The larger the income elasticity of export demand the larger the growth rate of the economy in the model used below. Our estimates allow calculating the steady-state part of the dynamic gains from trade conditional on assumptions about future employment growth.

Third, the literature on balance of payments constrained growth is closely linked to that of two-gap models. In these models, the standard approach is to solve the balance of payments for the relative growth rate of the country in question and the world and to assume that terms of trade are constant or have no impact (see Bertola et al., 2002, for a recent contribution). The terms of trade have been made endogenous by Fagerberg (1988), who assumes that they equal relative unit labour costs, which in turn are exogenous though. In Verspagen (1993, Chap.7) relative unit labour costs depend on a Verdoorn effect, thus the terms of trade are endogenous. However, in his model, demand has no direct effect on the terms of trade as in the Bardhan and Lewis model, on which we base our estimates. In short, the demand side is added to that literature and we

1
2
3 estimate its parameters in order to determine the effects of both, technological change and
4 demand, on the terms of trade.
5
6

7
8 Fourth, there is the literature concerning the effects of devaluations or concerning the
9 explanation of terms of trade movements. Here, the income and price elasticities of
10 export demand are estimated from export demand functions (Riedel and Athukorala,
11 1995; Mody and Yilmaz, 1997; Senhadji and Montenegro, 1998), from partial
12 equilibrium models of export demand and supply (Muscatelli, 1995; Madsen, 1999;
13 Catão and Falcetti, 1999) and from demand side parts of a general equilibrium model (see
14 Reinhart, 1995). In contrast to those approaches relying on partial equilibrium models,
15 we use a growth model for our estimates.

26

27 Fifth, the slightly modified Bardhan and Lewis model serves as a theoretical
28 foundation of the thoughts of Prebisch and Singer (see Ziesemer, 1995). Our estimates
29 are the empirical complement to that theory, containing both parts of the history of
30 economic thought, namely the engine and the handmaiden part of growth. As a by-
31 product of our procedure, we also get estimates of total-factor-productivity growth and of
32 scale economies for Brazil, which is the country for which we carry out the estimation.

41 The paper is set up as follows. In section 2 we present the model and compare it to
42 the neoclassical growth model. Section 3 describes the data. Estimates of the growth
43 model using the general method of moments estimator (GMM) are presented in section 4.
44 In section 5, we use the estimated results to calculate steady-state growth rates, engine
45 and handmaiden effects, and dynamic steady-state gains from trade. Section 6 relates the
46 results to the aforementioned branches of the literature.

2. The Model

The question dealt with in this section is whether imports of capital goods and low (high) export demand elasticities could account for slow (fast) growth in comparison with the Solow (1956) growth model. The model assumes flexible wages and exogenous employment. A Cobb-Douglas production function with exogenous technical progress is used:

$$Y = e^{bt} AK^\beta L^\alpha U, 0 < \alpha, \beta < 1, \alpha + \beta \geq (\leq) 1 \quad (1)$$

Y denotes output, K capital, L labour, b the rate of technological progress, 'A' is a time independent constant, U a stochastic term and α and β the elasticity of production of labour and capital. We allow for increasing, decreasing and constant returns to scale. Labour is assumed to grow at rate ε , which is determined exogenously:

$$L(t) = L(0)e^{\varepsilon t}, \hat{L} = \varepsilon \quad (2)$$

A "hat" over a variable indicates a growth rate. The fact that they are importers of capital goods seems to be a fundamental problem of developing countries. Importing less luxury consumption goods may be helpful but cannot be a solution by itself. Therefore, it is assumed that no luxury items are imported. Problems referring to the terms of trade or growth may occur despite the absence of imports other than capital goods. Fundamental obstacles for developing economies are rather the importation of capital goods as well as limited export demand. By assumption, capital goods invested in developing countries must be imported:

$$M = \dot{K} \quad (3)$$

A "dot" over a variable denotes its derivative with respect to time, and M represents imports. Capital goods are the only imports – another simplification besides the absence of foreign debt – and have to be paid for by exports. This requirement stems from the trade-balance equilibrium. Investments are, therefore, limited by exports, denoted by X , which are expressed in terms of the imported capital goods:

$$\hat{K} = \frac{\dot{K}}{K} = p \frac{X}{K} - \delta, \quad \hat{K} = \hat{p} + \hat{X} - \hat{K} \quad (4)$$

p represents the terms of trade, defined as the price of domestic goods in terms of imported capital goods. Investments need to be paid for by domestic savings measured in terms of imported capital goods. The savings rate s is assumed to be a constant proportion of output in this theoretical part and depreciation is δK :

$$\hat{K} = \frac{\dot{K}}{K} = sp \frac{Y}{K} - \delta, \quad \hat{K} = \hat{p} + \hat{Y} - \hat{K} \quad (5)$$

Investments are limited by exports. Exports in turn are assumed to depend on the trade partners' income, Z , and on the terms of trade. For the sake of simplicity, a log-linear export function with a constant B^3 and a stochastic term V is used:

$$X = BZ^\rho p^\eta V, \quad \rho > 0, \eta < 0 \quad (6)$$

ρ denotes the income elasticity and η represents the (negative) price elasticity of export demand. Together, these six equations explain the six variables $Y, L, M, p, K,$ and X .

Inserting the functions for exports and output, (6) and (1), into the export and saving constraint for investment, (4) and (5), respectively, writing the depreciation rate on the left hand side and taking natural logs, denoted \ln , yields:

$$\ln(\hat{K} + \delta) = \ln B + \rho \ln Z + (1 + \eta) \ln p + \ln V - \ln K \quad (4')$$

$$\ln(\hat{K} + \delta) = \ln p + bt + \ln A + (\beta - 1) \ln K + \alpha \ln L + \ln U \quad (5')$$

Uncertainty is kept as inessential and simple as possible here because we are not interested in any uncertainty aspect per se but rather need this aspect only to relate it to econometric models. Basically, the assumption is that firms know L and K (from the previous period) with certainty and produce after U has become known. Households then decide to save a fraction s of their income Y and this determines gross investment. When the V -term in the export function is known, p can adjust to determine external equilibrium. All rigidities and the implied consequences for the future are assumed to be absent for the sake of simplicity. In particular, the irreversibility of capital is assumed to be irrelevant. In a more sophisticated investment theory this is only justified if the optimal capital stock never decreases by more than depreciation.

In our model, the output per worker in units of domestic goods is considered a rough indicator of welfare. The driving forces behind the expected value (denoted by E) of the latter are the rate of technical progress and the growth rate of the capital-labour ratio, which is denoted by k (with $E(\ln U) = 0$):

$$\hat{y} = b + \beta \hat{k} + (\alpha + \beta - 1) \hat{L} \quad (7)$$

The last term corrects for scale economies. Since the rate of technical progress is given, the remaining question is whether a low income elasticity of export demand hinders rapid growth of the capital-labour ratio by restricting the importation of capital goods. The growth rates for the long-term equilibrium growth path are of crucial interest in this respect. Solving equations (4') and (5') for the natural log of the terms of trade and the left hand side variable yields:

$$\ln(\hat{K} + \delta) = \frac{-\ln B}{\eta} + \ln A \frac{(\eta+1)}{\eta} + \frac{\eta+1}{\eta} \ln s + \frac{b(\eta+1)}{\eta} t + \frac{\beta\eta + \beta - \eta}{\eta} \ln K$$

$$+ \frac{\alpha(\eta+1)}{\eta} \ln L + \frac{-\rho}{\eta} \ln Z + \frac{\eta+1}{\eta} \ln U - \frac{1}{\eta} \ln V \quad (8)$$

$$\ln p = \frac{\ln A - \ln B}{\eta} + \frac{1}{\eta} \ln s + \frac{b}{\eta} t + \frac{\beta}{\eta} \ln K + \frac{\alpha}{\eta} \ln L - \frac{\rho}{\eta} \ln Z + \frac{1}{\eta} (\ln U - \ln V) \quad (9)$$

The expected value (setting $\ln U = \ln V = 0$ henceforth) of equation (8) is a differential equation of K with negative slope. K has an impact on equation (9) but $\ln p$ has none on (8).

The next step is to take the derivative with respect to time of both equations, set both sides equal to zero and assume a constant savings ratio in the steady state. Then the steady-state growth rate can be written as follows:

$$\hat{k} = \frac{\rho \hat{Z} - \varepsilon - (1+\eta)[(\alpha + \beta - 1)\varepsilon + b]}{-\eta(1-\beta) + \beta} \quad (10)$$

Inserting this solution into the equation determining the change in the terms of trade and into equation (7) yields the following solutions for the terms of trade and income per capita, respectively:

$$\hat{p} = \frac{(1-\beta)(\rho\hat{Z}-\varepsilon) - (\alpha+\beta-1)\varepsilon - b}{-\eta(1-\beta) + \beta} \quad (11)$$

$$\hat{y} = \frac{\beta(\rho\hat{Z}-\varepsilon) - \eta((\alpha+\beta-1)\varepsilon + b)}{-\eta(1-\beta) + \beta} \quad (12)$$

The numerators of equations (10) to (12) consist of three terms, the first of which reflects the "engine of growth" part from the export demand function: the growth rate of world income multiplied by the income elasticity of export demand minus the population growth rate. The product of trade partners' income and income elasticity is the driving force on the demand side. Hence, this part represents the ideas of Prebisch. The last part, on the other hand, captures the handmaiden part (see Kravis 1970). This term supports the view that technical progress leads to an increase in exports via decreased prices if exports are price elastic. Consequently, the causality of this last effects runs from growth to exports, opposite to what the engine of growth supporters propose. Our model contains both parts. Note, however, that the handmaiden part drops out if a country has no technical progress. The third part is only relevant in case of non-constant returns to scale. With increasing returns to scale we have an additional cost reduction which drops out only if $(\alpha+\beta=1)$ in (10)-(12).

The direct effect of technical progress and returns to scale is to decrease production costs and to reduce the terms of trade as can be read off equation (11). The question then arises whether this will cause exports and investments to rise or fall. Assuming exports are price-elastic, there will be an increase in exports and investments as well as in the capital-labour ratio in equation (10). If exports are price-inelastic, however, technical progress has a negative impact on the growth rate of the capital-labour ratio. Considering the growth rate of income per capita, it is obvious that technical progress has not only a direct but also an indirect effect on this variable. The latter effect is due to changes in the capital-labour ratio induced by technical progress. The direct effect outweighs the indirect one so that technical progress always has a positive impact on real wages.

Summing up, technical progress and returns to scale have a negative impact on the terms of trade while they influence per capita income positively. The higher the income elasticity the higher the growth of export demand for any growth rate of world income and the higher the growth rate of capital imports in equation (10). The latter aspect causes income in equation (12) to grow at a higher rate and the growth rate of the terms of trade is driven up as well. A higher growth rate of income in the trade partners' countries will lead to an increase in exports. Yet, the critical point is whether the change in income multiplied by the income elasticity, $\rho\hat{Z}$, exceeds the population growth rate ε . This difference governs the growth rate of the capital-labour ratio in equation (10) in case of constant returns to scale. If the income elasticity of export demand is low and the population growth rate is high, the effect on the growth rates concerning the terms of trade, the capital-labour ratio, and income per capita will be negative.

In conclusion, the terms of trade will fall on condition that the rate of technical progress and scale economies is not exceeded by a large difference between the export growth rate and the population growth rate in equation (12). The growth rates of the capital-labour ratio and income per capita may be negative because of low income and price elasticities. With respect to income elasticity and trade partners' income growth, the terms of trade are an indicator of economic development because they boost both, per capita income and the terms of trade.

Comparison with the Results of the Solow Growth Model

The Prebisch-Singer thesis poses the task of presenting trade conditions which result in a slower growth rate for the main economic indicators of welfare than in the Solow model. Considering a Solow model with a constant-returns-to-scale production function like equation (1), the capital-labour ratio and per capita income grow at the same rate, $b/(1-\beta)$. In the model examined above, this result can be obtained by means of taking into account two special cases. First, equation (12) can be written in the form:

$$\hat{y} = \frac{b}{(1-\beta)} \left\{ 1 - \frac{\beta}{[\eta(1-\beta)]} \right\} + \frac{(\rho\hat{Z} - \varepsilon)\beta}{[-\eta(1-\beta) + \beta]}, \quad (12')$$

For any value of $\rho\hat{Z}$, it holds that $\hat{y} = b/(1-\beta)$ assuming that η approaches minus infinity. This is the small country case in neoclassical models. Second, it can be shown that $\hat{y} = b/(1-\beta)$ and $\hat{p} = 0$, both if $\rho\hat{Z} - \varepsilon = b/(1-\beta)$, just like a closed economy in the Solow model. Then, the engine of growth, $\rho\hat{Z} - \varepsilon$, has the same effect as the handmaiden part, $b/(1-\beta)$, and therefore, the growth rate coincides with that of the Solow model.

Figure 1 presents \hat{y} as a function of ρ for different values of η under the assumption – made to emphasize the role of the income elasticity – that $\hat{Z} = \varepsilon + b/(1 - \beta)$ and of constant returns for both models because the Solow model is normally presented in this way. The vertical intercept increases with the price elasticity of exports. The slope, on the other hand, is less steep the more price-elastic exports are.

FIGURE 1 OVER HERE

Due to equation (12'), there is one straight line for each value of η , being equal to $b/(1 - \beta)$ at $\rho=1$. The horizontal line represents the small country case with the price elasticity being equal to minus infinity. It shows that in this case exports constitute no constraint to growth, a conclusion that is in line with traditional neoclassical thinking. Figure 1 reveals that the capital importing economy grows at a lower rate than in Solow's model if the income elasticity is lower than one. For income elasticities greater than one, the economy grows faster than predicted by the Solow model. These conclusions do not hold for a price elasticity of minus infinity, since this is the small country case.

In view of the interplay between the growth rate of the terms of trade and the income elasticity of export demand, a similar graph is drawn in figure 2. The less price-elastic exports the steeper the slope and the more negative the vertical intercept. For income elasticities smaller than one, the growth rate of the terms of trade fall and real wages grow at a lower rate than in the Solow model. There is, thus, a close relationship between the latter two variables. The driving force behind both of them is the income elasticity of export demand. The effect of the latter is reinforced by a lower price elasticity of export

1
2
3 demand. The obvious corollary is that of a high price elasticity weakening the impact of
4
5 the income elasticity of export demand on the developments of real income and the terms
6
7 of trade. As in the previous graph, the relationship is drawn for $\hat{Z} = \varepsilon + b/(1 - \beta)$ and
8
9 alternative values for the price elasticity. To summarize, the price and income elasticities
10
11 of export demand are crucial determinants for a developing country's growth prospects.
12
13
14
15
16
17

18 FIGURE 2 OVER HERE
19
20
21
22

23 In this model the importation of capital goods and low (high) elasticities of export
24 demand contribute to explaining the slow (fast) growth of developing countries. The
25 question now arises whether these price and income elasticities are indeed low. That issue
26
27 is taken up in the following sections.
28
29
30
31

32 Again, we would like to point out the simplifying assumptions we have made:
33 absence of domestic capital goods, imported consumption goods, foreign debt, and
34 unbalanced trade. None of these assumptions holds true for Brazil as can easily be seen
35
36 by examining the World Development Indicators.⁴ Whether or not the abstraction is *too*
37 strong will be revealed by the econometric work. After all, the widely used Solow growth
38 model is a special case of our model. The former ignores imported inputs and the exports
39 used to pay for them, whereas we ignore that a large part of capital goods is produced
40 domestically. Furthermore, past empirical studies estimating export demand income and
41 price elasticities use a similar export demand function but do not make use of a growth
42 model for the supply side as we do. Integrating all of these neglected aspects in a fully-
43 fledged model would require the estimation of many more parameters with a small
44
45
46
47
48
49

51
52
53
54
55
56
57
58
59
60

1
2
3 number of observations. Therefore, it is not necessarily a drawback to use this simple
4
5 model. In a model including domestic capital goods, these would have to grow at a rate
6
7 that is proportional to that of foreign capital goods in order to avoid running too much
8
9 into decreasing returns to the accumulation of one of them only. Absence of debt is dealt
10
11 with by using the investment/GDP ratio rather than the savings ratio. Khan and Knight
12
13 (1988), and Esfahani (1991) also assume all imports to be inputs. It can only be hoped for
14
15 that the other aspects would merely change the intercept of the regressions below. This is
16
17 a matter left for future work.
18
19

20
21 The equations estimated below are (8) and (9). Note that these equations hold for both,
22
23 the steady state and the transition path. We want to estimate the equations as a
24
25 simultaneous system. Once one equation is estimated, it is obvious that all parameters can
26
27 be identified. Therefore, we have one constraint per regressor except for the intercept and
28
29 the world income variable, which has the same coefficient in both equations.
30
31
32
33
34
35
36

37 **3. The data**

38
39 We decided to carry out the empirical estimation for Brazil because all data are available.
40
41 In order to estimate the equations, time series for the savings or investment/GDP ratio,
42
43 capital, trade partners' income and employment are required. The data for gross fixed
44
45 capital formation as percentage of (GDP minus depreciation) are taken from the World
46
47 Development Indicators 2004 and represent investment. We make use of this figure
48
49 instead of the savings ratio in order to account for that part of investment financed by
50
51 foreign debt, which is ignored by our model. The data for capital are constructed by
52
53
54
55
56
57
58
59
60

1
2
3 cumulating Gross Fixed Capital Formation after subtraction of the data for depreciation,
4
5 starting from an initial value determined according to the formula⁵
6
7
8
9

$$10 \quad K_0 = \frac{I_1}{(\hat{K}_1 + \delta)}$$

11
12
13
14
15 Depreciation is assumed to be 3.7% of capital for all periods because this is the average
16
17 value of available figures in earlier national accounts data. For I_1 we use gross fixed
18
19 capital formation as of 1970. The initial growth rate of the capital stock in the above
20
21 formula is assumed to be .1, which corresponds to the order of magnitude of the growth
22
23 rates of GDP and employment in those years. With the capital stock obtained in this way
24
25 we can determine growth rates as log differences and add the rate of depreciation to get
26
27 the dependent variable of equation (8). The employment data are taken from the ILO
28
29 website. The time series starts in 1972 but values for the years 1974, 1975, 1980, 1991,
30
31 1994, 2000, 2001 are missing. We do not try to interpolate them because in an earlier
32
33 attempt we found that different ways of doing so removed the unit root processes in the
34
35 time series. Trade partners' income is taken to be world income since Brazil is trading
36
37 with all the countries in the world. The terms of trade are calculated as 'Exports as
38
39 capacity to import' divided by 'exports of goods and services', both in terms of constant
40
41 local currency units. Data are available in the appendix to the working paper version.

50 **4. Econometric methods and estimation results for the system of equations**

51
52 Econometric methods have been developed traditionally either for stationary
53
54 variables and more recently for variables being integrated of order one, $I(1)$. Before
55
56
57
58
59
60

1
2
3 discussing the methods we check whether the time series follow unit root processes and
4 determine the order of integration of the variables. Testing for unit roots suffers from the
5 fact that these tests have been designed for a large number of observations whereas we
6 deal with only a few observations. Hence, the tests have low explanatory power. For
7 world income the ADF test does not reject the unit root hypothesis. All other variables do
8 not follow unit root processes. Consequently, we use equations (8) and (9) with only one
9 modification: we replace $\ln Z$ by $d(\ln Z)^*t$, which can be based on rewriting the export
10 function as $X = e^{\rho d \ln Z^*t} p^\eta = Z^\rho p^\eta$. The latter version of the variable does not have a unit
11 root according to the standard ADF test. So we can use equations (8) and (9) in their
12 current form.

23
24
25
26

27 The system has three important properties. First, there are constraints on the
28 coefficients, generating a non-linear problem of estimation. Second, both equations of the
29 system contain the random terms from the production function and the export function
30 and therefore the residuals of the two equations will not be independent. These two
31 properties together suggest using the seemingly unrelated regression (SUR) method.
32 Third, equation (8) is a differential equation. Residuals have a positive impact on the
33 dependent variable, enhancing the capital variable on the right hand side in the next
34 period. As this is a stock variable, the effect is permanent. In other words, the residuals
35 have an impact on all future variables of capital and the regressor in the first equation is
36 not exogenous although it is predetermined (see Davidson and Mackinnon 2004, chapter
37 3.2). As this would bias the estimates, we use the generalized method of moments
38 (GMM-HAC with heteroscedasticity and autocorrelation correction of the coefficient
39 standard deviations) including all regressors and lagged variables of capital as

3 instruments. We present the GMM estimate in the first column of Table 1 (see also
4 unpublished Appendix to the working paper version).
5
6

7
8 TABLE 1 OVER HERE
9

10 The over-identifying constraints for the additional instruments are significant since
11 the product of the J-statistic and the number of observations is low enough. As there are
12 four constraints in the two equations, we have at least four degrees of freedom. However,
13 the number of lagged instruments has to be added (see Greene 2003, p.548/9). The
14 income elasticity of export demand (0.19) is at the lower end of the range of earlier
15 estimates and the price elasticity (-1.86) is larger in absolute terms than in previous
16 studies (see Table 2 for a comparison).
17

20
21
22
23
24
25

26
27 TABLE 2 OVER HERE
28

29 The time trend representing technical progress is significant and has the expected
30 sign. The rate of total factor productivity growth is about 2%. Given the elasticity of
31 production of labour of about .5, the labour augmenting rate of technical change is 4%.
32 This figure is a bit larger than in estimations assuming constant returns to scale.
33 However, the sum of the elasticities of production is $.81 < 1$ and indicates decreasing
34 returns to scale at a measure of .19. If we arbitrarily (and therefore not shown) drop the
35 time variable, we get increasing returns to scale. As shown above, the Solow growth
36 model is a special case of our model in which the price elasticity should equal minus
37 infinity. This would require $c(2)=1$. Given the high significance of the value around 0.5 it
38 is clear that the alternative (to our model) hypothesis of the Solow model will be rejected
39 by an F-test. The formulas for the identification of the parameters of the production
40 function indicate that the estimated coefficients have to be in narrowly defined ranges in

2
3 order to get reasonable parameter values for the model. In this sense the estimate for the
4 system is quite encouraging. The only trouble here comes from the serial correlation as
5 indicated by a very low DW statistic⁶. The standard procedure is to add lagged dependent
6 variables. The result of adding one lag in each equation is shown in the second equation
7 in Table1. The income elasticity of export demand is slightly higher now. The price
8 elasticity has doubled. The growth rate of total factor productivity is now much smaller at
9 about 1%. The decreasing returns measure is still .19 because the elasticity of production
10 of capital is enhanced at the cost of that of labour. There still is autocorrelation in the first
11 equation (also according to a Breusch-Godfrey test, which is not shown). In order to
12 correct for this autocorrelation we save the residuals from the first equation and add their
13 lagged values to the regression (also as instruments).⁷ The result is the third regression in
14 Table 1. The total factor productivity growth rate has fallen again to one third of a
15 percent and has become insignificant again. We now get almost exactly constant returns
16 to scale. The export elasticities are a bit lower than in the previous regression but still
17 higher than in the first. Due to this last step of including lagged values of the residuals
18 five observations are lost. Trying to carry out another Breusch-Godfrey test including one
19 more lag leaves us with too little observations to do so.

5. Steady state growth rates, engine and handmaiden effect, and dynamic gains from trade

We have estimated the model for its non-steady-state version. For long-run predictions, the theory gives us the steady-state formulas for growth rates of expected values. Note that in the estimated parts of the model, no use was made of the assumption of perfect

competition, which is not in accordance with increasing returns to scale. In this section, we calculate the steady-state growth rates for equations (10)-(12) numerically so as to specify the long-run predictions of the estimated models. We define and calculate the engine and handmaiden effect in order to compare them to each other and in order to compare them to the effect export growth rates have on GDP per capita growth rates in the survey of Lewer and van den Berg (2003). Finally, we calculate the corresponding growth rates of the Solow growth model as well as define the difference between the predicted growth of our model and that of the corresponding Solow model as the dynamic gains from trade.

TABLE 3 OVER HERE

In Table 3, we report the steady-state results for the growth rates of k , p and y . Additionally, the following effects – extracted from equations (10)-(12) – are presented: g (m , s) indicates the engine (handmaiden, scale) effect, obtained as the derivative of the formula for the growth rate of y with respect to the growth rate $d \ln Z$ (b , $d \ln L$).

$$g = \frac{\beta \rho}{\beta(\eta+1) - \eta}, m = \frac{-\eta}{\beta(\eta+1) - \eta}, s = \frac{-\eta(\alpha + \beta - 1)}{\beta(\eta+1) - \eta}$$

The scale effect is the effect of $d \ln L$ only to the extent that it would drop out if there were constant returns to scale. Next, x represents the corresponding growth rate of the Solow model under the assumption that its parameters are identical to those of our estimates. Finally, the difference in the growth rates of our model, $d \ln y$, and the corresponding Solow model, denoted as t , is defined as the dynamic steady-state gains from trade. The parameter values are those from the last equation of Table 1.

$$x = \frac{b + (\alpha + \beta - 1)\varepsilon}{\beta\eta + \beta - \eta}, t = d \ln y - x$$

All calculations are done under the assumption that world income will continue to grow at 2.6%. Finally, we need an assumption for the growth rate of employment. This rate was anything but constant in the past as can be seen from the following regression:

$$\ln L = 9.71 + .06t - .00057t^2 \quad \text{adj. } R^2 = .993$$

(212) (17.2) (-9.16)

A plot of the regression result and its time derivative representing the growth of employment appears in Figure 3. The result indicates that the growth rate of labour drops to zero at time $t > 50$, which is after the year 2010.

FIGURE 3 OVER HERE

The results are as follows. The steady-state growth rates of capital and income per capita are positive only if employment growth is sufficiently small, at about 1%. This is due to the low income elasticity of export demand and little technical progress. The presence of the scale effect is too weak to outweigh these two effects. The positive growth rates of the past are therefore generated by the transitional growth of capital accumulation. The terms of trade are falling – as the data reveals for the past – because the growth of the supply force, employment plus technical change, is larger than that of the demand force, world income multiplied by the income elasticity. The terms of trade are not falling, only in a steady state where population growth occurs at a rate of roughly .1%. The handmaiden effect, $m = 1.27$, is larger than the engine effect, $g = .024$, and the scale effect, $s = -.0077$, again because the income elasticity of export demand and the measure of decreasing returns are very small. The handmaiden effect multiplied by the rate of technical change is still larger than the engine effect multiplied by the difference of world income growth rate and population growth rate. With lower population growth,

1
2
3 this effect gets larger (see third but last line in Table 3) and the scale effect vanishes (last
4
5
6 line of Table 3).

7
8 The closed economy growth rate is driven by decreasing returns to scale,
9
10 employment growth and technical change. The lower future employment growth the
11
12 higher will be the hypothetical autarkic growth rate. The growth rate of our model and the
13
14 autarkic ones are higher if employment growth is lower. The steady-state part of the
15
16 dynamic gains from trade becomes positive before employment growth is as low as .001
17
18 which will be the case around the year 2012 according to Figure 3, with period 1
19
20 representing the year 1960. Lewer and van den Berg (2003) illustrate that dynamic gains
21
22 from trade are large when export growth rates are high in the transition after taking policy
23
24 measures. Therefore, static gains from trade and the ones during transition may be larger
25
26 than those in the steady state even if the latter are negative, which need not be the case if
27
28 population growth falls far enough.

38 **6. Conclusion**

39 From the perspective of the exports and growth literature, we add economic causality
40
41 – in the sense of estimating a growth model that contains an economic mechanism
42
43 turning world income growth through exports via imported inputs into growth – to the
44
45 econometric Granger causality of the literature. The model shows that the size of the
46
47 income elasticity is crucial. According to our estimates, it is fairly low for Brazil and
48
49 therefore the engine of growth effect is low as well.
50
51

52 From the perspective of the literature on balance of payments constrained growth, we
53
54 have added the element of demand side effects on flexible terms of trade. It is obvious
55
56
57
58
59
60

1
2
3 that price movements matter for the value of exports: If the income elasticity is larger
4 than unity, growth will be enhanced through exports. If the income elasticity is lower
5 than unity, growth will be reduced unless the price elasticity is minus infinity. A low
6 income elasticity in connection with some technical progress leads to falling terms of
7 trade in the steady state, giving rise to a relaxation of the balance of payments constraint.
8 In the opposite cases, endogenous terms of trade lead to a tightening of the balance of
9 payments constraint. This effect should be taken into account. Our empirical study shows
10 that a low income elasticity dilutes the engine effect, the terms of trade will continue to
11 fall in the steady state and therefore the balance of payments constraint is relaxed. Due to
12 a relatively high price elasticity of about minus four growth is not hampered.
13
14
15
16
17
18
19
20
21
22
23
24
25
26

27 Next, there is the literature on devaluations, emphasizing the effects of devaluations
28 or explaining the terms of trade movements. Keeping in mind that nominal devaluations
29 have real effects (Bahmani-Oskooee and Miteza, 2002) our finding of a price elasticity of
30 about minus four implies higher growth following devaluations.
31
32
33
34
35

36 Finally, from the perspective of the Prebisch-Singer thesis, the results clearly
37 demonstrate that income and price elasticities of export demand may be important for the
38 growth of Brazil in the period we have considered. In particular, if technical progress is
39 low, a high world income growth multiplied by the income elasticity of export demand
40 has to outweigh the population growth multiplied by the decreasing returns measure.
41 Without the engine effect, i.e. in a closed economy, there would be no long-run per capita
42 income growth if there are constant returns to scale and no technical change. Under
43 increasing (decreasing) returns the impact of employment growth is less (more) negative
44 than under constant returns. If population growth is low enough, the model allows for
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 positive per capita income growth through imported capital goods, positive dynamic
4 gains from trade and increasing terms of trade. However, if employment growth is large,
5
6 negative rates are also possible. According to our estimates, the income elasticity is
7
8 small, thus hampering growth and driving down the terms of trade in line with the
9
10 Prebisch's expectations. However, the effect is only weak due to a relatively high price
11
12 elasticity of export demand, which translates the falling terms of trade and therefore the
13
14 effect of technical progress into a high export demand as expected by Kravis. Both
15
16 arguments interact and are quantitatively relevant. According to our model, neither of the
17
18 two can be dismissed because technical change matters on the supply side and exports are
19
20 important determinants on the demand side.
21
22
23
24
25
26

27 The steady-state part of dynamic gains from international trade is dependent on the
28 magnitude of employment growth: high employment growth yields negative dynamic
29 gains from trade in the steady state whereas low employment growth brings about
30 positive gains from trade. If employment continues to grow at such a high rate as in the
31 past, dynamic gains from trade will be negative in the future. But the trend in
32 employment data points to the opposite direction. As population growth approaches zero,
33 positive dynamic gains from trade are generated by world income growth, which
34 translates into higher demand for exports, and technical change multiplied by the price
35 elasticity.

(a) Instruments:regressors, plus lnk(-2) to (-7) in the first equation and none in the second.

(b) for the first equation at the 5%; degrees of freedom is number of constraints, which is 4, plus number of lagged instruments.

(c) for the second equation at the 5%;degrees of freedom is number of constraints, which is 4, plus number of lagged instruments.

(d) Instruments: regressors plus dlnk(-1) to (-5) and two lags of the dependent variable in the first equation and ln p(-2) to (-4) in the second.

(e) Instruments as in previous regression plus lagged residual regressor

Table 2: Overview of income and price elasticities of export demand for Brazil

¹ We want to thank Harry Bloch and Bart Verspagen for useful comments on an earlier draft and Abraham Garcia, Clemens Kool, Pierre Mohnen, Franz Palm, Jean-Pierre Urbain for useful talks. Responsibility is entirely ours.

² Two recent publications are Dritsakis (2004) and Dawson and Hubbard (2004). They provide evidence for Central and Eastern European countries and many recent references to this bulk of literature.

³ A separate estimate of the export demand function in terms of growth rates yields a growth rate of B which is insignificantly different from zero.

⁴ For Brazil, Gross fixed Capital formation (GFCF) is about twice as large as total imports. For 1995 (but not for other years) we can calculate from the WDI that production of machinery and transport equipment is about \$US 38.1 billion. This is about 25% of GFCF. However, of these \$US38mln, 8.8 are exported, leaving about 29 for domestic investment. On the other hand, 21 are imported according to the UN Intern. Trade Statistics Yearbook, indicating that about 42% of machinery and transport equipment is imported provided it is not re-exported. Unfortunately it seems impossible to construct separate stocks of domestic and foreign capital without having similar information for other items and periods of GFCF than just machinery and transport as of 1995.

⁵ See Verspagen (1995) for an extensive explanation.

⁶ Below we will also employ the Breusch-Godfrey test because of the endogeneity problem discussed earlier, because the DW statistic is not the adequate tool in case of endogeneity.

⁷ The idea comes from the standard Breusch-Godfrey test where the lagged residuals are added to the regression equation (see Davidson and MacKinnon 2004). We are aware of the fact that our procedure to use it as a correction for autocorrelation is only loosely related and that our approach may evoke a discussion. The only alternative we have is to focus on the other regressions with serial correlation.

Simultaneous Estimation of Income and Price Elasticities of Export Demand, Scale Economies and Total Factor Productivity Growth for Brazil

Christine Mutz, Leipzig Graduate School of Management

Thomas Zieseemer, Maastricht University, Department of Economics and UNU-MERIT,
P.O.Box 616, NL 6200 MD Maastricht. T.Zieseemer@algec.unimaas.nl

Abstract

This paper focuses on a growth model in which (unlike other models) low (high) export demand elasticities and the fact that developing countries are importers of capital goods help explaining the slow (high) growth of these countries in the transition and in the steady state. The question arises whether export demand elasticities are low or high. For answering this question, export demand elasticities for the case of Brazil are obtained by estimation of the model. As a by-product of estimating the model, we obtain estimates for total-factor productivity growth and for scale economies. Based on the results from estimation we calculate steady-state growth rates, engine and handmaiden effects of growth as well as dynamic steady-state gains from trade. The model and the results are discussed in regard to several strands of literature.

Keywords: Development, international linkages, open-economy growth models, time-series.

Simultaneous Estimation of Income and Price Elasticities of Export Demand, Scale Economies and Total Factor Productivity Growth for Brazil

1. Introduction

Income and price elasticities of export demand are important for several reasons. When real devaluations occur, the value of exports increases (decreases) if export demand is price-(in)elastic. Therefore, more (less) imports can be bought from abroad. If imports are investment goods, this increases (decreases) investment. In particular, if technical progress yields lower terms of trade, this transmits more or less strongly into growth rates of exports and investment; and if booming exports drive up the terms of trade, it depends on price elasticities how strongly this boom is curtailing itself by boosting the terms of trade. Income elasticities of export demand determine how strongly growth abroad is translated into growth in exports. Again, if investment goods are paid for by these exports, the income elasticities of export demand have an impact on growth and on dynamic gains from trade.

In this paper, we estimate income and price elasticities of export demand from a slightly modified version of a two-gap growth model with imported inputs, introduced by Bardhan and Lewis (1970). In doing so, we hope to contribute to several strands of literature. First, the literature on exports and growth has benefited much from the insight that imported inputs paid by exports are the major mechanism in the relation between exports and growth in the short run (see Khan and Knight, 1988) and in the long run (see Esfahani, 1991). Similarly, Levine and Renelt (1992), and Wacziarg (2001) found that the major channel for trade and growth is investment. Edwards (1998) found a robust relation between openness and productivity, and pointed to open issues in regard to

1
2
3 causality. In line with that idea, recent time-series literature found that the causality going
4
5 from exports to output growth is stronger than that going vice versa (see Riezman et al.,
6
7 1996; Islam, 1998; Asafu-Adjaye and Chakraborty, 1999; Krishna et al., 2003).¹ Riezman
8
9 et al. (1996) pointed out that this ‘may serve as a guide to theorists who are currently
10
11 working to develop better theories of economic growth’. We would like to recall that
12
13 such a theory already exists since long. In the widely ignored model by Bardhan and
14
15 Lewis (1970), exports are a second driving force for growth besides technical change
16
17 because investment goods are imported² and the terms of trade are endogenous. An
18
19 extensive comparison with related models was provided by Ziesemer (1995). Models that
20
21 either assume the importation of consumption goods rather than inputs or make a small
22
23 country assumption will fail in giving the terms of trade a positive correlation with GDP
24
25 per capita over time³, and to give exports a crucial impact on growth even in the steady
26
27 state. In the presence of technical change, the model can generate two-way causality
28
29 between exports and growth. One-way causality whenever it is found in the empirical
30
31 work (see Fosu 2001 for Africa) then indicates absence of technical change. A further
32
33 advantage of the model is that it allows for permanent positive and negative growth even
34
35 in case of absence of technical change rather than only for transitional growth as the
36
37 neoclassical closed economy model does. Leung (2000) has pointed to the similarity of
38
39 this type of models with that of endogenous growth models in case that the terms of trade
40
41
42
43
44
45
46
47
48

49
50 ¹ Two recent publications are Dritsakis (2004) and Dawson and Hubbard (2004). They provide evidence for
51 Central and Eastern European countries and many recent references to this huge literature.

52 ² Some authors call this the ‘Bhagwati assumption’.

53 ³ Eaton and Kortum (2001) show that prices of equipment relative to consumer prices - the inverse of our
54 terms-of-trade measure - are negatively correlated across countries in 1985. These differences in prices
55 explain 25% of productivity differences in their analysis. They attribute 50% of the cross country price
56 differences to geographic and other barriers to trade, whereas our model emphasizes the growth of exports
57 relative to total factor productivity growth, over time in explaining terms of trade growth. These export
58
59
60

1
2
3 are increasing. Endogenous growth models endogenize the rate of labour-augmenting
4 technical change through research and development expenditures, multi-nationalization
5 and imitation. In these models the rate of growth is proportional to that of the number of
6 northern and southern goods, the latter produced by multinationals or imitating domestic
7 firms (Lai 1998). The growth rates of these numbers are all the same in a steady state and
8 are also equal to the difference in the rates of growth of labour demand and labour supply
9 if there are complete international spillovers of R&D knowledge. The reason for this
10 similarity with the Solow model is the unit income elasticity of demand for all goods,
11 which makes sure that the South and the North grow at the same rate. Unlike our
12 modified Bardhan/Lewis model, there is no possibility of catching up or falling behind in
13 the steady-state of these models.⁴ If spillovers are only national or limited to an industry
14 or to some goods of an industry Northern and Southern growth rates may diverge
15 (Grossman and Helpman 1995). However, because of the assumption of homothetic
16 preferences, the income and price elasticities of export demand never appear in the
17 formulas for long-run growth rates, as they do in our modified Bardhan/Lewis model.
18
19 Of course, the Bardhan/Lewis model is an exogenous growth model. But the increase
20 (decrease) in the terms of trade when world income (per domestic worker) grows quickly
21 (slowly) or the income elasticity of export demand is high (low) allows for positive (or

45
46

47 constraints can be broadly interpreted as part of their ‘capacity to absorb advanced technology from abroad’
48 (p.1218).

49 ⁴ Closely related are models with trade in capital goods. Homothetic preferences and production functions
50 are used in international real business cycle models with trade in capital goods. There is no effect of trade
51 in capital goods on the long run growth rate, but rather only on the volatility (Boileau 1999), because of the
52 implied unit income elasticity. Similarly, Honkapohja and Turunen-Red (1999) show that two symmetric
53 R&D driven economies when trading capital goods may have multiple steady states. Trade liberalization
54 may induce the vanishing of some of them. These may be the high-growth or low-growth steady states.
55 Again, there is no role for income and price elasticities of export demand in long-run growth. Moreover,
56 these models as those for international real business cycles are more suitable for developed countries,
57 because they have no developing country features.
58
59
60

1
2
3 negative) permanent growth even without technical progress. With and without technical
4
5 change, the long-run growth rates may be positive, zero, or even negative, which is
6
7 important because all three cases can be seen in the data (see Temple 1999, Table 2). We
8
9 use that model but go one step further. We estimate equations as derived from a full-
10
11 fledged growth model. We hope that this is a step as interesting as the estimation of
12
13 purely empirical models⁵, each of which has his own problems (see Durlauf, Johnson and
14
15 Temple forthcoming) as does ours. Through this approach we get estimates of the export
16
17 elasticities, total factor productivity growth and scale economies in the same form as they
18
19 appear in theoretical models. In particular, this is very much different from estimating
20
21 growth regressions using variables of the Solow growth model and then adding trade and
22
23 openness indicators. Rather the model integrates trade and growth right from the
24
25 beginning, has a clear explanation of the link between trade and growth, and estimates
26
27 income and price elasticities of export demand and other parameters of the model, all of
28
29 which need to be within reasonable ranges. As the model has the above mentioned
30
31 realistic properties we thus obtain a strong integration of the theoretical model and the
32
33 econometric estimate rather than having them connected only loosely. In other words, it
34
35 is a well-known statement in econometric textbooks that models also provide a
36
37 straightjacket, and therefore estimates based on theoretical models are the more ambitious
38
39 task we want to pursue.
40
41
42
43
44
45
46
47
48

49 Sachs and Warner (1995a) found that natural resource abundance is related to lower
50
51 growth. One of the reasons for this may be the low income elasticities of export demand
52
53

54
55 ⁵ Examples of purely empirical models are extended production functions, or purely empirical
56
57 specifications as in the traditional cross-country regressions (Fosu 2001), panel estimates (Savvides 1995),
58
59
60

1
2
3 for these goods, which translate into lower imported investments according to our variant
4
5 of the Bardhan-Lewis model.⁶ In this model, openness and capital accumulation are not
6
7 competing explanations of growth (see Fosu 2001, p.287), because openness enhances
8
9 the export volume, which is available for importing investment goods, as emphasized by
10
11 Sachs and Warner (1997) and Rodrik (2000). Specialization on goods, natural resources
12
13 or others, contribute positively (negatively) to growth if they have high (low) income
14
15 elasticities of export demand. High export taxes may be an effort to deal with falling
16
17 terms of trade in order to keep tax revenues high. This has been suggested to have
18
19 negative effects on growth though (see Sachs and Warner 1995b, Collier and Gunning
20
21 1999 and Fosu 2001 on Africa, and Berg and Krueger for a broad survey). From the
22
23 perspective of our model these may be negative effects on the transitional part of the
24
25 growth rate as an extension to export taxes can have only level effects in the steady-state
26
27 of our model. Thus, trade policy liberalization is expected to contribute to transitional
28
29 growth if trade taxes are higher than the optimal ones (see Fosu 2001) according to our
30
31 model.
32
33
34
35
36
37
38
39

40 Much of the evidence uses three indicators for openness: the Sachs-Warner (1995b,
41
42 1997) measure, black market premia for exchange rates (Easterly and Levine 2001), and
43
44 the sum of exports and imports (trade volume) divided by the GDP (Savvides 1995,
45
46 Easterly and Levine 2001, Dollar and Kraay 2004⁷) to show a positive relation between
47
48
49

50 the above mentioned time-series literature and vector-autoregressive models and related advanced
51 techniques (Awokuse 2005).

52 ⁶ Sachs and Warner (1995a) themselves favour a Dutch disease interpretation. The subsequent literature
53 has emphasized many other aspects. For example, Kronenberg (2004) found a relation with corruption and
54 a neglect of basic education for former communist countries. They can all be viewed as complementary to
55 our explanation.

56 ⁷ Surprisingly, Dollar and Kraay do not include the standard variables investment/GDP, population growth
57 and human capital in their regression of growth on trade volumes. Even if trade is correlated with
58
59
60

1
2
3 trade and growth.⁸ Some doubts on the robustness of these cross-section regressions have
4
5 been raised. Harrison and Hanson (1999) decompose the Sachs-Warner measure of
6
7 openness and show that the trade policy components are not significant in their growth
8
9 regressions. They conclude that the time-series dimension should be included.⁹ Similarly,
10
11 Rodríguez and Rodrik (2001) show that in many often cited papers it is not the trade
12
13 policy component of openness indicators that drive the results, and misspecifications are
14
15 discussed extensively leaving the authors with the conclusion that there is no conclusive
16
17 evidence for a positive or negative correlation between trade liberalization and growth
18
19 ‘for levels of trade restrictions observed in practice’. One of the theoretical underpinnings
20
21 for the possible absence of growth effects from trade liberalization comes from the
22
23 possibility that import-competing sectors may *produce and receive* stronger dynamic
24
25 learning effects than the other sectors. Trade liberalization lowers these effects resulting
26
27 in a negative net effect of trade liberalization on growth (Rodríguez and Rodrik 2001).
28
29 For the case that the import-competing sector produces stronger learning effects than
30
31 other sectors, but the effects are received by all sectors equally this may be outweighed
32
33 by positive effects from importing capital goods more cheaply in a balanced growth
34
35 model with North and South growing at the same rates in the long run if the learning
36
37 effects generated by the two sectors are not too different (Goh and Olivier 2002). In
38
39 short, there is no way of excluding a zero or negative relation between trade and growth
40
41 in economic theory and the evidence is so far inconclusive. Growth represents potential
42
43
44
45
46
47
48
49
50

51 investment, the inclusion of the latter two variables seems to be a ‘must’ to us. Similarly, Sachs and Warner
52 (1997) do not include labour force growth or population growth but rather only the difference of the two.

53 ⁸ See the survey by Berg and Krueger (2003) for many other references and other approaches.

54 ⁹ Harrison and Hanson (1999) do not include population or labour force growth. Moreover, the authors
55 include the relative price of investment goods, which turns out to be highly significant. This variable may
56 be correlated with trade policy variables. Rodríguez and Rodrik (2001) argue that these prices are likely to
57 be endogenous. This casts some doubts on the robustness of this approach to checking robustness.
58
59
60

1
2
3 future benefits of trade liberalization. But, as Rodrik (2000) points out, these should not
4 be oversold because of doubts on the robustness, and the costs of adjustment, and because
5 losers should not be overlooked but rather dealt with by accompanying reforms in a
6 country-specific manner and, given scarce resources, other reforms may be more
7 worthwhile. The critique of Rodríguez and Rodrik (2001) though is focussed on trade
8 policy indicators, not the trade volume indicators recently used by Savvides 1995 and
9 Dollar and Kraay (2004). The missing link therefore is to show that trade liberalization is
10 causing higher trade volumes as one would expect from the partial reasoning of basic
11 trade theory.¹⁰ Moreover, the empirical literature has not tried to make a distinction
12 between countries being on this or that side of the optimal tariff. Our model could be
13 extended to include an optimal tariff but this is not the purpose of this paper and, given
14 the weak evidence, not even necessarily improving realism. Instead we focus on income
15 and price elasticities of export demand as determinants of the growth of exports, terms of
16 trade and growth. So much about exports and growth, including trade policy; we hope to
17 have indicated that our model can reconcile some seemingly controversial views in that
18 literature once the emphasis shifts to imported capital goods and income elasticities of
19 export demand.¹¹

¹⁰ Establishing this link is not as easy as it might be expected. Wilson, Mann and Otsuki (2003) find that the significance of the effect of tariffs on bilateral trade flows in a gravity model break down once due time lags and omitted variable biases are treated adequately.

¹¹ Other theoretical links between trade (liberalization) and growth are discussed by Fosu (2001) and Berg and Krueger (2003). They are understandable on the basis of the static theory of international trade and the comparative static growth effects: 1. Resources move to the exporting sectors, which have higher productivity than other sectors, and therefore give more weight to the higher productivity of the exporting sectors. 2. Economies of scale are realized in the exporting sector – with corresponding losses in the shrinking importing sectors. 3. Reductions in inefficiencies through more fierce competition. 4. Imported capital goods as emphasized by our model would also include new technologies and management knowledge. 5. Knowledge spillovers from R&D of trading partners enhance productivity. In how far these links work is a matter of emphasis of the respective authors. 6. The dynamic analogue to point 1 is that exporting sectors may have higher productivity growth rates than the other sectors. Giving more weight to them implies a higher growth rate. It should be pointed out though that all studies of factor productivity

Second, growth and dynamic gains from trade are closely related since the question is whether trade increases the growth rate of the economy (see Lewer and van den Berg, 2003, for a recent survey). The larger the income elasticity of export demand the larger the growth rate of the economy in the model used below. Our estimates allow calculating the steady-state part of the dynamic gains from trade conditional on assumptions about future employment growth.

Third, the slightly modified Bardhan and Lewis model serves as a theoretical foundation of the thoughts of Prebisch and Singer (see Ziesemer, 1995 for the theory and Ocampo and Parra 2003 for a recent contribution on the empirics). Our estimates are the empirical complement to that theory, containing both parts of the history of economic thought, namely the engine and the handmaiden part of growth, the first emphasizing exports' effect on growth (Prebisch 1950) and the second growth's effect on exports (Kravis 1970). In a modified form though, these opposing views appear nowadays among the openness proponents and the sceptics with the latter emphasizing technical change

growth find quite a few countries with no factor productivity growth. On the other hand, trade liberalizations when stretched out over a long time repeat the static effects making them look like dynamic ones unless the time structure of liberalization policies are explicitly incorporated in the regressors. 7. Demonstration and learning effects from foreign subsidiaries to domestic firm may induce learning. This aspect seems to remain controversial among empirical researchers. 8. Similarly, productivity effects from learning-by-doing or by exporting, which were well established in the literature, are challenged now by the econometrics of self-selection.

In addition we have (often similar) arguments from endogenous growth theory: 9. Compared to autarky, opening up enhances available ideas and intermediate inputs (Romer/Rivera-Batiz). Note that this can be valid only for closed countries or if transmission of ideas depends on trade contacts. Without the latter assumption it is unlikely that more ideas flow if there is a small tariff reduction. Flows of ideas and availability of intermediates depend on having some trade but not necessarily on trade volumes. 10. If countries specialize on high- and low-skill intensive goods respectively and growth is produced by an even more high-skill intensive non-traded third R&D sector, the country relatively abundant with high-skilled people will get lower growth and the other country higher growth because of the competition for high-skilled people, who move out of (into) the R&D sector in the country specialized in high-skilled (low-skilled) goods (Grossman/Helpman). 11. If import-competing goods have stronger learning effects related to production, growth may get higher through tariffs as long as the dynamic effect is stronger than the static distortion (Rodríguez and Rodrik 2001 referring to Matsuyama). This is the dynamic mirror image of the static argument in point 2. 12. Point 11 may be invalid if capital goods are imported by the country supposed to slow down (Goh/Olivier).

1
2
3 (see Fosu 2001, p.290).¹² However, a model with imported capital goods and endogenous
4 term of trade reconciles the views on the conceptual level, and the empirical relevance
5 may differ from country to country¹³ and across historical phases. The reason is that
6 countries may be specialized on goods with high or with low income elasticities. As
7 Ocampo and Parra (2003) show, the terms of trade for commodities are captured by
8 indices with two structural breaks in 1921 – a sudden drop with no trend before and after
9 1921 - and in 1979, with a negative trend afterwards. Both breaks occur when world
10 demand is weak. The phase of falling terms of trade in the 1980s suggests a stronger
11 growth of supply compared to demand, in our model captured respectively by technical
12 change and world income growth multiplied by the income elasticity of export demand.
13 The stationary phases suggest equal growth of supply and demand. The indices used
14 consist of single commodities some of which have strong positive growth rates, others
15 have negative ones, and those with no trends may have a strong accumulation of shocks.
16 Depending on their specialization countries may be lucky or not. In our model this luck is
17 captured by the income elasticity of export demand, which may be high or low depending
18 on the commodities produced. The structural break of the 1920s had been found earlier
19 by Powell (1991), who also found one for 1937 and 1975, all related to the cointegration
20 of terms of trade for commodities and manufactures. Bleaney and Greenaway (1993)
21 found a shock after 1980, but constant terms of trade from 1925-1980. UNCTAD (2005)
22 reports strongly rising commodity terms of trade since 2002 and also falling prices of
23

51
52 ¹² Emphasizing trade issues in no way should imply deemphasizing the relevance of public services,
53 education and infrastructure. They are the domestic counterparts of trade, creating and destroying the
54 comparative advantages.

55 ¹³ Readers more interested in country-specific analyses (as Easterly and Levine 2001) should not overlook
56 the survey by Reynolds (1983), which reconciles the historical evidence with what is captured by growth
57 and development models.
58
59
60

1
2
3 manufactures of developing countries relative to those of the developed countries. The
4
5 rise in commodity terms of trade is likely to be another structural break caused by the
6
7 growth of India and China. Given the fact that the share of primary products in many
8
9 countries is much less nowadays than it was in the 1950s, the question is, which of these
10
11 trends is stronger. Moreover, Cashin and Pattillo (2006) show for Sub-Saharan Africa
12
13 that the commodity terms of trade have no stable relation with the net barter terms of
14
15 trade. Therefore it is important to emphasize that what matters for growth and investment
16
17 is export revenues and therefore the net barter terms of trade (used in our model) and not
18
19 just one of their components. Moreover, the growth of India and China is part of that of
20
21 world income, which we will use as an argument in an export demand function. In short,
22
23 the arguments of Prebisch and Singer - imported capital goods and income and price
24
25 elasticities of export demand - are still important, but the relevance of primary
26
27 commodities has diminished in many countries.
28
29
30
31
32

33
34 As a by-product of our procedure, we also get estimates of total-factor-productivity
35
36 growth and of scale economies for Brazil, which is the country for which we carry out the
37
38 estimation. Our theoretical view expressed is that the Solow growth model is a good
39
40 starting point - simply because investment, population growth and a diminishing marginal
41
42 product of capital are relevant aspects of growth - but needs modification to grasp the
43
44 effects of trade.¹⁴
45
46
47

48 The paper is set up as follows. In section 2 we present the model and compare it to
49
50 the neoclassical growth model. Section 3 describes the data. Estimates of the growth
51
52 model using the general-method-of-moments estimator (GMM) are presented in section
53
54

55
56 ¹⁴ Similar modification of the Solow model can be made for the public sector aspects; see Ziesemer 1990
57 relating public factors, democracy and growth in a semi-endogenous growth model.
58
59
60

4. In section 5, we use the estimated results to calculate steady-state growth rates, engine and handmaiden effects, and dynamic steady-state gains from trade. Section 6 relates the results to the aforementioned branches of the literature and provides some tentative policy conclusions.

2. The Model

The question dealt with in this section is whether imports of capital goods and low (high) export demand elasticities could account for slow (fast) growth in comparison with the Solow (1956) growth model. The model assumes flexible wages and exogenous employment. A Cobb-Douglas production function with exogenous technical progress is used:

$$Y = e^{bt} AK^\beta L^\alpha U, 0 < \alpha, \beta < 1, \alpha + \beta \geq (\leq) 1 \quad (1)$$

Y denotes output, K capital, L labour, b the rate of technological progress, 'A' is a time independent constant, U a stochastic term and α and β the elasticity of production of labour and capital. We allow for increasing, decreasing and constant returns to scale. Labour is assumed to grow at rate, ε , which is determined exogenously:

$$L(t) = L(0)e^{\varepsilon t}, \hat{L} = \varepsilon \quad (2)$$

A "hat" over a variable indicates a growth rate. The fact that they are importers of capital goods seems to be a fundamental problem of developing countries. Importing less luxury consumption goods may be helpful but cannot be a solution by itself. Therefore, it is assumed that no luxury items are imported. Problems referring to the terms of trade or growth may occur despite the absence of imports other than capital goods. Fundamental

obstacles for developing economies are rather the importation of capital goods as well as limited export demand. By assumption, capital goods invested in developing countries must be imported:

$$M = \dot{K} \quad (3)$$

A "dot" over a variable denotes its derivative with respect to time, and M represents imports. Capital goods are the only imports – another simplification besides the absence of foreign debt – and have to be paid for by exports. This requirement stems from the trade-balance equilibrium. Investments are, therefore, limited by exports, denoted by X , which are expressed in terms of the imported capital goods:

$$\hat{K} = \frac{\dot{K}}{K} = p \frac{X}{K} - \delta, \quad \hat{K} = \hat{p} + \hat{X} - \hat{K}, \quad \hat{K} \equiv d(\log(\hat{K} + \delta)) \quad (4)$$

p represents the terms of trade, defined as the price of domestic goods in terms of imported capital goods. Investments need to be paid for by domestic savings measured in terms of imported capital goods. The savings rate s is assumed to be a constant proportion of output in this theoretical part and depreciation is δK :

$$\hat{K} = \frac{\dot{K}}{K} = sp \frac{Y}{K} - \delta, \quad \hat{K} = \hat{p} + \hat{Y} - \hat{K} \quad (5)$$

Investments are limited by exports. Exports in turn are assumed to depend on the trade partners' income, Z , and on the terms of trade, p . For the sake of simplicity, a log-linear export function with a constant B ¹⁵ and a stochastic term V is used:

$$X = BZ^\rho p^\eta V, \rho > 0, \eta < 0 \quad (6)$$

ρ denotes the income elasticity and η represents the (negative) price elasticity of export demand. Together, these six equations explain the six variables Y, L, M, p, K , and X .

Inserting the functions for exports and output, (6) and (1), into the export and saving constraint for investment, (4) and (5), respectively, writing the depreciation rate on the left hand side and taking natural logs, denoted \ln , yields:

$$\ln(\hat{K} + \delta) = \ln B + \rho \ln Z + (1 + \eta) \ln p + \ln V - \ln K \quad (4')$$

$$\ln(\hat{K} + \delta) = \ln s + \ln p + bt + \ln A + (\beta - 1) \ln K + \alpha \ln L + \ln U \quad (5')$$

Uncertainty is kept as inessential and simple as possible here because we are not interested in any uncertainty aspect per se but rather need this aspect only to relate it to econometric models. Basically, the assumption is that firms know L and K (from the previous period) with certainty and produce after U has become known. Households then decide to save a fraction s of their income Y and this determines gross investment. When the V -term in the export function is known, p can adjust to determine external

¹⁵ A separate estimate of the export demand function in terms of growth rates yields a growth rate of B , which is insignificantly different from zero.

equilibrium. All rigidities and the implied consequences for the future are assumed to be absent for the sake of simplicity. In particular, the irreversibility of capital is assumed to be irrelevant. In a more sophisticated investment theory this is only justified if the optimal capital stock never decreases by more than depreciation.

In our model, the output per worker in units of domestic goods is considered a rough indicator of welfare. The driving forces behind the expected value (denoted by E) of the latter are the rate of technical progress and the growth rate of the capital-labour ratio, which is denoted by k (with $E(\ln U)=0$):

$$\hat{y} = b + \beta \hat{k} + (\alpha + \beta - 1) \hat{L} \quad (7)$$

The last term corrects for scale economies. Since the rate of technical progress is given, the remaining question is whether a low income elasticity of export demand hinders rapid growth of the capital-labour ratio by restricting the importation of capital goods. The growth rates for the long-term equilibrium growth path are of crucial interest in this respect. Solving equations (4') and (5') for the natural log of the terms of trade and the left hand side variable yields:

$$\begin{aligned} \ln(\hat{K} + \delta) = & \frac{-\ln B}{\eta} + \ln A \frac{(\eta+1)}{\eta} + \frac{\eta+1}{\eta} \ln s + \frac{b(\eta+1)}{\eta} t + \frac{\beta\eta + \beta - \eta}{\eta} \ln K \\ & + \frac{\alpha(\eta+1)}{\eta} \ln L + \frac{-\rho}{\eta} \ln Z + \frac{\eta+1}{\eta} \ln U - \frac{1}{\eta} \ln V \end{aligned} \quad (8)$$

$$\ln p = \frac{\ln A - \ln B}{\eta} + \frac{1}{\eta} \ln s + \frac{b}{\eta} t + \frac{\beta}{\eta} \ln K + \frac{\alpha}{\eta} \ln L - \frac{\rho}{\eta} \ln Z + \frac{1}{\eta} (\ln U - \ln V) \quad (9)$$

The expected value (setting $\ln U = \ln V = 0$ for the rest of this section) of equation (8) is a differential equation of K with negative slope. K has an impact on equation (9) but $\ln p$ has none on (8).

The next step is to take the derivative with respect to time of both equations, set both sides equal to zero and assume a constant savings ratio in the steady state. Then the steady-state growth rate can be written as follows:

$$\hat{k} = \frac{\rho \hat{Z} - \varepsilon - (1 + \eta)[(\alpha + \beta - 1)\varepsilon + b]}{-\eta(1 - \beta) + \beta} \quad (10)$$

Inserting this solution into the equation determining the change in the terms of trade and into equation (7) yields the following solutions for the terms of trade and income per capita, respectively:

$$\hat{p} = \frac{(1 - \beta)(\rho \hat{Z} - \varepsilon) - (\alpha + \beta - 1)\varepsilon - b}{-\eta(1 - \beta) + \beta} \quad (11)$$

$$\hat{y} = \frac{\beta(\rho \hat{Z} - \varepsilon) - \eta((\alpha + \beta - 1)\varepsilon + b)}{-\eta(1 - \beta) + \beta} \quad (12)$$

The numerators of equations (10) to (12) consist of three terms, the first of which reflects the "engine of growth" part from the export demand function: the growth rate of world income multiplied by the income elasticity of export demand minus the population growth rate. The product of trade partners' income and income elasticity is the driving force on the demand side. Hence, this part represents the ideas of Prebisch. The last part,

1
2
3 on the other hand, captures the handmaiden part (see Kravis 1970). This term supports
4 the view that technical progress leads to an increase in exports via decreased prices if
5 exports are price elastic. Consequently, the causality of this last effects runs from growth
6 to exports, opposite to what the engine of growth supporters propose. Our model contains
7 both parts. Note, however, that the handmaiden part drops out if a country has no
8 technical progress. The third part in the middle of the formulas is only relevant in case of
9 non-constant returns to scale. With increasing (decreasing) returns to scale we have an
10 additional cost reduction (enhancement) which drops out only if $(\alpha+\beta=1)$ in (10)-(12).
11
12
13
14
15
16
17
18
19
20
21

22 The direct effect of technical progress and returns to scale is to decrease production
23 costs and to reduce the terms of trade as can be read off equation (11). The question then
24 arises whether this will cause exports and investments to rise or fall. Assuming exports
25 are price-elastic, there will be an increase in exports and investments as well as in the
26 capital-labour ratio in equation (10). If exports are price-inelastic, however, technical
27 progress has a negative impact on the growth rate of the capital-labour ratio. Considering
28 the growth rate of income per capita, it is obvious that technical progress has not only a
29 direct but also an indirect effect on this variable. The latter effect is due to changes in the
30 capital-labour ratio induced by technical progress. The direct effect outweighs the
31 indirect one so that technical progress always has a positive impact on real wages.
32
33
34
35
36
37
38
39
40
41
42
43
44
45

46 Summing up, technical progress and returns to scale have a negative impact on the
47 terms of trade while they influence per capita income positively. The higher the income
48 elasticity the higher the growth of export demand for any growth rate of world income
49 and the higher the growth rate of capital imports in equation (10). The latter aspect causes
50 income in equation (12) to grow at a higher rate and the growth rate of the terms of trade
51
52
53
54
55
56
57
58
59
60

1
2
3 is driven up as well. A higher growth rate of income in the trade partners' countries will
4
5 lead to an increase in exports. Yet, a critical point is whether the change in income
6
7 multiplied by the income elasticity, $\rho\hat{Z}$, exceeds the population growth rate ε . This
8
9 difference governs the growth rate of the capital-labour ratio in equation (10) in case of
10
11 constant returns to scale and absence of technical progress. If the income elasticity of
12
13 export demand is low and the population growth rate is high, the effect on the growth
14
15 rates concerning the terms of trade, the capital-labour ratio, and income per capita will be
16
17 negative.
18
19
20
21

22
23 In conclusion, the terms of trade will fall on condition that the rate of technical
24
25 progress and scale economies is not exceeded by a large difference between the export
26
27 growth rate and the population growth rate in equation (12). The growth rates of the
28
29 capital-labour ratio and income per capita may be negative because of low income and
30
31 price elasticities. With respect to income elasticity and trade partners' income growth, the
32
33 terms of trade are an indicator of economic development because they boost both, per
34
35 capita income and the terms of trade.
36
37
38
39

40 *Comparison with the Results of the Solow Growth Model*

41
42
43 The Prebisch-Singer thesis poses the task of presenting trade conditions which result
44
45 in a slower growth rate for the main economic indicators of welfare than in the Solow
46
47 model. Considering a Solow model with a constant-returns-to-scale production function
48
49 like equation (1), the capital-labour ratio and per capita income grow at the same rate,
50
51 $b/(1-\beta)$. In the model examined above, this result can be obtained by means of taking into
52
53 account two special cases. First, equation (12) can be written in the form:
54
55
56
57
58
59
60

$$\hat{y} = \frac{b}{(1-\beta)} \left\{ 1 - \frac{\beta}{[\eta(1-\beta)]} \right\} + \frac{(\rho\hat{Z} - \varepsilon)\beta}{[-\eta(1-\beta) + \beta]}, \quad (12')$$

For any value of $\rho\hat{Z}$, it holds that $\hat{y} = b/(1-\beta)$ assuming that η approaches minus infinity. This is the small country case in neoclassical models. Second, it can be shown that $\hat{y} = \frac{b}{(1-\beta)}$ and $\hat{p} = 0$, both if $\rho\hat{Z} - \varepsilon = b/(1-\beta)$, just like a closed economy in the Solow model. Then, the engine of growth, $\rho\hat{Z} - \varepsilon$, has the same effect as the handmaiden part, $b/(1-\beta)$, and therefore, the growth rate coincides with that of the Solow model.

Figure 1 presents \hat{y} as a function of ρ for different values of η under the assumption – made to emphasize the role of the income elasticity – that $\hat{Z} = \varepsilon + b/(1-\beta)$ and of constant returns for both models because the Solow model is normally presented in this way. The vertical intercept increases with the price elasticity of exports. The slope, on the other hand, is less steep the more price-elastic exports are.

FIGURE 1 OVER HERE

Due to equation (12'), there is one straight line for each value of η , being equal to $b/(1-\beta)$ at $\rho = 1$. The horizontal line represents the small country case with the price elasticity being equal to minus infinity. It shows that in this case exports constitute no constraint to growth, a conclusion that is in line with traditional neoclassical thinking. Figure 1 reveals that the capital importing economy grows at a lower rate than in Solow's model if the income elasticity is lower than one. For income elasticities greater than one, the economy grows faster than predicted by the Solow model. These conclusions do not hold for a price elasticity of minus infinity, since this is the small country case.

In view of the interplay between the growth rate of the terms of trade and the income elasticity of export demand, a similar graph is drawn in figure 2. The less price-elastic exports the steeper the slope and the more negative the vertical intercept. For income elasticities smaller than one, the growth rate of the terms of trade fall and real wages grow at a lower rate than in the Solow model. There is, thus, a close relationship between the latter two variables. The driving force behind both of them is the income elasticity of export demand. The effect of the latter is reinforced by a lower price elasticity of export demand. The obvious corollary is that of a high price elasticity weakening the impact of the income elasticity of export demand on the developments of real income and the terms of trade. As in the previous graph, the relationship is drawn for $\hat{Z} = \varepsilon + b/(1 - \beta)$ and alternative values for the price elasticity. To summarize, the price and income elasticities of export demand are crucial determinants for a developing country's growth prospects.

FIGURE 2 OVER HERE

In this model the importation of capital goods and low (high) elasticities of export demand contribute to explaining the slow (fast) growth of developing countries. The question now arises whether these price and income elasticities are indeed low. That issue is taken up in the following sections.

Again, we would like to point out the simplifying assumptions we have made: absence of domestic capital goods, imported consumption goods, foreign debt, and unbalanced trade. None of these assumptions holds exactly true for Brazil as can easily be seen by examining the World Development Indicators.¹⁶ Whether or not the

¹⁶ For Brazil, Gross fixed Capital formation (GFCF) is about twice as large as total imports. For 1995 (but not for other years) we can calculate from the WDI that production of machinery and transport equipment is about \$US 38.1 billion. This is about 25% of GFCF. However, of these \$US38mln, 8.8 are exported, leaving about 29 for domestic investment. On the other hand, 21 are imported according to the UN Intern.

1
2
3 abstraction is *too* strong will be revealed by the econometric work. After all, the Solow
4 growth model, which is widely used in empirical work, is a special case of our model.
5
6 The former ignores imported inputs and the exports used to pay for them, whereas we
7
8 ignore that a large part of capital goods is produced domestically. Furthermore, past
9
10 empirical studies estimating export demand income and price elasticities use a similar
11
12 export demand function but do not make use of a growth model for the supply side as we
13
14 do. Integrating all of these neglected aspects in a fully-fledged model would require the
15
16 estimation of many more parameters with a small number of observations. Therefore, it is
17
18 not necessarily a drawback to use this simple model. In a model including domestic
19
20 capital goods, these would have to grow at a rate that is proportional to that of foreign
21
22 capital goods in order to avoid running too much into decreasing returns to the
23
24 accumulation of one of them only. Absence of debt is dealt with by using the
25
26 investment/GDP ratio rather than the savings ratio. Khan and Knight (1988), and
27
28 Esfahani (1991) also assume all imports to be inputs. It can only be hoped for that the
29
30 other aspects would merely change the intercept of the regressions below. This is a matter
31
32 left for future work.
33
34
35
36
37
38
39

40 We have made strong claims in the introduction in regard to the relevance of this model
41
42 when compared to other models. Therefore this model should be estimated and tested. In
43
44 order to do so, we should stick as closely as possible to the model because other
45
46 specifications might be too general and impossible to be interpreted as support for the
47
48 model. Moreover, for the calculation of long-run values using the model in section 5, we
49
50
51
52

53
54 Trade Statistics Yearbook, indicating that about 42% of machinery and transport equipment is imported
55 provided it is not re-exported. Unfortunately it seems impossible to construct separate stocks of domestic
56 and foreign capital without having similar information for other items and periods of GFCF than just
57 machinery and transport as of 1995.
58
59
60

1
2
3 need the values of the parameters as obtained from an estimate of the model. Therefore
4
5 the equations estimated in section 4 are (8) and (9). Other types of purely empirical
6
7 regression equations would not yield estimates of all of these parameters. Note that these
8
9 equations hold for both, the steady state and the transition path. We want to estimate the
10
11 equations as a simultaneous system. Once one equation is estimated, it is obvious that all
12
13 parameters can be identified. Therefore, we have one constraint per regressor except for
14
15 the intercept and the world income variable, which has the same coefficient in both
16
17 equations.
18
19
20
21

22 23 24 25 **3. The data**

26
27 We decided to carry out the empirical estimation for Brazil for several reasons. First, the
28
29 model is dynamic in nature and all parameters are likely to have country-specific values.
30
31 Therefore we focus on a time-series estimate for just one country. Second, we like to
32
33 consider a large country in order to avoid strong dependence of the results on single
34
35 products, which one often finds for small countries. Third, for Brazil the data availability
36
37 is better than for other countries we have checked. This is not meant to say, though, that
38
39 similar estimates cannot be done for other countries as well, but the problems in regard to
40
41 the number of observations will be greater. In order to estimate the equations, time series
42
43 for the savings or investment/GDP ratio, capital, trade partners' income, the terms of
44
45 trade and employment are required.
46
47
48
49

50
51 The data for gross fixed capital formation as percentage of (GDP minus depreciation)
52
53 are taken from the World Development Indicators 2004 and represent investment. They
54
55 stem from the World Bank national accounts following the SNA (System of National
56
57
58
59
60

1
2
3 Accounts of the UN) conventions. We make use of this figure instead of the savings ratio
4
5 in order to account for that part of investment financed by foreign debt, which is ignored
6
7 by our model.
8
9

10 The data for capital are constructed by cumulating Gross Fixed Capital Formation after
11 subtraction of the data for depreciation, starting from an initial value determined
12 according to the formula¹⁷
13
14
15
16

$$K_0 = \frac{I_1}{(\hat{K}_1 + \delta)}$$

17
18
19
20
21
22
23 Depreciation is assumed to be 3.7% of capital for all periods because this is the average
24 value of available figures in earlier national accounts data. For I_1 we use gross fixed
25 capital formation as of 1970. The initial growth rate of the capital stock in the above
26 formula is assumed to be .1, which corresponds to the order of magnitude of the growth
27 rates of GDP and employment in those years. With the capital stock obtained in this way
28 we can determine growth rates as log differences and add the rate of depreciation to get
29 the dependent variable of equation (8).
30
31
32
33
34
35
36
37
38

39
40 The employment data are taken from the ILO website. These are numbers of employed
41 persons irrespective of the number of hours worked. The time series starts in 1972 but
42 values for the years 1974, 1975, 1980, 1991, 1994, 2000, 2001 are missing. We do not try
43 to interpolate them because in an earlier attempt we found that different ways of doing so
44 have an impact on the unit root properties of the time series.

60

Trade partners' income is taken to be world income since Brazil is trading with all the countries in the world. The world income is the sum over the GDP in constant 1995 US dollars of 208 countries, of which some do not provide these data though.

The terms of trade are calculated as 'Exports as capacity to import' divided by 'exports of goods and services', both in terms of constant local currency units.¹⁸ Exports as a capacity to import equal the current price value of exports of goods and services, deflated by the import price index. They stem from the World Bank national accounts and we took them from the World Development Indicators.

4. Econometric methods and estimation results for the system of equations

Econometric methods have been developed traditionally either for stationary variables and more recently for variables being integrated of order one, I(1). Before discussing the methods we check whether the time series follow unit root processes and determine the order of integration of the variables. Testing for unit roots suffers from the fact that these tests have been designed for a large number of observations whereas we deal with only a few observations. Hence, the tests have low power. For world income the ADF test does not reject the unit root hypothesis. The other variables do not follow unit root processes according to the ADF test. Consequently, we use equations (8) and (9) with only one modification: we replace $\ln Z$ by $d(\ln Z)^*t$, which can be based on rewriting the export function as $X = e^{\rho d \ln Z^* t} p^\eta = Z^\rho p^\eta$. The latter version of the variable does not have a unit root according to the standard ADF test. So we can use equations (8) and (9) in their current form.

¹⁸ Data are available in the appendix to the working paper version.

The system has three important properties. First, there are constraints on the coefficients, generating a non-linear problem of estimation. Second, both equations of the system contain the random terms from the production function and the export function and therefore the residuals of the two equations will not be independent. These two properties together suggest using the seemingly unrelated regression (SUR) method. Third, equation (8) is a differential equation. Residuals have a positive impact on the dependent variable, enhancing the capital variable on the right hand side in the next period. As this is a stock variable, the effect is permanent. In other words, the residuals have an impact on all future variables of capital and the regressor in the first equation is not exogenous although it is predetermined (see Davidson and Mackinnon 2004, chapter 3.2). As this would bias the estimates, we use the generalized method of moments (GMM-HAC with heteroscedasticity and autocorrelation correction of the coefficient standard deviations) including all regressors and lagged variables of capital as instruments to correct for endogeneity. The GMM-HAC estimator corrects the standard deviation but a serial-correlation bias of the coefficients cannot be excluded. Therefore we present estimates with and without autocorrelation correction. We present the first GMM estimate without autocorrelation correction in the first column of Table 1. Table 1 shows the formulas and the values of the coefficients of regression equation (8) from which the parameters of the model can be inferred. The coefficients of equation (9) are non-linear formulas of these coefficients.¹⁹

The over-identifying constraints for the additional instruments require that the product, nJ , of the J-statistic and the number of observations, n , are chi-square distributed. The value nJ in Table 1 has to be smaller than the critical value for the relevant degrees of freedom reproduced in the Table as c(d.f.). As there are four constraints in the two equations, we have at least four degrees of freedom. However, the number of lagged instruments has to be added for the chi-square test (see Greene 2003, p.548/9), which is passed at the 5% significance level for the three regressions of Table 1.

TABLE 2 OVER HERE

In the first regression, the income elasticities of export demand (0.19) is at the lower end of the range of earlier estimates and the price elasticity (-1.86) is larger in absolute terms than in previous studies (see Table 2 for a comparison). The time trend representing technical progress is significant and has the expected sign. The rate of total factor productivity growth is about 2%. Given the elasticity of production of labour of about .5, the labour augmenting rate of technical change is 4%. This figure is a bit larger than in estimations assuming constant returns to scale. However, the sum of the elasticities of production is $.81 < 1$ and indicates decreasing returns to scale at a measure of .19. If we arbitrarily (and therefore not shown) drop the time variable, we get increasing returns to scale. As shown above, the Solow growth model is a special case of our model if the price elasticity is equal to minus infinity. This would require $c(2)=1$. Given the high significance of the value around 0.5 it is clear that the alternative (to our model) hypothesis of the Solow model will be rejected by an F-test. The formulas for the identification of the parameters of the production function indicate that the estimated coefficients have to be in narrow ranges in order to get reasonable parameter values for

1
2
3 the model. In this sense the estimate for the system is quite encouraging. The only trouble
4 here comes from the serial correlation as indicated by a very low DW statistic²⁰. The
5 standard procedure is to add lagged dependent variables to the regression equation(s).
6
7 The result of adding one lag in each equation is shown in the second equation in Table 1.
8
9 The income and price elasticity of export demand is slightly higher now, at .33. The price
10 elasticity has doubled and is now -4.9. The growth rate of total factor productivity is now
11 much smaller at about 1%. The decreasing returns measure is still .19 because the
12 elasticity of production of capital is enhanced at the cost of that of labour. There still may
13 be some autocorrelation in the first equation. We save the residuals from the previous
14 (second) regression and add their lagged values to the regression (also as instruments).
15
16 This carries out the standard Breusch-Godfrey test after application of the Frisch-Waugh-
17 Lovell theorem saying that the lagged residuals can be added to the regression equation to
18 test for serial correlation (see Davidson and MacKinnon 2004). The third regression in
19 Table 1 shows the result that we still have some autocorrelation as can be seen from the
20 significant coefficient of the lagged residuals. Due to this last step of including lagged
21 values of the residuals five observations are lost, leaving us with a test of low power.²¹
22
23 However, with lagged residuals in the regression the estimates of the third regression are
24 inconsistent as an estimate of the model, because lagged instruments can only mitigate
25 but not completely remove the inconsistency²² and inference of parameters values is
26 therefore invalid. This regression then is at best valid as a Breusch-Godfrey test for serial

51
52 ²⁰ Below we will also employ the Breusch-Godfrey test because of the endogeneity problem discussed
53 earlier, because the DW statistic is not the adequate tool in case of endogeneity.

54 ²¹ Panel data are not a way out for the low number of observations in our case, as at least income and price
55 elasticities of export demand and TFP growth rates will not obey the homogeneity assumption and
56 therefore lead to biases.

57 ²² We are grateful to Pierre Mohnen and an anonymous referee for pointing this out to us.
58
59
60

1
2
3 correlation; the reservation coming from the low number of observations. Using the
4
5 second regression seems then to be more appropriate. If we except regression three as an
6
7 autocorrelation test, this means that we have a serial correlation bias in the second
8
9 regression. However, we take it from a similar problem in Epple and McCallum (2006,
10
11 p.376/7) that the Durbin-Watson statistic for both equations of regression two is in a
12
13 region where we do not have to worry about the bias, because it is likely to be small. For
14
15 regression two to be consistent we have to assume that it has no autocorrelation, which
16
17 means that we need to reject regression three as an autocorrelation test, because of the
18
19 low number of observations. Using the second regression in Table 1 as our best result is
20
21 done therefore at the risk of having some bias and some inconsistency, or assuming
22
23 absence of serial correlation in spite of regression three. Future work therefore should
24
25 concentrate on model variants that are better able to capture cycles. In spite of all these
26
27 problems it is worth pointing out that we get the expected signs and all coefficients are
28
29 significant at the seven percent level in spite of a low number of observations.

39 **5. Steady state growth rates, engine and handmaiden effect, and dynamic gains** 40 41 **from trade**

42
43 We have estimated the model for its non-steady-state version. For long-run predictions,
44
45 the theory gives us the steady-state formulas for growth rates of expected values. Note
46
47 that in the estimated parts of the model, no use was made of the assumption of perfect
48
49 competition, which is not in accordance with increasing returns to scale. In this section,
50
51 we calculate the steady-state growth rates for equations (10)-(12) numerically so as to
52
53 specify the long-run predictions of the estimated models. We define the engine and
54
55
56
57
58
59
60

handmaiden effects and calculate their values in order to compare them to each other and in order to compare them to the effect export growth rates have on GDP per capita growth rates in the survey of Lewer and van den Berg (2003). Finally, we calculate the corresponding growth rates of the Solow growth model as well as the difference between the predicted growth of our model and that of the corresponding Solow model as the dynamic gains from trade.

TABLE 3 OVER HERE

In Table 3, we report the steady-state results for the growth rates of k , p and y . Additionally, the following effects – extracted from equations (10)-(12) – are presented: g (m , s) indicates the engine (handmaiden, scale) effect, obtained as the derivative of the formula for the growth rate of y with respect to the growth rate $d \ln Z$ (b , $d \ln L$).

$$g = \frac{\beta \rho}{\beta(\eta+1)-\eta}, m = \frac{-\eta}{\beta(\eta+1)-\eta}, s = \frac{-\eta(\alpha + \beta - 1)}{\beta(\eta+1)-\eta}$$

The scale effect is the effect of $d \ln L$ only to the extent that it would drop out if there were constant returns to scale. Next, x represents the corresponding GDP per capita growth rate of the Solow model under the assumption that its parameters are identical to those of our estimates. Finally, the difference in the growth rates of our model, $d \ln y$, and the corresponding Solow model, denoted as t , is defined as the dynamic steady-state gains from trade. The parameter values are those from the second equation of Table 1.

$$x = \frac{b + (\alpha + \beta - 1)\varepsilon}{1 - \beta}, t = d \ln y - x$$

All calculations are done under the assumption that world income will continue to grow at 2.6% in the steady state. Finally, we need an assumption for the growth rate of

employment. This rate was anything but constant in the past as can be seen from the following regression:

$$\ln L = 9.71 + .06t - .00057t^2$$

(212) (17.2) (-9.16) adj.R² = .993

A plot of the regression result and its time derivative representing the growth of employment appears in Figure 3. The result indicates that the growth rate of labour drops to zero at time $t > 50$, which is after the year 2010.

FIGURE 3 OVER HERE

The results are as follows.²³ The steady-state growth rates of capital and income per capita are positive only if employment growth is sufficiently small, at about one or two percent respectively. This is due to the low income elasticity of export demand and technical progress being diminished by the negative scale effect. The strongly positive growth rates of the past with non-zero population growth are therefore generated by the transitional growth of capital accumulation. The terms of trade are falling – as the data reveals for the past – because the growth of the supply force, employment (multiplied by the decreasing returns measure) plus technical change, is larger than that of the demand force, world income multiplied by the income elasticity. The handmaiden effect, $m = 1.39$, is larger than the engine effect, $g = .033$, and the scale effect, $s = -.27$, again because the income elasticity of export demand is low. The handmaiden effect multiplied by the rate of technical change, $m*b$, is larger than the total engine effect expressed as

$$e = \frac{\beta(\rho\hat{Z} - \varepsilon)}{-\eta(1 - \beta) + \beta},$$

even for the lowest rates of population growth. With lower population

1
2
3 growth, this latter effect gets larger (see third but last line in Table 3) and the scale effect
4
5 vanishes (last line of Table 3), whereas the handmaiden effect is independent of
6
7 population growth. We also would like to emphasize the importance of the price
8
9 elasticity. The denominator of the engine, handmaiden and size effects is the same as that
10
11 of the steady-state growth rates in equations (10)-(12). Under the parameter values
12
13 obtained from the second regression it has a value of about 3.55 compared to $1-\beta = .65$
14
15 under autarky. Under the more traditional estimate of a price elasticity of minus one it
16
17 would have the value unity. The denominator is much larger now. But the price elasticity
18
19 is also multiplied to the scale effect and the rate of technical change. They are also
20
21 enlarged now, except for the engine effect and the terms of trade formula, where it does
22
23 not appear in the numerator. A high price elasticity of almost minus five is working
24
25 towards a dominance of the handmaiden and the scale effect.
26
27
28
29
30

31
32 The closed economy growth rate is driven by decreasing returns to scale, employment
33
34 growth and technical change. The lower future employment growth the higher is the
35
36 hypothetical autarkic growth rate. The steady-state part of the dynamic gains from trade
37
38 becomes almost zero as employment growth goes to zero. Lewer and van den Berg
39
40 (2003) illustrate that dynamic gains from trade are large when export growth rates are
41
42 high in the transition after taking policy measures. Therefore, static gains from trade and
43
44 the ones during transition may be larger than those in the steady state even if the latter are
45
46 negative.
47
48
49
50
51
52
53
54
55

56
57 ²³ The results are very similar to those obtained from using the parameters from the third regression as the
58 income elasticity of export demand is low in both regressions and technical change is larger in the second
59
60

6. Conclusion

The introduction has pointed out that the modified Bardhan/Lewis model is the only one that has income and price elasticities of export demand in the long-run growth formula. Therefore this model is particularly well-suited to understand and contribute to the literature on export and growth, the Prebisch-Singer thesis, and dynamic gains from trade. As we have made strong claims in regard to these strands of literature and alternative models, the model should be estimated and tested. We believe that any regression that is less closely tied to the model would not really test the model. The estimates suffer from a low number of observations and an autocorrelation bias cannot be excluded but is likely to be small. The estimated values for the parameters of the production and export functions for Brazil are very plausible and therefore provide some support for the model. This allows us to draw the following conclusions.

From the perspective of the exports and growth literature, the model adds economic causality to the econometric Granger causality of the literature in the sense of estimating a growth model that contains an economic mechanism turning world income growth through exports via imported inputs into growth. An explicit model that can provide a causal explanation can be estimated and tested. The low number of observation and possibly the serial correlation allow for some doubts in regard to a bias and inconsistency in the parameters. But getting expected signs and reasonable orders of magnitude reasonable and a significance at the seven percent level obtained provides some support for the model.

From the perspective of the Prebisch-Singer literature, the results clearly demonstrate that income and price elasticities of export demand may be important for the growth of

regression at the cost of obtaining decreasing rather than constant returns to scale.

1
2
3 Brazil in the period we have considered. If population growth is low enough, the
4 theoretical model allows for positive per capita income growth through technical
5 progress, imported capital goods, positive dynamic gains from trade and changing terms
6 of trade. However, if employment growth is large, negative rates are also possible.
7
8 According to our estimates, the income elasticity is small, thus hampering growth and
9 driving down the terms of trade in line with the Prebisch's expectations. However, the
10 effect is only weak due to a relatively high price elasticity of export demand, which
11 translates the falling terms of trade and therefore the scale effect and technical progress
12 into a high export demand as expected by Kravis. Both arguments interact and are
13 quantitatively relevant. According to our model, neither of the two can be dismissed
14 because technical change matters on the supply side and exports are important
15 determinants on the demand side. In addition, decreasing returns seem to play a role that
16 was underemphasized so far in the literature as opposed to the classical economists.

31
32
33

34 The steady-state part of dynamic gains from international trade is dependent on the
35 magnitude of employment growth: high employment growth yields negative dynamic
36 gains from trade in the steady state whereas low employment growth brings about
37 positive gains from trade if the income elasticity of export demand is high enough and the
38 price elasticity low enough. If employment continues to grow at such a high rate as in the
39 past, dynamic gains from trade will be negative in the future. But the trend in
40 employment data points to the opposite direction. As population growth approaches zero,
41 gains from trade also go to almost zero although world income growth and technical
42 change (plus scale effect) multiplied by the price elasticity translate into higher demand
43 for exports. The reason is that the high price elasticity enhances the denominator of the

1
2
3 major effects more strongly (from 2/3 under autarky to 3.55 under trade) than the
4
5 numerator and therefore reduces both effects.
6

7
8 In regard to policy we would like to emphasize that the implementation of WTO
9
10 agreements is not costless (Rodrik 2000, p.13). Therefore trade reforms have to be
11
12 compared to their opportunity costs and benefits from other political decisions on
13
14 investments like improvements of institutions and human capital investment. In these
15
16 analyses it should be taken into account though, that gains from trade are not only static
17
18 but rather dynamic. In particular, we speculate that investments increase with trade
19
20 volumes and therefore trade liberalization may enhance transitional growth rates and
21
22 long-run levels, both depending on the income and price elasticities of export demand. In
23
24 short, the dynamic theory and empirics of trade and growth should be included in
25
26 comparative cost-benefit analyses. But these suggestions require further research on the
27
28 links from trade liberalization to growth as contributions to cost-benefits analyses.²⁴ For
29
30 the time being it therefore seems to be most adequate not to put all eggs into one basket
31
32 and to pursue a balanced strategy of improving institutions, factor accumulation,
33
34 technical change and trade relations, the latter focussing in a balanced way on black
35
36 market premia, other macroeconomic issues and trade liberalization. Given the slow pace
37
38 of trade negotiations this should leave ample opportunity for the other measures.

(a) Instruments: regressors and lnk(-2) to (-7) in the first equation and none in the second.

(b) c(d.f.) is the critical value for degrees of freedom indicated in brackets for the first equation at the 5% significance level of the chi-square test for the over-identifying constraints of the estimates; degrees of freedom is number of constraints, which is 4, plus number of lagged instruments.

(c) c(d.f.) is the critical value for degrees of freedom indicated in brackets for the second equation at the 5% significance level of the chi-square test for the over-identifying constraints of the estimates; degrees of freedom is number of constraints, which is 4, plus number of lagged instruments.

(d) Instruments: regressors and dlnk(-1) to (-5) and two lags of the dependent variable in the first equation and lnp(-2) to (-4) in the second.

(e) Instruments as in previous regression plus lagged residual regressor.

Table 2: Overview of income and price elasticities of export demand for Brazil

Year	Author	Period	y	pm/pd	pm	pd
1969	Houthakker, Magee	1951-1966	0,34	-0,39		
1976	Lemgruber	1965-1974	1,97*	-0,41*		
1984	Aggarwal	1969-1978	0,253*	-1,23*		
1986	Bahmani- Oskooee	1974:1- 1980:4	0,007	-0,151		
1988	Zini	1970:1- 1986:3	0,690*		-0,171*	0,131
1992	Faini, Pritchett, Clavijo	1967-1983	0,60*	-1,51*		
1993	Bairam	1964-1985	3,93			
1995	Reinhart	1970-1991	2,447	-0,148		

y: foreign market income

pm: import unit value index

pd: domestic producer price or wholesale index

*: significance at 5% level

Source: Bairam (1988), Fullerton et al. (1999), Houthakker and Magee (1969), Reinhart (1995).
