13  
14 Abstract:

15  
16 In order to evaluate the efficiency of the monetary transmission mechanism, we develop the  
17  
18 formulas for testing rational expectations theory in the term structure of interest rates with  
19  
20 VAR models of stochastically switching regimes in which all the parameters are regime-  
21  
22 dependent. These formulas are obtained for the strict version of rational expectations as well  
23  
24 as for the case where measurement errors are assumed in the expectations relationship.  
25  
26 They are extensible to other contexts that involve variables linked by rational-expectations  
27  
28 behaviours. The testing procedure is implemented on interest rates of the Spanish inter-bank  
29  
30 money market. Measurement errors must be assumed to find signs favourable to the theory.

**MARKOV-SWITCHING MODELS, RATIONAL EXPECTATIONS**  
**AND THE TERM STRUCTURE OF INTEREST RATES**

**1. Introduction**

It is commonly accepted that monetary authorities have more direct control on short-term interest rates than on longer-term rates. As soon as the Central Bank modifies the reference interest rate, this has an impact on the short-term interest rate and it is then hoped that these modifications be progressively transmitted to the longer term rates via the term structure. This so-called “monetary transmission mechanism” is more effective if the hypothesis of Rational Expectations (REH) governs the term structure. This explains why this theory has been extensively tested over the last twenty years, especially on US data. Unexpectedly for most economists, it has very often been rejected. This also explains why there is a vast literature trying to find the reasons for these surprising results and many attempts have been made to reconcile the Expectations Hypothesis with the data.

Mankiw and Miron (1986) argue that the Expectations hypothesis is likely to perform better empirically under a policy of monetary targeting rather than under interest rate smoothing. Kugler (1988) examined the Mankiw-Miron hypothesis on US, German and Swiss data and obtained support for REH only for German data. In a pioneering paper, Campbell and Shiller (1987) developed a VAR methodology for present value models that has been extensively used to test REH in the term structure context. When applied on US data, this methodology generally leads to a rejection of the hypothesis (see for instance Evans and Lewis, 1994, Campbell and Shiller, 1991, Shea, 1991). Somewhat better results have been obtained with data on other countries, although the evidence in favour of REH is far from overwhelming (see among many others Prats Albertosa and Beyaert, 1998, Cuthbertson et al., 2000, Ghazali and Low, 2002, Cooray, 2003). Using another approach, based on a linear regression of the expectation error on the lags of interest rates, Johnson (1997) obtains some

1  
2  
3  
4  
5  
6 support for REH in the US, although Kalev and Inder (2006) express serious doubts about  
7 the econometric validity of these results; with more sophisticated -although linear- methods,  
8 they reach opposite conclusions. Tzavalis and Wickens (1997) present evidence that a time-  
9 varying term premium might be the clue to explain the econometric failures of the  
10 Expectations hypothesis of the term structure. Accounting for such a time-varying term  
11 premium and using a cross-section approach instead of more traditional time-series  
12 techniques, Harris (2004) strongly rejects REH in the context of the US bond market. In  
13 recent years, Chen (2001) and Gravelle and Morley (2005) make use of the Kalman filter  
14 technique to account for changes in the term premia. Gravelle and Morley reject the  
15 Expectations Hypothesis for their Canadian data set. Chen models the relationship among  
16 inflation, real interest rates and the term structure and obtains with US data that the  
17 expectations hypothesis could hold up well for the data under the assumption of a time-  
18 varying term premium and a random walk for the real interest rate.

33 Other authors argue that the economy is subject to changes that give rise to important  
34 nonlinearities in the dynamic relationships among economic variables and that this calls for a  
35 model able to represent these changing states of the economy. As argued by Ang and  
36 Beekaert (2002), changes in business cycle conditions and monetary policy may cause  
37 interest rates to behave differently in different time periods. The Markov-Switching (MS)  
38 models, first introduced in economics by Hamilton (1988, 1989, 1990) and further developed  
39 in the subsequent literature, have proved to be adequate for the type of changing dynamics  
40 of the interest rates (Hamilton, 1988, Gray, 1996, Sola and Drifill, 1994, Blix, 1997, Beyaert  
41 and Perez-Castejon, 2000, Bekaert et al., 2001, Ang and Bekaert, 2002, Humala, 2005, etc.).  
42 Our paper belongs to this line of research. Our main objective is to develop a method of  
43 testing the Rational Expectations Hypothesis (REH) for the term structure of interest rates in  
44 VAR models that allow for unobservable Markov switching regimes.

4  
5  
6 In the past, Hamilton (1988) and Sola and Driffill (1994) applied this type of non-linear models  
7  
8 to the U.S. term structure of interest rates with results that improved with respect to the case  
9  
10 where linear models were used. Hamilton works with a one-equation model, whereas Sola  
11  
12 and Driffill generalize bivariate VAR models of the type considered by Campbell and Shiller  
13  
14 (1987), allowing for switching regimes in the variance matrix and in the intercept, but with  
15  
16 constant autoregressive coefficients. In this particular case, testing rational expectations is  
17  
18 very similar to the case where switching regimes are not considered. Kugler(1996) –with US  
19  
20 and Swiss data- and Engsted and Nyholm (2000) – with Danish data- extended the Sola and  
21  
22 Driffill approach<sup>1</sup>. They consider a VAR(1) model linking a one-period with a three-period  
23  
24 interest rates, letting the autoregressive parameters depend on the current state of the  
25  
26 economy; they obtain the expression for the Rational Expectations restrictions for this specific  
27  
28 case only.  
29  
30

31 In the present paper, we also consider a two-state model where the mean vector, the  
32  
33 variance matrix, as well as the autoregressive coefficients of the bivariate model are allowed  
34  
35 to change and we obtain the restrictions on the latter coefficients that guarantee the fulfilment  
36  
37 of the rational expectations hypothesis. However, our approach differs from Kluger and from  
38  
39 Engsted and Nyholm in various aspects. On the one hand, there is a difference in how the  
40  
41 structure of the VAR model alters with a change in the regime. On the other hand, we obtain  
42  
43 very general expressions for the Rational Expectations restrictions that are valid for any order  
44  
45 of the VAR and for any number of periods that separate the maturities of the short and the  
46  
47 longer interest rate. We obtain the restrictions both for the case where there are no  
48  
49 measurement errors and for the case where such errors affect the agents in their decision-  
50  
51 making process and/or the econometrician in the model-building process. Moreover, these  
52  
53 formulas can easily be adapted for testing other economic theories, which involve variables  
54  
55 linked by a rational expectations relationship (such as the asset pricing model, the uncovered  
56  
57 interest parity or even the rational expectations theory of intertemporal consumption).  
58  
59  
60

The paper is organized as follows. In section 2 we describe the model. In section 3 we obtain the general form of the testable restrictions implied by the rational expectations hypothesis. In section 4 we apply these formulas to the Spanish inter-bank one-week, two-week and one-month weekly interest rates. Section 5 concludes.

## 2. The model

### 2.1 Starting point: expectations theory and Campbell-Shiller methodology in a linear model

Let  $R_{t,n}$  be the interest rate at time  $t$  of an asset with maturity in  $(t+n)$ , and let  $r_t$  be the interest rate of an asset maturing in  $(t+1)$ . According to the Rational Expectations Theory of the term structure of interest rates, when  $R_{t,n}$  and  $r_t$  correspond to assets both with a short maturity, typically measured in terms of days, weeks or months, Shiller, Campbell and Schoenholz (1983) suggest the following formula:

$$R_{t,n} = \frac{1}{n} \sum_{i=0}^{n-1} E_t[r_{t+i}] + k \quad [1]$$

where  $E_t$  represents the rational expectations of the agents conditional on the information available at moment  $t$  and  $k$  is a constant liquidity premium. An alternative expression is based on the spread between the longer-term and shorter-term rates: <sup>2</sup>

$$S_{t,n} = R_{t,n} - r_t = \sum_{i=1}^{n-1} \left(1 - \frac{i}{n}\right) E_t[\Delta r_{t+i}] + k = E_t[S_{t,n}^*] + k \quad [2]$$

Campbell and Shiller (1987) develop a procedure to test the present-value relation of the type expressed in [2] for the case when  $n$  is infinite. For any maturity, it is easy to show that if the interest rates are  $I(1)$  and the expectations theory is true there exists an Error Correction Model (ECM) that relates  $\Delta r_t$  and  $\Delta R_{t,n}$ . From this model it is possible to derive a bivariate VAR defined on  $\Delta r_t$  and  $S_{t,n}$ , which are stationary variables:

$$\begin{bmatrix} S_{t,n} \\ \Delta r_t \end{bmatrix} = \begin{bmatrix} a(L) & b(L) \\ c(L) & d(L) \end{bmatrix} \begin{bmatrix} S_{t-1,n} \\ \Delta r_{t-1} \end{bmatrix} + \begin{bmatrix} u_{1t} \\ u_{2t} \end{bmatrix} \quad [3]$$

where  $a(L)$ ,  $b(L)$ ,  $c(L)$  and  $d(L)$  are lag polynomials of order  $p$ . From [3], it is possible to deduce and test the restrictions implied by the expectations theory, whether  $n$  is infinite or finite and small. The difference takes place in the form of these restrictions: they are linear and very easy to test in the infinite horizon case, while they are highly non-linear in the finite horizon case<sup>3</sup>.

## 2.2 A two-state switching regime VAR model

In model [3], all the parameters are constant. The possibility of behavioural modifications of economic agents caused by political, institutional or economic changes are not considered. However, as argued by Ang and Bekaert (2002), changes in business cycle conditions and monetary policy may cause interest rates to behave differently in different time periods. We allow for such behavioural changes by introducing the possibility of stochastic changes of regime, generalizing the approach first considered by Hamilton (1988) and Sola and Driffill (1994).

We consider the same VAR( $p$ ) as in [3], with the added feature that the variance-covariance matrix of the errors, the mean of the multivariate process and the autoregressive coefficients are allowed to switch endogenously between two possible states or regimes; according to this view, the economy would switch stochastically between two regimes, associated with periods of different economic characteristics (such as expansion or recession, high or low risk, etc.). The state is a variable that the econometrician does not observe and has to be inferred from the data, along with the parameter estimates. The resulting Markov-Switching VAR model (MS-VAR) might be represented as follows:<sup>4</sup>

$$\begin{aligned}
S_t - \mu_{S,x_t} &= \sum_{i=1}^p a_{i,x_{t-i}} (S_{t-i} - \mu_{S,x_{t-i}}) + \sum_{i=1}^p b_{i,x_{t-i}} (\Delta r_{t-i} - \mu_{\Delta r,x_{t-i}}) + u_{S,t} \\
\Delta r_t - \mu_{\Delta r,x_t} &= \sum_{i=1}^p c_{i,x_{t-i}} (S_{t-i} - \mu_{S,x_{t-i}}) + \sum_{i=1}^p d_{i,x_{t-i}} (\Delta r_{t-i} - \mu_{\Delta r,x_{t-i}}) + u_{\Delta r,t}
\end{aligned}
\tag{4}$$

where  $x_t$  is an unobservable variable that takes the value 0 or 1, according to the state of the economy at date  $t$ . It is governed by a first-order Markov process, with transition probabilities  $P(x_t = 0 / x_{t-1} = 0) = p_{00}$ , and  $P(x_t = 1 / x_{t-1} = 1) = p_{11}$ . Note that  $p_{01} = P(x_t = 1 / x_{t-1} = 0) = 1 - p_{00}$ , and  $p_{10} = P(x_t = 0 / x_{t-1} = 1) = 1 - p_{11}$ . In this model, the distribution of the errors conditional on all past information  $(x_t, x_{t-1}, \dots; S_t, S_{t-1}, \dots; \Delta r_t, \Delta r_{t-1}, \dots)$  is assumed to depend only on  $x_t$  and it has the following form:

$$u_t / x_t \sim N(0, \Omega_{x_t}) \quad \text{with} \quad \Omega_{x_t} = \begin{bmatrix} \sigma_{S,x_t}^2 & \sigma_{S\Delta r,x_t} \\ \sigma_{S\Delta r,x_t} & \sigma_{\Delta r,x_t}^2 \end{bmatrix}$$

This model extends the Hamilton (1988) approach in two directions: it allows the shorter rate  $r_t$  to depend on the past values of the longer rate  $R_t$  and it allows not only the means, the variances and covariances, but also the autoregressive coefficients to vary with the state<sup>5</sup>. Only the first extension has been contemplated by Sola and Driffill (1994), who centre their study on the specific and simplest case in which the maturity of the longer rate  $R_t$  is twice the maturity of the short rate  $r_t$  ( $n=2$ ). We also deal with other values of  $n$ .

In specification [4], the autoregressive coefficient corresponding to lag  $i$  ( $i=1, \dots, p$ ) depends on the state the economy was in at time  $(t-i)$ . A second possibility consists of having the coefficient at lag  $i$  depending on the state the economy is in at time  $t$ , instead of at time  $(t-i)$ ; in this case, model [4] would transform into:

$$\begin{aligned}
S_t - \mu_{S,x_t} &= \sum_{i=1}^p a_{i,x_t} (S_{t-i} - \mu_{S,x_{t-i}}) + \sum_{i=1}^p b_{i,x_t} (\Delta r_{t-i} - \mu_{\Delta r,x_{t-i}}) + u_{S,t} \\
\Delta r_t - \mu_{\Delta r,x_t} &= \sum_{i=1}^p c_{i,x_t} (S_{t-i} - \mu_{S,x_{t-i}}) + \sum_{i=1}^p d_{i,x_t} (\Delta r_{t-i} - \mu_{\Delta r,x_{t-i}}) + u_{\Delta r,t}
\end{aligned}
\tag{4'}$$

1  
2  
3  
4  
5  
6 In model [4], the influence of past interest rates on present ones varies according to whether  
7 the market was in state 0 or 1 at that past date; on the other hand, in model [4'], the influence  
8 of past information depends on the state the market is in at the present date. Does it make  
9 more sense to consider that what happened in the past affects today's behaviour according  
10 to the state the economy today (Model 4'), or according to the state of the economy at the  
11 date at which that past information was generated (Model 4)? It is not easy to decide on a  
12 priori theoretical grounds which option is better<sup>6</sup>. It is wise to let the data tell which version is  
13 better. Beyaert and Perez-Castejón (2000) apply Schwartz information criterion to  
14 discriminate between [4] and [4'] on the same data (except that in this paper contains three  
15 additional years of information). They obtain a systematic and overwhelming dominance of  
16 version [4] over version [4'] for  $p=1,2,3$  and 4. This strong dominance, together with the fact  
17 that estimating these models is not a straightforward task, justifies that we centre on model  
18 [4] in the rest of the paper.

19  
20  
21 Note that in model [4], the value of the implicit "intercept", which is a function of the means  
22 and of the autoregressive coefficients, will depend on  $x_{t-j}$ ,  $j = 0,1,\dots,p$ .

23  
24  
25 The full set of parameters to be estimated may be represented by

$$26 \theta = \left\{ p_{00}, p_{11}, \mu_{S,0}, \mu_{S,1}, \mu_{\Delta r,0}, \mu_{\Delta r,1}, \sigma_{S0}^2, \dots, \sigma_{\Delta r1}^2, \sigma_{S\Delta r,0}, \sigma_{S\Delta r,1}, \right. \\ 27 \left. a_{10}, a_{11}, \dots, a_{p0}, a_{p1}, b_{10}, \dots, b_{p1}, c_{10}, \dots, d_{p1} \right\}$$

28  
29  
30 This vector contains  $12+8p$  parameters. They are estimated by Maximum Likelihood,  
31 applying numerical optimisation techniques. A 5-steps filter process is used, similar to the  
32 one described for instance in Hamilton (1988) and Sola and Driffill (1994). This procedure  
33 slows down very fast as  $p$  increases. It is therefore essential to make a sensible selection of  
34 the starting values given to the parameters in the estimation algorithm. For that purpose, we  
35 use the procedure described in Beyaert and Perez-Castejon (2000). This allows to consider

values of  $p$  above  $p=1$  (we consider  $p=1, \dots, 5$ ), instead of limiting the estimation to the only case of a VAR(1) model as done by Sola and Drifill(1994), Kugler(1996) and Engsted and Nyholm (2000).

### 3. The restrictions implied by the expectations theory

In order to obtain the restrictions imposed on the coefficients of [4] by REH, we proceed in a similar way as in Blix (1997). We obtain the expressions of the conditional forecasts of  $\Delta r_t$ , from the companion form of the MS-VAR( $p$ ); these forecasts are therefore expressed in terms of the MS-VAR( $p$ ) coefficients. Plugging them in equation [2] provide testable restrictions on these coefficients that guarantee that the term structure fulfil the REH. The algebraic details are developed in Appendix A. It is shown there that the restrictions to be tested, for any finite value of  $p$  and  $n$ , are as follows:

$$(1,0)J = \sum_{i=1}^{n-1} (0,1 - \frac{i}{n}) C_{\bar{x}_t}^{(i)} \quad [5]$$

with  $J = (I_{2 \times 2}, 0_{2 \times 2}, \dots, 0_{2 \times 2})_{(2 \times 2p)}$ ,  $C_{\bar{x}_t}^{(1)} = J \cdot B_{\bar{x}_t}$ ,  $\bar{x}_t = (x_t, \dots, x_{t-p+1})$

$$C_{\bar{x}_t}^{(i)} = J \cdot \left[ \sum_{x_{t+i-1}=0}^1 \dots \sum_{x_{t+1}=0}^1 \left( \prod_{m=1}^i B_{\bar{x}_{t+i-m}} \right) \left( \prod_{m=0}^{i-2} p_{x_{t+m} x_{t+m+1}} \right) \right] = J \cdot E \left[ \prod_{m=1}^i B_{\bar{x}_{t+i-m}} / \bar{x}_t \right] \text{ if } i \geq 2 \text{ (ie. } n > 2)$$

where

$$B_{\bar{x}_t} = \begin{pmatrix} B_{x_t}^{(1)} & B_{x_{t-1}}^{(2)} & \dots & \dots & B_{x_{t-p+1}}^{(p)} \\ I_{2 \times 2} & 0_{2 \times 2} & \dots & \dots & 0_{2 \times 2} \\ 0_{2 \times 2} & I_{2 \times 2} & \dots & \dots & 0_{2 \times 2} \\ \dots & \dots & \dots & \dots & \dots \\ 0_{2 \times 2} & 0_{2 \times 2} & \dots & I_{2 \times 2} & 0_{2 \times 2} \end{pmatrix}_{2p \times 2p}$$

and

$$\mathbf{B}_{x_t}^{(j)} = \begin{pmatrix} a_{j,x_t} & b_{j,x_t} \\ c_{j,x_t} & d_{j,x_t} \end{pmatrix} \quad \forall j = 1, \dots, p$$

Expression [5] includes  $2p$  one-dimensional restrictions. They have to be fulfilled for any possible value of the  $p$ -dimensional process  $\bar{X}_t$ , which includes  $2^p$  alternatives. There are thus a total of  $p2^{p+1}$  one-dimensional restrictions to be tested, which may include some redundant ones that have to be removed before testing. For small  $p$  and  $n$ , the restrictions simplify and the redundant ones are easily detected.

Expression [5] can be tested using a non-linear Wald test, asymptotically distributed as a chi-square variable with degrees of freedom equal to the number of non-redundant restrictions. This test is not invariant to the form in which the non-linear restrictions are expressed (see Gregory and Veal, 1985). An alternative consists of estimating the restricted model and applying an LR or LM test. However, as soon as  $p > 1$  or  $n > 2$ , the restricted model is extremely difficult to estimate; therefore, the alternative based on an LR test is considered here only when  $p=1$  and  $n=2$ .

Note also that the restrictions [5] can be extended to other contexts in which rational expectations theory linking variables has to be tested (such as the asset pricing model or the uncovered interest rate parity). The only thing to do is to adapt suitably the vectors  $N_j$ .

Before testing [5], it might be wise to test weaker conditions deduced from [2]. If [2] is true, then the spread  $S_t$  should Granger-cause  $\Delta r_t$ . As is well known, this can be checked through a joint significance test of  $S_{t-i}$ ,  $i=1, \dots, p$  in  $\Delta r_t$  equation in [4]. This involves testing  $c_{i,x_{t-i}} = 0$ ,  $i = 1, \dots, p$  in the second equation of [4], against the alternative that at least one of these coefficients differs from 0.

#### 4. Application on the term structure of interest rates of Spain

##### 4.1. The data set and the motivation of its use

The data correspond to the interest rates of the Spanish inter-bank money market between January 1986 and May 1995. There are several reasons why we have chosen this sample. On the one hand, Prats-Albentosa and Beyaert (1996) apply on these data a linear model of the type described by equation [3] which accepts the hypothesis for  $n=24$ , but rejects it for  $n=2,4$  and  $12$ ; the rejection is very strong in the case of  $n=2$  (two weeks)<sup>7</sup>; it is our purpose to check whether these conclusions change for  $n=2$  and  $n=4$  when a non-linear model of the type of [4] is adjusted, using [5] to test the theory. On the other hand, Spain joined the European Economic Union in January 1986 and entered the European Monetary Union (EMU) in January 1999; the entrance in EMU was far from automatic and intensive efforts were made in order to fulfil compulsory economic conditions imposed by the Maastricht Treaty; one of these conditions referred to the level of the market interest rates, which by May 1998 could not surpass the average of the three lowest interest rates of the EU by more than 1.5 percentage points; this requirement provoked very steep downward trends in all the Spanish interest rates in the years preceding the entrance in the EMU. In order to make sure that these exceptional circumstances did not interfere in any direction with the results of the tests, we preferred to exclude from the sample the data corresponding to the last years before the entrance of Spain in the EMU.

From an initial sample of daily observations, the data of the days 1,8,15 and 22 of each month were selected, as representative of the first, second, third and fourth week respectively. In this way, there are 4 observations per month and 48 observations per year<sup>8</sup>. Three different terms have been considered: one week, two weeks and four weeks (relative to the one-month rate). The short-term rate  $r_t$  is in all cases the one-week rate, the other two interest rates play the role

of the longer term rate  $R_t$ . The following spreads have thus been considered:

$$S_{t,n} = R_{t,n} - r_t \quad n = 2,4.$$

#### 4.2 The estimation results

Model [4] has been estimated for  $n=2$  and  $n=4$  by maximum likelihood methods in a 5-step algorithm, described for instance in Hamilton (1988) and Sola and Driffill (1994). The convergence of this algorithm and its speed is very much affected by the number of parameters to be estimated, as well as by the starting values. For this reason, the maximum value of  $p$  we have considered is 5 and the starting values have been determined applying the procedure of Beyaert and Perez-Castejon (2000).

##### 4.2.1 Specification tests and model selection

To check the empirical validity of the models, we applied specification tests that constitute bivariate extensions of those developed by Hamilton (1996). They are based on the scores of the likelihood function with respect to the parameters at time  $t$ : if the model is correctly specified, these scores must be uncorrelated between  $t$  and  $(t-1)$ . It can be shown that a test of correlation of the scores with respect to the elements of the mean vectors may be seen as a test of autocorrelation of the errors; by the same token, a test of correlation of the scores with respect to the variances can be seen as a test of generalized ARCH effect.<sup>9</sup> An illustration of the results of these tests is presented in Table 1, where we reproduce the results for the MS-VAR(1) case. The test statistics are joint tests corresponding in the first column to the scores with respect to all the means (16 pairs of parameters), and in the second column to the scores with respect to the variances (8 pairs of parameters). For that model, the absence of autocorrelation is accepted for both values of  $n$ : the test statistic

1  
2  
3  
4  
5  
6 stands below the  $\chi_{16}^2$  critical value; with only one lag, the first order dynamics of the data is  
7  
8 therefore adequately covered.  
9

10  
11  
12 Things are different for the second-order dynamics: there are clear symptoms of non modelled  
13 ARCH effects. However, it must be noted that the heteroskedasticity still present in these models  
14 is far below the heteroskedasticity detected in linear VAR models with the same data<sup>10</sup>.  
15  
16  
17

18  
19  
20 We used Schwartz criterion in order to select a model among those that do not present  
21 autocorrelation. With that procedure, a MS-VAR(1) model has been selected both for n=2 and  
22 n=4. It is interesting to note that when the linear model [3] had been adjusted to the same data,  
23 much higher values of p had to be considered.<sup>11</sup>  
24  
25  
26  
27

28  
29  
30 On these MS-VAR(1) models, we applied the Hansen (1992,1996) linearity test against the non-  
31 linear switching-regime specification. This test tackles the problem of the existence of  
32 unidentified parameters under the null hypothesis, which rules out the application of standard  
33 Likelihood Ratio tests. It requires Monte-Carlo simulations in every application, in order to obtain  
34 the critical value. For multivariate model, this computer-intensive procedure is extremely long.  
35 Usually, it is not carried out, except for simple single-equation models. In Table 2, we reproduce  
36 the value of this test for our MS-VAR(1) model. Based on 1000 simulations, the one percent  
37 critical value is below 40 for the two-week (n=2) model and below 35 for the one-month (n=4)  
38 model. As can be seen, the test statistics are far above these values, indicating the domination  
39 of the non-linear model [4] over the linear model [3].  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49

50  
51 Table 3 reproduces the estimated value of the parameters of model [4] for n=2, n=4 and p=1.  
52 Various parameters of this table seem to accept some type of restriction that might be worth  
53 taking into account in order to simplify the estimation and increase the efficiency. The means  
54 of both models seem in most cases to be equal in both states; some of them even seem to  
55  
56  
57  
58

1  
2  
3  
4  
5  
6 be equal to zero. Note that this is compatible with the constant premium of equations [2], as  
7  
8 well as with a stricter version of the rational expectations theory. Also, some of the  
9  
10 autoregressive coefficients seem to be non-significant. We tested these simplifying  
11  
12 restrictions, both jointly (all of them together) and separately (one at a time). When they were  
13  
14 accepted, we proceeded to re-estimate the model under the corresponding restrictions. The  
15  
16 results are presented in Table 4.a; in Table 4.b, we reproduce the corresponding Hamilton  
17  
18 specification tests. As can be seen in that table, for  $n=2$ , the results do not differ qualitatively  
19  
20 from those of the unrestricted model; for  $n=4$ , the null of no autocorrelation is now marginally  
21  
22 rejected at 5% but accepted at 2.5% and 1%.

23  
24  
25 Besides the simplification restrictions, there are two more aspects of the estimation process that  
26  
27 are worth mentioning. The probability  $p_{00}$  of staying in state 0 is high and systematically above  
28  
29  $p_{11}$ . This fact is reinforced by the relative size of variances: those of state 0 are small and far  
30  
31 below those of state 1. The former may be qualified as a “low-variance high-persistence stable  
32  
33 state”, whereas the latter would be more a “high-variance unstable state”.

#### 34 35 36 37 4.2..2 The smoothed probabilities

38  
39  
40  
41 From these estimations, the so-called “smoothed probabilities” may be inferred: on the basis of  
42  
43 the estimated vector of parameter and the full sample of  $T$  observations, an inference is drawn  
44  
45 about the historical state the process was in at some date  $t$ . These probabilities are shown in  
46  
47 Figure 1.a for the two-week simplified model, and in Figure 1.b for the one-month simplified  
48  
49 model. The probability of being in the stable state (state 0) is represented on the y-axis, and the  
50  
51 dates on the x-axis. An analysis of these graphs provides an additional proof of the usefulness of  
52  
53 the types of model used in this paper. A striking feature of these graphs refers to the much  
54  
55 higher stability of the market from the middle of 1989 onwards, with the exception of the period  
56  
57 extending from October 1992 to the third term of 1993. These dates coincide with specific events

1  
2  
3  
4  
5  
6 that affected the market: June 1989 is the date of the entrance of Spain into the European  
7  
8 Monetary System (EMS); the instability period of 92-93 coincides with the crisis of the EMS,  
9  
10 marked by the “monetary turmoil” of 1992, and the depreciation of the Peseta in September and  
11  
12 November of that same year and of May of 1993; the EMS crisis ended in August 1993 with the  
13  
14 enlargement of the fluctuation bands, although the monetary authorities purposely let the rates  
15  
16 increase to very high levels in the autumn of 1993. The short instability periods observable at the  
17  
18 beginning of 1991 are also attributable to known events: the overvaluation of the Peseta with  
19  
20 respect to the DM that called for increases in the interest rates, together with the Gulf war and  
21  
22 the political and economic instability in the East European countries were events that all created  
23  
24 tensions in the financial markets. As far as the first years of the graph are concerned, it is  
25  
26 interesting to note the instability discernible in the figures during the first half of 1987: it  
27  
28 corresponds to the serious liquidity crisis of the public system, with important frictions between  
29  
30 the monetary and exchange policies. The end of 1988 and beginning of 1989 is also  
31  
32 characterised by relative instability; it is well known that this was a period of expectations of high  
33  
34 interest rates that alters the markets. To sum up, the overall impression transmitted by these  
35  
36 graphs is that the model is able to perceive the characteristics of the market.

### 37 38 4.3 Testing the expectations theory

#### 39 40 41 42 4.3.1 Exact Rational Expectations Hypothesis

43  
44  
45  
46 The form and the complexity of the REH restrictions [5] vary substantially as a function of n  
47  
48 and p. For the models estimated in Section 4.2, the parameters n and p take the following  
49  
50 values: n= 2 and 4, p=1. The low value of p greatly simplifies the procedure. Note that when  
51  
52 p=1 we have indeed:

$$53  
54  
55 \mathbf{B}_{\bar{x}_t} = \mathbf{B}_{x_t}^{(1)} = \begin{pmatrix} a_{1,x_t} & b_{1,x_t} \\ c_{1,x_t} & d_{1,x_t} \end{pmatrix}$$

56  
57  
58 and we may omit the redundant superscript (1).

Moreover, when  $n=2$ , only one element intervenes in the sum of the right-hand side of [5], so that we have, for any value of  $p$ :

$$c_{1,x_t} = 2 \quad \forall x_t = 0,1 \quad [6.1]$$

$$c_{j,x_t} = 0 \quad \forall j = 2, \dots, p \text{ (for } p > 1), x_t = 0,1 \quad [6.2] \quad [6]$$

$$d_{j,x_t} = 0 \quad \forall j = 1, \dots, p, x_t = 0,1 \quad [6.3]$$

For further analysis it is useful to note that the restrictions [6.1] imply the same value of 2 for  $c_1$  in both states. It is easy to see that the specific value of 2 stems from the value of the (1,1) element of the matrix that pre-multiplies  $C^{(0)}$  in [5]; this element derives directly from the fact that the expectations theory as expressed in version [1] asserts that the long rate is a simple average of the present and future short rate when  $n=2$ :

$$R_{t,n} = \frac{1}{2}r_t + \frac{1}{2}E[r_{t+1} / H_t] + k \quad [7]$$

On the other hand, the fact that  $c_1$  takes the same value in both states is a consequence of the fact that the weights in the average [7] are state-independent.

For  $n=4$ , that is for the one-month model, when  $p=1$ , [5] transforms into 4 restrictions that can be written as:

$$(0, 3)B_{x_t} + (0, 2)E[B_{x_{t+1}} / x_t]B_{x_t} + (0, 1)E[B_{x_{t+2}} B_{x_{t+1}} / x_t]B_{x_t} = (4, 0) \quad \forall x_t = 0,1 \quad [8]$$

These restrictions are not as easily interpretable as in the case of  $n=2$ .

We tested [6] and [8] both in the unrestricted and in the simplified models; we tested also Granger causality from the spread  $S_t$  to  $\Delta r_t$  (the so-called "weak" restrictions). The results are reproduced in Table 5.a and 5.b.

1  
2  
3  
4  
5  
6 Table 5.a indicates for the two-week model that the “weak” implications of the expectations  
7 theory are strongly supported by the data, since the null hypothesis of no causality is strongly  
8 rejected. It is symptomatic that in the simplification process from the general unrestricted  
9 model to the simplified one, the only significant coefficients in the equation of  $\Delta r_t$  are  
10 precisely those associated with the spread, i.e. with Granger causality. As far as the “strong”  
11 implications of the expectations theory (restrictions [6]) are concerned, the results in Table  
12 5.b are quite different: these restrictions are strongly rejected by the data, both using a non-  
13 linear Wald test and a LR test. Note, however, that the rejection is entirely attributable to the  
14 requirement that  $c_{1,0} = c_{1,1} = 2$ , since the requirement that  $d_{1,0} = d_{1,1} = 0$ , checked in the  
15 simplification process of the model, is fulfilled. We therefore also tested  $c_{1,0} = c_{1,1}$  without  
16 imposing a common value of 2; this hypothesis is accepted at different probability levels  
17 depending on the version of the model and the test used (see Table 5.b).  
18  
19  
20  
21  
22  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32

33 For the one-month model ( $n=4$ ), global Granger causality from  $S_t$  to  $\Delta r_t$  is confirmed (see  
34 Table 5.a), although this result has to be qualified, since we have seen in the simplification  
35 process that  $S_{t-1}$  does not influence  $\Delta r_t$  in state 0, that is, in the stable state (see Table 4.a).  
36  
37 As far as the strong implications are concerned, these are rejected.  
38  
39  
40  
41  
42

#### 43 4.3.2 Rational Expectations Hypothesis with “measurement errors”

44  
45  
46  
47 It is often the case that the strict version of REH, as considered in the Section 4.3.1, is  
48 rejected, but a weaker version that makes allowance for a random error term in the REH  
49 relation is accepted. Hamilton(1988) provides a detailed justification of the existence of such  
50 a random error, which is often called “measurement error”. The existence of this  
51 measurement error is equivalent to assuming that the agents build their expectations for  
52  
53  
54  
55  
56  
57  
58  
59  
60

period  $t$  on the basis of the information relative to period  $(t-2)$ , instead of using information from period  $(t-1)$  as in the stricter (or “exact”) version of the theory.

The implication of this measurement error for the testing of the theory is that even with a MS-VAR of order 1 ( $p=1$ ), all the REH restrictions on the parameters will now be non-linear. No linear restrictions subsist. Although it is relatively easy to derive the *theoretical* expression of these new restrictions from what has been done for the case where no measurement errors are assumed, their *practical implementation* has to be reduced to small values of  $p$  and  $n$ . In Appendix B, it is shown that the restrictions to be satisfied and tested are now as given in [9] instead of [5]:

$$(-1, 0) \cdot C_{\bar{x}_t}^{(1)} + \sum_{j=2}^n \left( 0, 1 - \frac{j}{n} \right) C_{\bar{x}_t}^{(j)} = 0 \quad [9]$$

Due to the difficulty of their practical implementation, we applied them only on our two-week model, in which case  $n=2$  and  $p=1$ .

When  $n=2$ , [9] simplifies to:

$$\left( 0, \frac{1}{2} \right) C_{\bar{x}_t}^{(j)} = (1, 0) \cdot C_{\bar{x}_t}^{(1)}$$

With  $p=1$ , the right-hand side becomes:

$$(1, 0) \cdot C_{\bar{x}_t}^{(1)} = (1, 0) B_{\bar{x}_t} = (1, 0) B_{x_t}^{(1)} = (1, 0) B_{x_t}$$

where the redundant superscript (1) is omitted. Similarly, the left-hand side simplifies to:

$$\left( 0, \frac{1}{2} \right) C_{\bar{x}_t}^{(j)} = \left( 0, \frac{1}{2} \right) \sum_{x_{t+1}=0}^1 B_{x_{t+1}} B_{x_t} p_{x_t, x_{t+1}}$$

Thus, there are four restrictions to be tested that may be represented as

$$\left( 0, \frac{1}{2} \right) (B_0 B_{x_t} p_{x_t, 1} + B_1 B_{x_t} p_{x_t, 2}) - (1, 0) B_{x_t} = 0 \quad \forall x_t = 1, 2 \quad [10]$$

1  
2  
3  
4  
5  
6 The results of testing [10] in the two-week model are reproduced in Table 6. The upper part  
7 of that table corresponds to the original unrestricted model, whereas the lower part  
8 corresponds to the simplified model. In the simplified model, the simplifying restrictions  
9 coincide with three of the four restrictions included in [10]. So, only one REH restriction is left  
10 to be tested. Thus, with this simplified model, REH is in fact tested step by step. Given the  
11 inherent complexity of the model, this is in fact an advantage.  
12  
13  
14  
15  
16  
17  
18

19 According to the results of Table 6, three of the four REH restrictions are accepted at any  
20 conventional level of significance, while the fourth one is compatible with the data at least at  
21 a 2.5% level of probability. So, with the type of nonlinear Markov Switching model that we  
22 have used and assuming measurement errors (or that agents adjust their expectations with a  
23 lag of two periods), there are signs of reconciliation of the Rational Expectations Hypothesis  
24 with the data in the Spanish financial market.

## 5. Summary and Conclusions

In this paper, we obtain very general formulas to test the Rational Expectations Hypothesis in the term structure of interest rates in the framework of a Markov-switching VAR model. Our theoretical results cover not only the strict version of REH, but also the weaker one where so-called “measurement errors” affect the decision-making process of the economic agents.

Although our interest in this paper lies in testing REH for the term structure of interest rates, the formulas are extensible to other contexts whenever REH can be expressed as a present-value relationship. This is similar, in a Markov-Switching context, to what occurs with the Campbell-Shiller (1987) methodology in a linear framework.

We apply the theoretical results on Spanish weekly data of the inter-bank market, comparing the one-week interest rate with the two-week rate and with the one-month rate. The period extends from January 1986 to May 1995, mainly in order to avoid the exceptional evolution of the Spanish interest rates in the last years before the entrance of this country in the EMU. For these rates, the expectations theory had been overwhelmingly rejected in previous studies where linear VAR models were used. The estimation results and the specification tests indicate that the switching-regime models specified in this paper very strongly dominate the linear ones when applied to these data. This conclusion stems not only from the results of Hansen’s linearity test, but also from the fact that the data are represented with a smaller number of lags and with far fewer heteroskedasticity symptoms than in a linear model. The analysis of the “smoothed probabilities”, which provide information about the most probable state of the economy in each point in time, also indicates that the model correctly identifies the successive stability and instability periods through which the Spanish economy and the Spanish financial markets evolved between 1986 and 1995.

1  
2  
3  
4  
5  
6 As far as REH is concerned, it is rejected in its exact version although the weak conditions of  
7  
8 Granger causality from the spread to the interest differential are supported by the data. When  
9  
10 measurement errors are considered, that is, if we assume that the agents form their  
11  
12 expectations on the basis of what happened in the economy two periods ago, there is some  
13  
14 reconciliation of the REH theory with the data for the two-week model. For the one-month  
15  
16 model, REH with measurement errors is much more complex to test and has not been  
17  
18 considered so far.

19  
20  
21 In summary, according to our results, the hypothesis of linearity imposes severe  
22  
23 misspecifications on the models and might be responsible for excessive rejection of the  
24  
25 Rational Expectations hypothesis in the term structure of interest rates. A non-linear model  
26  
27 fits much better the data and provides some signs of fulfilment of the rational expectations  
28  
29 hypothesis in the term structure of the Spanish inter-bank interest rates.

## APPENDIX A

In order to obtain testable restrictions, let us operate as in Sola and Drifill(1994) and in Blix (1997).

In terms of our model, this theory is fulfilled if

$$S_{t,n} = \sum_{i=1}^{n-1} \left(1 - \frac{i}{n}\right) E[\Delta r_{t+i} / H_t] + \lambda_{\bar{X}_t} \text{ with } \bar{X}_t = (x_t, \dots, x_{t-p+1})$$

or alternatively

$$\sum_{j=0}^{n-1} N_j E(y_{t+j} / H_t) = \lambda_{\bar{X}_t} \quad \forall \bar{X}_t = (x_t, \dots, x_{t-p+1}) \quad [A.1]$$

with  $H_t = \{S_{t,n}, \dots, S_{t-p+1,n}, \Delta r_t, \dots, \Delta r_{t-p+1}, x_t, \dots, x_{t-p+1}\}$ ,  $y_t = (S_{t,n}, \Delta r_t)'$

$$\text{and } N_j = \begin{cases} (1,0) & j=0 \\ (0, \frac{j}{n} - 1) & \forall j=1, \dots, n-1 \end{cases}$$

In order to obtain the restrictions that equation [A.1] imposes on the parameters of model [4], it is useful to resort to the ‘‘companion form’’ of VAR model [4]. For that purpose, first define:

$$Y_t = (y'_t, \dots, y'_{t-p+1})'$$

Next, express  $Y_{t+j}$ ,  $j=1,2,\dots$  in terms of the centred variables that intervene in this model:

$$Y_{t+j}^c = (Y_{t+j} - \bar{\mu}_{\bar{X}_{t+j}}) \text{ with } \bar{\mu}_{\bar{X}_t} = (\mu'_{x_t}, \dots, \mu'_{x_{t-p+1}})' \text{ and } \mu_{x_t} = (\mu_{S,x_t}, \mu_{\Delta r,x_t})' \quad [A.2]$$

Define also the following vectors and matrices:

$$\mathbf{B}_{x_t}^{(j)} = \begin{pmatrix} a_{j,x_t} & b_{j,x_t} \\ c_{j,x_t} & d_{j,x_t} \end{pmatrix} \quad \forall j = 1, \dots, p$$

$$\mathbf{B}_{\bar{X}_t} = \begin{pmatrix} \mathbf{B}_{x_t}^{(1)} & \mathbf{B}_{x_{t-1}}^{(2)} & \dots & \dots & \mathbf{B}_{x_{t-p+1}}^{(p)} \\ \mathbf{I}_{2 \times 2} & \mathbf{0}_{2 \times 2} & \dots & \dots & \mathbf{0}_{2 \times 2} \\ \mathbf{0}_{2 \times 2} & \mathbf{I}_{2 \times 2} & \dots & \dots & \mathbf{0}_{2 \times 2} \\ \dots & \dots & \dots & \dots & \dots \\ \mathbf{0}_{2 \times 2} & \mathbf{0}_{2 \times 2} & \dots & \mathbf{I}_{2 \times 2} & \mathbf{0}_{2 \times 2} \end{pmatrix}_{2p \times 2p}$$

$$\mathbf{J} = (\mathbf{I}_{2 \times 2}, \mathbf{0}_{2 \times 2}, \dots, \mathbf{0}_{2 \times 2})_{(2 \times 2p)}$$

$$\mathbf{C}_{\bar{X}_t}^{(1)} = \mathbf{J} \cdot \mathbf{B}_{\bar{X}_t},$$

$$\mathbf{C}_{\bar{X}_t}^{(i)} = \mathbf{J} \cdot \left[ \sum_{x_{t+i-1}=0}^1 \dots \sum_{x_{t+1}=0}^1 \left( \prod_{m=1}^i \mathbf{B}_{\bar{X}_{t+i-m}} \right) \left( \prod_{m=0}^{i-2} p_{x_{t+m} x_{t+m+1}} \right) \right] = \mathbf{J} \cdot \mathbf{E} \left[ \prod_{m=1}^i \mathbf{B}_{\bar{X}_{t+i-m}} / \bar{X}_t \right] \text{ if } i \geq 2$$

Writing model [4] in ‘‘companion form’’ with the use of the coefficient matrix  $\mathbf{B}_{\bar{X}_t}$ , we obtain:

$$\mathbf{Y}_{t+j}^c = \mathbf{B}_{\bar{X}_{t+j-1}} \mathbf{Y}_{t+j-1}^c + \mathbf{J}' \cdot \mathbf{u}_{t+j}$$

For  $j=1$ , multiplying by  $\mathbf{J}$ , and transferring  $\mu_{x_{t+1}}$  to the right-hand side, we get:

$$y_{t+1} = \mu_{x_{t+1}} + \mathbf{J} \cdot \mathbf{B}_{\bar{X}_t} \mathbf{Y}_t^c + \mathbf{u}_{t+1} \quad [\text{A.3}]$$

For  $j>1$ , we obtain by recursion:

$$\begin{aligned}
Y_{t+j}^c &= B_{\bar{X}_{t+j-1}} (B_{\bar{X}_{t+j-2}} Y_{t+j-2}^c + J' u_{t+j-1}) + J' u_{t+j} \\
&= \prod_{i=1}^j B_{\bar{X}_{t+j-i}} \cdot Y_t^c + \sum_{h=1}^{j-1} \left( \prod_{i=1}^h B_{\bar{X}_{t+j-i}} \cdot Y_t^c \right) \cdot J' u_{t+j-h} + J' u_{t+j}
\end{aligned}$$

Again, multiplying by  $J$ , and transferring  $\mu_{x_{t+j}}$  to the right-hand side, we get:

$$y_{t+j} = \mu_{x_{t+j}} + J \cdot \prod_{i=1}^j B_{\bar{X}_{t+j-i}} \cdot Y_t^c + J \cdot \sum_{h=1}^{j-1} \left( \prod_{i=1}^h B_{\bar{X}_{t+j-i}} \cdot Y_t^c \right) \cdot J' u_{t+j-h} + u_{t+j} \quad \text{for } j > 1$$

[A.4]

We need the expressions of  $E[y_{t+j} / H_t]$ . For  $j=1$ , note that:

$$E[y_{t+1} / I_t, x_{t+1}, x_t, \dots, x_{t-p+1}] = \mu_{x_{t+1}} + J \cdot B_{\bar{X}_t} Y_t^c \quad \text{where } I_t = (y_t, y_{t-1}, \dots, y_{t-p+1})$$

Therefore:

$$E[y_{t+1} / H_t] = E[y_{t+1} / I_t, x_t, \dots, x_{t-p+1}] = \sum_{i=0}^{q-1} \mu_i p_{x_t, i} + J \cdot B_{\bar{X}_t} Y_t^c = \sum_{i=0}^{q-1} \mu_i p_{x_t, i} + J \cdot B_{\bar{X}_t} (Y_t - \bar{\mu}_{\bar{X}_t})$$

[A.5]

where  $q$  is the number of regimes (in our case,  $q=2$ ).

For  $j>1$ , proceeding similarly, we obtain:

$$E[y_{t+j} / I_t, x_{t+j}, \dots, x_t, \dots, x_{t-p+1}] = \mu_{x_{t+j}} + J \cdot \left( \prod_{m=1}^j B_{\bar{X}_{t+j-m}} \right) Y_t^c$$

Therefore:

$$\begin{aligned}
& E[y_{t+j}/H_t] = E[y_{t+j}/I_t, x_t, x_{t-1}, \dots, x_{t-p+1}] = \\
& = \sum_{i=0}^{q-1} \mu_i P(x_{t+j} = i/x_t) + J \cdot \left[ \sum_{x_{t+j}=0}^{q-1} \dots \sum_{x_{t+1}=0}^{q-1} \left( \prod_{m=1}^j B_{\bar{x}_{t+j-m}} \right) \right] P(x_{t+j-1}, \dots, x_{t+1}/x_t) Y_t^c \\
& = \sum_{i=0}^{q-1} \mu_i P(x_{t+j} = i/x_t) + J \cdot \left[ \sum_{x_{t+j-1}=0}^{q-1} \dots \sum_{x_{t+1}=0}^{q-1} \left( \prod_{m=1}^j B_{\bar{x}_{t+j-m}} \right) \right] P(x_{t+j-1}, \dots, x_{t+1}/x_t) (Y_t - \bar{\mu}_{\bar{x}_t})
\end{aligned}
\tag{A.6}$$

Separating the sums on  $\bar{\mu}_{\bar{x}_t}$  from those on  $Y_t$  and using a more compact notation, we may write, both for  $j=1$  and for  $j>1$ :

$$E[y_{t+j}/H_t] = A_{x_t}^{(j)} + C_{\bar{x}_t}^{(j)} \cdot \bar{\mu}_{\bar{x}_t} + C_{\bar{x}_t}^{(j)} Y_t \tag{A.7}$$

with  $A_{x_t}^{(1)} = \sum_{i=0}^{q-1} \mu_i P_{x_t, i}$  and  $A_{x_t}^{(j)} = \sum_{i=0}^{q-1} \mu_i P(x_{t+j} = i/x_t)$  for  $j>1$ .

Entering [A.7] in [A.1] and taking into account that  $E[y_t/H_t] = y_t = J \cdot Y_t$ , we obtain

$$N_0 \cdot J \cdot Y_t + \sum_{j=1}^{n-1} N_j \left[ A_{x_t}^{(j)} + C_{\bar{x}_t}^{(j)} \cdot \bar{\mu}_{\bar{x}_t} + C_{\bar{x}_t}^{(j)} Y_t \right] = \lambda_{\bar{x}_t}$$

Using the definition of  $N_j$ , reordering the elements and multiplying by  $-1$ , this can be expressed

as:

$$\left\{ \sum_{j=1}^{n-1} \left( 0, 1 - \frac{j}{n} \right) A_{x_t}^{(j)} + \sum_{j=1}^{n-1} \left( 0, 1 - \frac{j}{n} \right) C_{x_t}^{(j)} \bar{\mu}_{x_t} + \lambda_{x_t} \right\} + \left\{ \left[ (-1, 0) \cdot J + \sum_{j=1}^{n-1} \left( 0, 1 - \frac{j}{n} \right) C_{x_t}^{(j)} \right] Y_t \right\} = 0$$

[A.8]

The sum of terms in the first bracket refers to the restrictions on the term premium  $\lambda_{x_t}$ . The second bracket involves the implications of most interest, which correspond to the way in which the short and long rates have to be related dynamically with each other in order for the theory to be true. These implications are often called the “cross-equations” restrictions and we centre the testing on them.<sup>12</sup> For these restrictions to be true for any value of  $Y_t$  and any combination of past regimes  $X_t$ , it must be that:

$$(-1, 0) \cdot J + \sum_{j=1}^{n-1} \left( 0, 1 - \frac{j}{n} \right) C_{x_t}^{(j)} = 0 \quad [A.9]$$

which are the restrictions [5] in the core of the paper.

## APPENDIX B

As is well known, a weaker version of the expectation theory consists of accepting that the agents are affected in their decisions by measurement errors of different types (see among others Campbell and Shiller, 1987 and Sola and Driffill, 1994). As far as the testing is concerned, the existence of such errors amounts to assume that the agents use an information set that is lagged one period compared with what they would have used in absence of these errors. In other words, expression [A.1] has to be substituted by

$$\sum_{i=0}^{n-1} N_i E(y_{t+i} / H_{t-1}) = E[\lambda_{\bar{x}_t} / H_{t-1}] \quad [B.1]$$

which is equivalent to

$$\sum_{j=1}^n \tilde{N}_j E(y_{t+j} / H_t) = E[\lambda_{\bar{x}_{t+1}} / H_t] \quad [B.2]$$

with  $\tilde{N}_1 = (1, 0)$  and  $\tilde{N}_j = (0, \frac{j-1}{n})$ ,  $\forall j \geq 2$

The expression for  $E(y_{t+j} / H_t)$  in terms of the coefficients of the model has already been obtained in Appendix A (see [A.6]) and that is all what we need to specify the restrictions on the dynamics of the short and the long rate that would substitute [5] (or equivalently [A.9]). Therefore, applying to [B.2] the same reasoning as to [A.1] in Appendix A, it results that the restrictions with measurement errors are:

$$(-1, 0) \cdot C_{X_t}^{(1)} + \sum_{j=2}^n \left(0, 1 - \frac{j}{n}\right) C_{X_t}^{(j)} = 0 \quad [B.3]$$

Fig 1b: Simplified one-month VAR(1) model

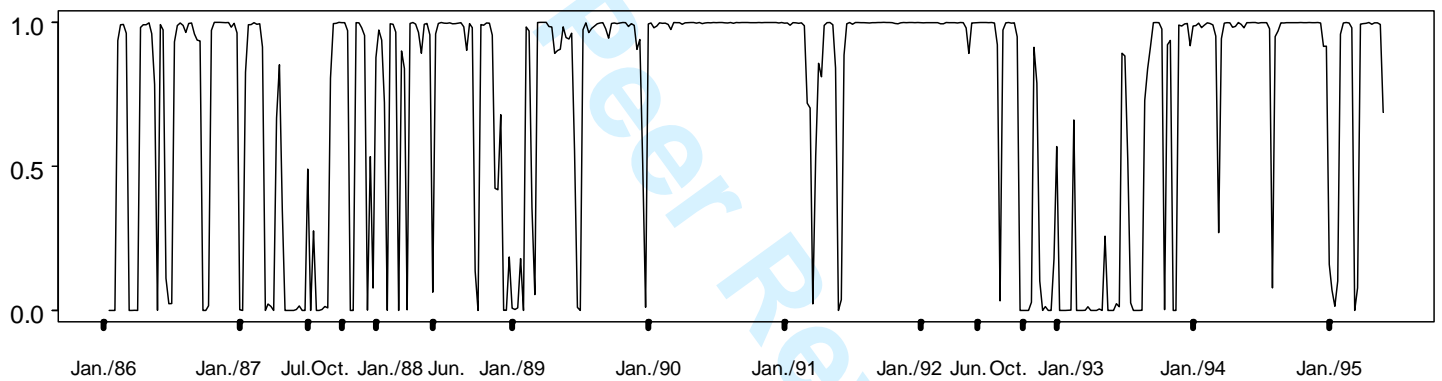

Figure 1: Smoothed probabilities for the Spanish data

<sup>1</sup> Bansal and Zhou (2002) also make use of Markov-switching model but in a different approach: they introduce a two-state MS process in the Cox-Ingersoll-Ross Model for the term structure and obtain strong empirical support for their model but do not test the expectations hypothesis. Other papers using Markov-switching models in relation with the term structure of interest rates are Ang and Bekaert (2005) and Tillmann (2005). These papers confirm the utility of the Markov-switching approach and its relation with the stance of monetary policy, but do not test REH.

<sup>2</sup> See for instance Prats Albentosa and Beyaert (1998)

<sup>3</sup> See for instance Campbel and Shiller(1987) and Prats-Albentosa and Beyaert (1998)

<sup>4</sup> The subscript  $n$  on  $S_t$  has been eliminated to simplify the notation. In what follows, it will be used only when necessary to avoid confusion.

<sup>5</sup> Kirikos (1996) considers a theoretical model of these characteristics, for the study of the exchange rate determination. However, at the estimation stage, he simplifies it down to a static non-autoregressive model, in which only the mean and the variance-covariance matrix is allowed to vary between states.

<sup>6</sup> Moreover, both options give rise to models with exactly the same total number of parameters. So there is no inferential reason to prefer one or another model, either.

<sup>7</sup> Prats-Albentosa and Beyaert (1998) obtain the same conclusions but with a shorter sample, which stops in 1992 .

<sup>8</sup> The weekly rates have been converted into rates of instantaneous capitalisation, in order to allow the comparison between interest rates of different terms.

<sup>9</sup> See Hamilton(1996) and Beyaert and Perez-Castejón(2000) for details.

<sup>10</sup> See Prats Albentosa and Beyaert (1998)

<sup>11</sup> See Prats Albentosa and Beyaert (1998)

<sup>12</sup> Obviously, it would be interesting to test also the restrictions on the premium ; given the difficulty that testing only [A.9] entails in the type of non-linear models that we are considering; this is left for

future research. Note however that a rejection of [A.9] implies a rejection of the theory, whereas an acceptance of [A.9] means that the data are compatible with the theory.
