Running Title: R. Crespo, TFP/Unobserved Components

Abstract

This work examines the presence of unobserved components in the time series of Total Factor Productivity, which is an idea central to modern Macroeconomics. The main approaches in both the study of economic growth and the study of business cycles rely on certain properties of the different components of the time series of Total Factor Productivity. In the study of economic growth, the Neoclassical growth model explains growth in terms of technical progress as measured by the secular component of Total Factor Productivity. While in the study of business cycles, the Real Business Cycle approach explains short-run fluctuations in the economy as determined by temporary movements in the production function, which are reflected by the cyclical component of the time series of the same variable. The econometric methodology employed in the estimation of these different components is the structural time series approach developed by Harvey (1989), Harvey and Shephard (1993), and others. An application to the time series of Total Factor Productivity for the 1948-2002 U.S. private non-farm business sector is presented.

1. Introduction

The seminal work of Solow's (1957), which derives a methodology to measure technological progress, has been of major importance in Macroeconomics. First, in the growth literature it has become the basis for an extensive theoretical body on growth accounting that tries to quantify the sources of economic growth. Second, the main approach in the study of business cycles, the Real Business Cycle approach, assumes technological innovations (measured by Solow's procedure) as the main driving force of short-run fluctuations in the economy, and employs it in the simulations of quantitative models. And third, as it is believed that technological progress is an important source of economic growth many researchers have attempted to explain it as the endogenous outcome of economic decisions, which has served as the basis of a new body of literature on endogenous economic growth.

Although the main approach in both the study of economic growth and business cycles relies on the time series behaviour of the same variable, technological progress, their interest is focused on different components of the series. Hence, in the study of economic growth the attention is centred on the pattern described by the non-stationary part of the series (which can keep steady, speed up or slow down), while in the study of business cycles, the interest is on the stationary part of this series. This distinction is commonly ignored in the empirical estimation of technical progress, which sometimes could have important effects on our conclusions about the pattern displayed by the secular component of the variable over time.

In this work the presence and characterisation of unobserved components in the time series of Total Factor Productivity is examined. The structure given to the paper is the following: in Section 2 a brief description of the methodology derived by Solow (1957) is presented, and some changes to the specification of the production function are introduced in order to give an explicit account of the different components of the series in accordance with the main approaches in the study of economic growth and the business cycle. In Section 3 the econometric methodology employed to get the estimates of the different components of the time series of technological progress is described. Section 4 shows the empirical results obtained in the analysis of Total Factor Productivity in the U.S. economy under this methodology. Finally, Section 5 presents the conclusions of the paper.

2. Theoretical Background

In the Growth Accounting literature, observed economic growth is partitioned into components associated with factor accumulation and a residual that reflects technical progress and other elements. This breakdown of the rate of growth of aggregate output into different components has its foundation in the pioneering work of Solow (1957). In this work, Solow derives a measure of technical progress, and shows how to employ it to correct the estimation of the production function. He starts with the Neoclassical production function¹

$$Y(t) = F(K(t), L(t), A(t)) \quad (2.1)$$

¹ By Neoclassical production function, we mean that the function is concave, twice continuously differentiable, satisfies the Inada (1964) conditions and that both factors are essential in production.

where $Y(t)$ is the flow of output produced at time t , $K(t)$ is the physical capital stock accumulated at time t , and $L(t)$ is the labour input at time t . The production function also depends on $A(t)$, the level of technology, and the notation makes explicit that it varies with time. Taking total (logarithmic) differential of equation (2.1) and dividing through by Y yields,

$$\frac{\dot{Y}}{Y} = g + \left(\frac{F_K \cdot K}{Y} \right) \left(\frac{\dot{K}}{K} \right) + \left(\frac{F_L \cdot L}{Y} \right) \left(\frac{\dot{L}}{L} \right) \quad (2.2)$$

where F_K and F_L are the factor (social) marginal products, and g (technical progress) is given by

$$g \equiv \left(\frac{F_A \cdot A}{Y} \right) \left(\frac{\dot{A}}{A} \right) \quad (2.3)$$

Solow assumed technological change to be Hicks-Neutral, so that it could be factored out of the production function in the following way²,

$$Y(t) = A(t)F(K(t), L(t)) \quad (2.4)$$

In this particular case technological change would be given by

²By assuming Hicks-Neutral technological change, as stated by Solow (1957, p. 312), shifts in the production function “leave marginal rates of substitution untouched but simply increase or decrease the output attainable from given inputs”.

$$g = \frac{\dot{A}}{A} \quad (2.5)$$

Equation (2.2) suggests that the rate of growth of real output can be decomposed into the growth rates of capital and labour, weighted by their output elasticities, and the rate of growth of technical progress. Consequently, the rate of technical progress can be obtained from this equation as a residual,

$$g = \frac{\dot{Y}}{Y} - \epsilon_K \cdot \frac{\dot{K}}{K} - \epsilon_L \frac{\dot{L}}{L} \quad (2.6)$$

where ϵ_K is the output elasticity with respect to capital and ϵ_L is the output elasticity with respect to labour. In practice, as these elasticities are not observable, to compute technical change researchers usually assume that each input is paid their (social) marginal products, so that $F_K = r$ (the rental price of capital) and $F_L = w$ (the wage rate). This substitution allows the rate of change of technical progress to be expressed in terms of observable income shares as

$$\hat{g} = \frac{\dot{Y}}{Y} - s_K \cdot \frac{\dot{K}}{K} - s_L \cdot \frac{\dot{L}}{L} \quad (2.7)$$

where s_K and s_L are the respective shares of each factor payment in total output, and \hat{g} is often described as an estimate of Total Factor Productivity (TFP) or the Solow residual.

1
2
3
4
5
6 Solow made it explicit that in applied work the residual would pick up any factor
7
8 shifting the production function. However, he labelled it technical progress under the
9
10 presumption that technological change would be the main influence being captured by it.
11
12 He found some ground for this assertion in his estimates of the factor $A(t)$ for the US
13
14 economy, which showed a strong upward trend during the period 1909-1949.³
15
16
17
18
19

20 The production function specified by Solow (1957) to measure technological
21
22 progress is the same specification given to the production function in the Solow-Swan
23
24 model or Neoclassical model of economic growth. In this model the factor $A(t)$ is
25
26 introduced in the production function in order to enable the modelled economy to
27
28 reproduce the observed pattern of some macroeconomic variables that register growth in
29
30 per capita terms over the years. Therefore, the specification of the production function is
31
32 intended to pick up those driving forces that bring about economic growth under the
33
34 Neoclassical model of economic growth. It is important to notice, however, that such a
35
36 specification for the production process does not provide an explicit account of any other
37
38 forces that drive short-run fluctuations in the economy as those ones claimed by the Real
39
40 Business Cycle approach. From this perspective, a more appropriate specification for the
41
42 production process seems to be one that explicitly distinguishes those forces that drive
43
44 economic growth from those associated with business cycles.
45
46
47
48
49
50
51
52
53
54
55

56
57 ³ A negative trend in $A(t)$ would imply the unreasonable case of technical regress, something that would
58 have discouraged Solow from writing his paper (see, Solow 1957, p.316).
59
60

1
2
3 In modern Macroeconomics the production function is specified in such terms
4 that it is allowed to pick up forces that drive both economic growth and business cycles,
5
6 and it is described as follows
7
8
9

$$Y(t) = \lambda(t)F(K(t), L(t), A(t)) \quad (2.8)$$

10
11
12
13
14
15
16
17

18 Here the production process is similar to that one specified in equation (2.1)
19 except that there is an explicit account of *temporary* changes in the production function
20 through a random variable $\lambda(t)$, while *secular* improvements in technology are measured
21 by $A(t)$. Hence, the production function establishes a clear distinction between forces that
22 drive economic growth from those that drive short-run fluctuations.⁴
23
24
25
26
27
28
29
30
31

32 In the economic growth literature the specification given to the production
33 process ignores the term $\lambda(t)$, while in the business cycle literature growth is omitted or it
34 is simply started with a transformed economy.⁵ Therefore, $\lambda(t)$ and $A(t)$ stand for
35 processes whose driving forces are completely different, and consequently they require
36 different specifications. In the business cycle literature $\lambda(t)$ is commonly described as a
37 stationary process, which displays considerable serial correlation, with first-differences
38 nearly serially uncorrelated, while in the economic growth literature $A(t)$ is usually
39 specified as a non-stationary process that can be expressed either as a trend-stationary
40
41
42
43
44
45
46
47
48
49
50
51

52
53
54 ⁴ This specification is found in papers such as King, Plosser and Rebelo (1988) and King and Rebelo (1999).

55
56 ⁵ In the analysis of business cycles, models with steady state growth are transformed into stationary economies. This transformation is introduced to the Neoclassical growth model by scaling all the trending variables by the growth component $A(t)$.
57
58
59
60

process or a difference-stationary process. Even though economists have considered it appropriate to separate these different processes according to the subject of study (i.e. economic growth or short-run fluctuations), it seems clearly inappropriate to ignore them in an empirical estimation of technological progress. For that reason, if equation (2.8) is employed and the same reasoning is carried out as before, we arrive at an expression for TFP for the particular case of Hicks-Neutral technological change given by

$$\hat{g} = \frac{\dot{\lambda}}{\lambda} + \frac{\dot{A}}{A} = \frac{\dot{Y}}{Y} - s_K \cdot \frac{\dot{K}}{K} - s_L \cdot \frac{\dot{L}}{L} \quad (2.9)$$

Equation (2.9) establishes an explicit distinction between fluctuations of the production function that occur in the short-run from those of a more permanent nature such as technological progress. This discrepancy between TFP and changes in technology, which is commonly ignored in the growth accounting literature, is the one that will be addressed in this paper by employing the structural time series approach.

3. Econometric Methodology

The econometric methodology employed in this paper is the structural time series approach developed by Harvey (1989) and Harvey and Shephard (1993), which builds on early work such as Nervole, Grether and Carlvalho (1979). The essence of this approach is to set up a model, which regards the observation as being made up of a trend (or permanent) component and an irregular (or temporary) component. Consequently, structural time series models are nothing more than regression models in which the explanatory variables are functions of time and the parameters are time varying. The

estimation is conducted by setting the model in state space form, with the state of the system representing the various unobserved components. In the case of linear models, the Kalman filter is employed, which provides the means of updating the state as new observations become available.⁶

The simplest structural time series model, usually referred to as the *local level model*, is given by a trend component and an irregular term, which is a white noise process. The model can be written in the following way,

$$y_t = \mu_t + \varepsilon_t \quad t = 1, 2, \dots, T \quad (3.1)$$

where y_t is the observed value, μ_t is a trend and ε_t is a white noise disturbance term, that is, a sequence of serially uncorrelated random variables with constant mean, in this case zero, and constant variance, σ_ε^2 . The trend component, μ_t , may take a variety of forms, the simplest being a level that fluctuates up and down according to a random walk

$$\mu_t = \mu_{t-1} + \eta_t \quad t = \dots, -1, 0, 1, \dots \quad (3.2)$$

where η_t is a white noise disturbance with variance σ_η^2 , which is uncorrelated with the stochastic term ε_t . No starting value needs to be specified for μ_t since it is assumed to have started at some point in the remote past.

⁶ A thorough discussion of the methodological and technical ideas underlying this approach is found in Harvey, A. (1989).

An alternative specification for the trend component is the following

$$\begin{aligned}\mu_t &= \mu_{t-1} + \beta_{t-1} + \eta_t \\ \beta_t &= \beta_{t-1} + \zeta_t\end{aligned}\quad t = \dots -1, 0, 1, \dots \quad (3.3)$$

where η_t and ζ_t are mutually uncorrelated white noise disturbances with zero means and variances σ_η^2 and σ_ζ^2 , respectively. Together, (3.1) and (3.3) form what is often referred to as the *local linear trend model*. The effect of η_t is to allow the level of the trend to shift up and down, while ζ_t allows the slope to change. The longer the variances the greater are the stochastic movements in the trend. We should notice that the trend specification given in (3.3) nests different processes such as, the random walk with drift trend ($\sigma_\zeta^2 = 0$) and the deterministic linear trend ($\sigma_\eta^2 = \sigma_\zeta^2 = 0$).

A cycle can be introduced to (3.1) in order to formulate a model more in line with economists' traditional view that the movements of an annually recorded time series for a macroeconomic variable are determined by a trend component, a cyclical component and a noise component. Formally,

$$y_t = \mu_t + \psi_t + \varepsilon_t \quad t = 1, \dots, T \quad (3.4)$$

where ψ_t is the cyclical component that is a function of time, and the other components have been specified above. Modelling the cyclical process takes the form

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho \begin{bmatrix} \cos \lambda & \sin \lambda \\ -\sin \lambda & \cos \lambda \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} \omega_t \\ \omega_t^* \end{bmatrix} \quad (3.5)$$

where ω_t and ω_t^* are uncorrelated white noise disturbance terms with variance σ_ω^2 and $\sigma_{\omega^*}^2$, respectively, and ψ_t^* appears by construction in order to form ψ_t . The disturbance terms make the cycle stochastic rather than deterministic. The parameter $0 \leq \lambda \leq \pi$ is the frequency of the cycle, which is measured in radians. The period of a cycle corresponding to a frequency of λ is $2\pi/\lambda$ years. The coefficient $0 \leq \rho \leq 1$ is a damping factor on the amplitude of the cycle. If $0 < \rho < 1$ the process is a damped sine or cosine, wave. While if $\rho = 1$ the process is again a sine or cosine wave, but no damping movement is present. A single equation for ψ_t can be obtained by writing the model as

$$\psi_t = \frac{(1 - \rho \cos \lambda L)\omega_t + (\rho \sin \lambda L)\omega_t^*}{1 - 2\rho \cos \lambda L + \rho^2 L^2} \quad (3.6)$$

where L is the lag operator. Equation (3.6) shows that the process described by ψ_t is an ARMA(2,1), which becomes an AR(2) whenever $\sigma_\omega^2 = 0$. A final point to note is that the stochastic cycle collapses to an AR(1) process when $\lambda = 0$ or π .

In the model described by equation (3.4) the cycle is introduced by adding it to a trend component and an irregular component. Such a model is usually referred to as the *trend plus cycle model*. An alternative way of introducing a cycle is by incorporating it into the trend. This specification is usually known as the *cyclical trend model*. In this case, trend and cycle are not separable, and the model can be formally written as

$$y_t = \mu_t + \varepsilon_t \quad t = 1, 2, \dots, T \quad (3.6)$$

$$\beta_t = \beta_{t-1} + \zeta_t \quad t = \dots, -1, 0, 1, \dots$$

$$\mu_t = \mu_{t-1} + \psi_{t-1} + \beta_{t-1} + \eta_t$$

The trend plus cycle model (3.4) and the cyclical trend model (3.6) are the most important formulations of structural time series models that exhibit cyclical process.

4. Empirical Results

In this section the empirical results of the paper will be presented. The time series to be analysed is the widely cited measure of Total Factor Productivity for the U.S. economy produced by the Bureau of Labour Statistics (BLS).⁷ Figure 1 shows the annually recorded TFP series in logarithmic terms for the period 1948-2002.

The series computed by the BLS uses for real output the national accounting data from the Bureau of Economic Analysis (BEA). The private non-farm business sector includes all of gross domestic product except the output of general government, government enterprises, non-profit institutions, the rental value of owner-occupied real estate, the output of paid employees of private households, and farms from the private business sector, but includes agricultural services. The output index, which is supplied by BEA, is computed as chained superlative index (Fisher Ideal Index) of components of real output, and then adjusted by the BLS. Labour input is obtained by Tornqvist-aggregation of the hours at work by all persons, classified by education, work experience, and gender with weight determined by their shares of labour compensation. Finally, the capital input measures the services derived from the stock of physical assets and software. The assets included are fixed business equipment, structures, inventories and land. The BLS produces an aggregate input measure obtained by Tornqvist aggregation of the capital stock of each asset type using estimated rental prices.⁸

The U.S. TFP series has been widely analysed and a growing body of research has emerged around it. Among the most salient and well-known features of the series are the patterns of productivity slowdowns after 1973, which has been associated by some researchers with the oil price shocks of the 1970s, and rebounds after 1995. Additionally, it has been recognised that TFP tends to move pro-cyclically; in periods of economic expansion, TFP is unusually large, while during recessions, it is low or even negative.

⁸ More detailed information on methods, limitations, and data sources is provided BLS Bulletin 2178 (September 1983), "Trends in Multifactor Productivity, 1948-81".

In the economic literature there are very few cases of an explicit treatment of the presence of different components in the TFP series. An exception to this is found in King and Rebelo (1999), where the productivity series is specified in terms of two components; a trend which is assumed to be linear and deterministic, and a cyclical component which follows an first-order autoregressive process, AR(1). Employing quarterly data of TFP for the U.S. economy during the period 1947 (first quarter) to 1996 (fourth quarter) they fit a linear trend to the series, and then use the residuals to estimate an AR(1) model –the resulting point estimate of the persistence parameter is 0.979. It is this decomposition of the TFP series that is addressed in this work, but by employing a formal econometric methodology in the specification process in order to get estimates of the different components of the series and to determine their main characteristics.

In order to narrow down the number of suitable structural time series models for the U.S. TFP series some statistics have been computed, which provide additional information in relation to the main characteristics of the different components of the variable. In relation to the trend of the variable, unit root tests can provide a valuable insight into the presence of either a deterministic or stochastic secular component in the series.

To determine whether or not the U.S. TFP series is characterised by having a unit root in their autoregressive representations, a modified Augmented Dickey-Fuller test (hereafter ADF-GLS[†]) developed by Elliot, Rothenberg and Stock (1996), which has

1
2
3 difference-stationary [or I(1)] as the null hypothesis will be employed. An important
4
5 property of this test is that it has more power than the original ADF tests, and is
6
7 approximately uniformly most power invariant. Similarly, a second test that is a version
8
9 of the Kwiatkowski, Phillips, Schmidt and Shin (1992) tests developed by Leybourne and
10
11 McCabe (1994), which has trend-stationary [or I(0)] as the null hypothesis [hereafter
12
13 KPSS(LM)] will be conducted.
14
15
16
17
18
19

20 The KPSS(LM) results will be used to corroborate the information obtained by
21
22 applying the ADF-GLS^τ test, and vice versa. Consequently, if the ADF-GLS^τ test rejects
23
24 the unit root hypothesis and the KPSS(LM) test fail to reject the stationary null
25
26 hypothesis then, these results will be considered as strong evidence in favour of a trend-
27
28 stationary process. By contrast, if the ADF-GLS^τ test fails to reject the null hypothesis
29
30 but the KPSS(LM) rejects it, we will consider this as strong evidence supporting the view
31
32 of the presence of a difference-stationary process. If both tests fail to reject their
33
34 respective null hypothesis then, it will be considered that the data does not contain
35
36 sufficient information to discriminate between these two kinds of processes.⁹
37
38
39
40
41
42
43

44 Null specific critical values for the ADF-GLS^τ tests using a preferred difference-
45
46 stationary specification following the approach specified by Cheung and Chinn (1997)
47
48 have been generated.¹⁰ Similarly, for the KPSS(LM) tests null specific critical values
49
50
51

52
53 ⁹ In cases where both tests reject their respective null hypothesis, as argued by Cheung and Chinn (1997), it
54
55 might be an indication that the data generating mechanism is more complex than that captured by standard
56
57 linear time series models.

58 ¹⁰ Cheung and Chinn (1997) generate null specific critical values using a selected difference-stationary
59
60 specification, which is chosen from models with lag parameters p and q ranging from 0 to 5 using the BIC
statistic.

using a preferred trend-stationary specification following the procedure suggested in Leybourne and McCabe (1996) have been computed.¹¹ In Table 1 the ADF-GLS^τ statistic and the KPSS(LM) statistic together with their associated 10%, 5% and 1% critical values for the U.S. TFP series are presented.

TABLE 1

In the first row of Table 1 the results obtained from applying the ADF-GLS^τ test is shown. It is possible to see that the actual statistic is well below the rejection area of the null hypothesis of a unit root. Additionally, in the second row of the table the results of the KPSS(LM) tests is presented. According to this result there is a clear rejection of the null hypothesis of a trend-stationary process as it is rejected at a 1% significant level. Based on the results obtained in both the ADF-GLS^τ tests and the KPSS(LM) tests we find strong evidence to disregard the possibility of having a deterministic linear trend in the times series of the TFP series for the U.S. economy.

It is known that unit root tests are sensitive to the presence of structural breaks in a series. Perron (1989) demonstrated that when there are structural changes in a series the standard tests for unit root hypothesis against the trend-stationary alternatives are biased towards the non-rejection of a unit root. Considering this possibility structural change tests following the methodology suggested by Perron (1997) have been conducted.

¹¹ Leybourne and McCabe (1996) generate null specific critical values by fitting an ARIMA (p,1,1) model with p set initially at 5, and then reducing it to 4 if the statistic $z(p=5) = |T^{1/2} \hat{\varphi}_5 \hat{\theta}| < 1.645$, and so on. Once the value of p has been determined a preferred trend-stationary description is obtained by re-estimating an ARIMA (p,0,0) model with a time trend.

Perron's technique consists of examining the likelihood of three different kinds of changes in the structure of a series: one that permits an exogenous change in the level of the series (Model A), one that allows an exogenous change in the slope (Model B), and finally one that considers changes in both level and slope (Model C).¹² Table 2 shows the results obtained by conducting structural break tests on the time series of the U.S. TFP.

TABLE 2

The table above shows those years in which the t-statistics of the null hypothesis of a unit root were found to be the highest in absolute value. For both models, the one that allows a change in level and the one that allows a change in level and slope, the suggested time break was at the early 1960s, while for the model with an exogenous change in slope the time break was at the beginning of the 1970s. The critical values were obtained from Perron's tables (1997) with a sample size selected according to the one that is closest to the size of the series under study. As can be seen from the table the tests fail to reject the null hypothesis of a unit root at 10% significant level for all the specifications. Consequently, these results seem to corroborate the absence of a deterministic linear trend in the time series of TFP in the U.S. economy.

In order to evaluate the possibility of the presence of a cyclical component in the U.S. TFP series some descriptive statistics such as the correlogram and the power

¹² Perron's (1997) methodology involves estimating the regressions for the three models for all possible break points, and selecting that point where the t-statistic of the null hypothesis of a unit root is the highest in absolute value.

spectrum can provide useful information. Figure 2 presents the estimates of these statistics for the series in first-differences (i.e. the U.S. TFP rate of growth).

FIGURE 2

The correlogram shows small individual autocorrelations not providing strong evidence of the presence of cyclical movement in the series, although there seems to be some evidence of cyclical movement buried with noise. However, a much clearer message emerges from the examination of the power spectrum, which shows what appears to be a cycle with a period between 6 to 7 years, and the possibility of additional cyclical movements.¹³

Based on the information gathered by conducting unit root tests and the descriptive statistics employed to evaluate the presence of cyclical movements in the series, some likely specification for the trend and the cyclical components of a structural time series model for the data have been estimated.¹⁴ Table 3 shows some basic diagnostic and goodness-of-fit statistics for these different structural time series models.

TABLE 3

All these models assume the presence of a trend, two cycles and an irregular component. The table shows diagnostic and goodness-of-fit statistics for three structural

¹³ On this graph the period is obtained as 2 divided by the frequency.

¹⁴ Structural time series models were estimated using the econometric software Stamp 5.0.

1
2
3 time series models with different specifications for the trend or secular component of the
4 series. The first statistical specification assumes that the trend component follows a
5 random walk with drift, which is specified by employing equation (3.3) and a
6 deterministic slope (i.e. $\sigma_{\zeta}^2 = 0$). The second statistical specification for the long-run
7 component is a variant of the local linear trend model, which introduces a somewhat
8 smoother trend by employing equation (3.3) with a deterministic level (i.e. $\sigma_{\eta}^2 = 0$) and a
9 stochastic slope. Finally, the last specification for the long-run component is the local
10 linear trend model, which stipulates the level and the slope to be stochastic (i.e. equation
11 3.3).

28 Diagnostic checking tests are conducted by computing the Box-Ljung $Q(p,q)$
29 statistic for serial correlation, which is based on the first p residual autocorrelations and
30 tested against a χ^2 distribution with q (i.e. $p + 1$ minus the number of estimated
31 parameters) degree of freedom. A simple diagnostic test for heteroskedasticity $H(h)$,
32 which is the ratio of the squares of the last h residuals to the squares of the first h
33 residuals, where h is set to the closer integer of $T/3$. This statistic is compared with the
34 appropriate significant point of an F distribution with (h,h) degrees of freedom.

47 The Prediction Error Variance (P.E.V.), the coefficient of determination (R_D^2) and
48 the information criteria (Akaike Information Criterion, AIC, and Bayesian Information
49 Criterion, BIC) provide the goodness-of-fit statistics. The Prediction Error Variance is the
50 variance of the one-step-ahead prediction errors in the steady state. These statistics have
51 been employed to compute the information criteria, which are the appropriate statistics to
52
53
54
55

59
60

1
2
3 compare models that have different numbers of parameters.¹⁵ The coefficient of
4
5 determination, R_D^2 , is the statistic recommended by Harvey (1989, chapter 5), which
6
7 enables the fit of the estimated model to be compared directly to a random walk with
8
9 drift. For $0 < R_D^2 \leq 1$ the model is giving a better fit than the random walk with drift; for
10
11 $R_D^2 = 0$ the fit is the same; while for $R_D^2 < 0$ the fit of the model is worse than the random
12
13 walk with drift. Table 1 also presents information related to the Log-Likelihood.

33 **FIGURE 3**

34
35
36
37 From the figure above it can be seen how the secular component of technological
38
39 progress has evolved over the years. The estimates of this component suggest that
40
41 technological progress slows down in the U.S. economy long before the oil price shocks
42
43 of the 1970s. Technological progress seems to have reached a peak at the beginning of
44
45 the 1960s when it starts to slow down until early 1980s to rebound then after. The
46
47 estimated standard error of the disturbances driving the slope (σ_ζ) is 0.0026. For the
48
49 cyclical component the model suggests the presence of two cycles with frequencies
50
51
52
53
54

56
57 ¹⁵ The information criteria have been computed using the procedure suggested in Harvey (1989), pp.269-
58 270.
59
60

1
2
3 $\lambda_1 = 0.979$ (6.42 years period) and $\lambda_2 = 0.535$ (11.74 years period). The estimate of ρ
4
5
6 for the first cycle is 0.810, while for the second cycle it is 0.998, which is very close to 1
7
8 indicating the presence of a deterministic cycle. The estimated standard errors of the
9
10 disturbances driving these two cycles are 0.0068 and 0.0006, respectively. Finally, the
11
12 irregular component seems to be the most volatile part of the model with an estimated
13
14 standard deviation of 0.0075.
15
16

17
18
19
20 An important issue to address at this stage is to compare the results
21
22 obtained in the study of the U.S. TFP series with those of the U.S. real output series. If
23
24 business cycles are mainly driven by short-run fluctuations in the production function, as
25
26 it is claimed by the Real Business Cycles approach, then we should expect close
27
28 similarities between the cyclical movements shown by the TFP series with those shown
29
30 by the real output series. Similarly, if the secular component of the TFP series drives
31
32 economic growth, then it should be found that both the TFP series and the real output
33
34 (per labour) series share a single common trend. In order to compute the correlogram and
35
36 the spectrum of the real output series it is important to determine the main characteristic
37
38 of the trend to conduct the proper de-trending procedure. In Table 4 the ADF-GLS[†]
39
40 statistic and the KPSS(LM) statistic together with their associated 10%, 5% and 1%
41
42 critical values for the U.S. real output series are presented.¹⁶

60

In the table above it is possible to observe that the ADF-GLS[†] statistic is below the rejection area as it is not possible to reject the null hypothesis of the presence of a unit root in the real output series at 5% significant level. Additionally, the results obtained by conducting the KPSS(LM) test does not allow the rejection of the null hypothesis of a trend stationary process either. Therefore, we should conclude that for the time series of real output in the U.S. economy the data does not contain sufficient information to discriminate between a difference-stationary process and a trend-stationary process.

As in the U.S. TFP series, structural change tests have been conducted on the U.S. real output series. Table 5 shows the results obtained from these tests.

TABLE 5

Interestingly, the results shown by the table above indicate likely time breaks similar to those obtained in the examination of the U.S. TFP series. However, as in the case of the U.S. TFP series, the tests fail to reject the null hypothesis of a unit root at 10% significant level for all possible specifications.

Based on the previous results it is necessary to establish an assumption in relation to the kind of process described by the trend of the series in order to render stationarity in the series and compute both the correlogram and the spectrum. In Figure 4 estimates of these descriptive statistics for the de-trended U.S. real output series under the assumption of a trend-stationary process are shown.

FIGURE 4

The information provided by the correlogram shows clear cyclical movements in the stationary component of the series. The data generating mechanism seems to be that of a second order autoregressive process, AR(2), with complex roots. Nevertheless, the message given by the power spectrum suggests the presence of a cycle with a very long period (λ is close to zero), which is not in accordance with the evidence of cyclical fluctuations observed in the economy. By contrast, under the assumption of a difference-stationary process for the U.S. output series the results are more in accordance with the empirical evidence on business cycles. In Figure 5 the correlogram and the power spectrum for the U.S. real output growth are shown.

FIGURE 5

The figure above shows the correlogram and power spectrum for the first-differences of the U.S. real output (i.e. the growth rate of real output). Similarly to the case of the TFP series, the autocorrelations are small providing weak evidence of cyclical movement in the series. However, an examination of the spectrum indicates a clear cycle with a period between 5 to 6 years, and the possibility of an additional cycle of longer periodicity. It is interesting to notice the close similarity between the power spectrum of the first-differences of TFP and the one obtained for the real output series. Based on these results, it seems reasonable to disregard the presence of a deterministic linear trend in the U.S.

3 real output series. Table 6 shows some basic diagnostic and goodness-of-fit statistics for
4
5
6 suitable structural time series models for the U.S. real output series.
7
8
9

10
11 **TABLE 6**
12

13
14
15 As in the case of the U.S. TFP series all these models assume the presence of a
16
17 trend, two cycles and an irregular component. The structural time series model with the
18
19 best goodness-of-fit based on both information criteria is the random walk with drift plus
20
21 cycle and irregular components. The diagnostic tests indicate no problem with the fit of
22
23 the model. Figure 6 displays the different components of the structural time series model
24
25 for the real output series of the U.S. economy.

32 **FIGURE 6**
33
34
35

36
37 Figure 6 shows the significant differences that exist between the long-run
38
39 components of the TFP series and the real output series of the U.S. economy. For the
40
41 latter the trend is better described as a random walk with a drift of 0.036. The standard
42
43 error of the disturbances of the level (σ_η) is 0.0149 making this component the most
44
45 volatile part of the model. The cyclical component, on the other hand, shows strong
46
47 similarities with those found for the U.S. TFP series. The model suggests the presence of
48
49 two cycles with frequencies $\lambda_1 = 1.093$ (5.75 years period) and $\lambda_2 = 0.564$ (11.14 years
50
51 period). The estimate of ρ for the first cycle is 0.817, while for the second cycle it is 1,
52
53 indicating the presence of a deterministic cycle. The estimated standard deviation of the
54
55
56
57
58
59
60

1
2
3 disturbances for the first cycle is 0.0103. The correlation between the cyclical component
4 of the U.S. TFP and the cyclical component of the real output series is 0.86. Finally, the
5 irregular component shows an estimated standard error of 0.0095.
6
7
8
9

10
11
12 In order to evaluate the existence of a single common trend between the time
13 series of TFP and real output (per labour) for the U.S. economy, as suggested by the
14 Neoclassical growth model, cointegration tests have been conducted.¹⁷ The econometric
15 investigation of this topic is based on the concept of cointegration introduced by Engle
16 and Granger (1987). Its aim is to determine the number and shape of stationary linear
17 combinations -named cointegrating relations- of time series which are themselves non-
18 stationary. In order to conduct the cointegration tests the methodology developed by
19 Johansen (1988, 1991, 1995) will be employed, which is based on maximum-likelihood
20 estimation within a Gaussian vector autoregression. Table 7 shows the results of applying
21 Johansen cointegration tests for the series under study.

43

44 **TABLE 7**

45 The unrestricted vector autoregressive (VAR) model for the variables in level was
46 set with two lags as suggested by the BIC. The diagnostic tests for this model did not
47 show problems of autocorrelation, heteroscedasticity or normality in the residuals. The
48 specification given to the deterministic components of the model was that of unrestricted
49 intercepts and restricted trend in the cointegration space. The results show that both
50 statistics, the λ_{trace} and the λ_{max} statistic, fall in the non-rejection area of the null-

1
2
3 hypothesis of no cointegration. Consequently, the results obtained do not provide
4
5 evidence of the presence of a single common trend for the series of TFP and real output
6
7 of the U.S. economy as it is suggested by economic theory. Although, it should be said
8
9 that both statistics are relatively close to the 10% significant level suggesting the
10
11 presence of one cointegrating relation.

17

18 **5. Conclusions**

19
20 In this work the presence of unobserved components in the time series of Total
21
22 Factor Productivity is considered. This idea is central to modern Macroeconomics as the
23
24 main approach in both the study of economic growth and the business cycle relies on
25
26 certain features of the different components belonging to the time series of this variable.
27
28 The econometric methodology employed in order to get the estimates of the different
29
30 components of Total Factor Productivity is the structural time series approach developed
31
32 by Harvey (1989) and Harvey and Shephard (1993) that build on early works such as
33
34 Nervole, Grether and Carlvalho (1979).
35
36
37
38
39
40

41 In the examination of the 1948-2002 annually recorded U.S. Total Factor
42
43 Productivity series computed by the Bureau of Labour Statistics the results indicate the
44
45 presence of different unobserved components (i.e. trend, cycle and irregular component)
46
47 as economic theory suggests. The secular component of the series seems to be better
48
49 represented as a smooth trend, that is, a process given by a deterministic level and a
50
51 stochastic slope. The estimates of this component suggest that technical progress in the
52
53 U.S. economy reached a peak at the beginning of the 1960s when it started to decline
54
55
56
57
58
59
60

1
2
3 until the early 1980s, to rebound afterward. This result contradicts the idea that
4 technology in the U.S. economy slowed down in the 1970s as a result of the oil price
5 shocks during this decade. Similarly, evidence supporting the view of the presence of a
6 deterministic linear trend as it is sometimes assumed in the business cycles literature was
7 strongly rejected. In relation to the cyclical component of the series, it seems to be best
8 represented by two cycles with a period of 6.42 years and 11.74 years, respectively.
9
10
11
12
13
14
15
16
17
18
19

20 The results obtained in the analysis of the Total Factor Productivity series were
21 compared with those obtained from a similar analysis of the U.S. real output series.
22 Economic theory suggests that both the secular component of Total Factor Productivity
23 and real output (per labour) should be the same. In addition, if shifts in the production
24 function are the main driving forces generating short-run fluctuations in the economy,
25 then the cyclical components of Total Factor Productivity and real output should share
26 some of their main characteristics. The empirical results for the U.S. economy seem to
27 suggest different secular components for the two series, as there is no evidence of the
28 existence of cointegration between the series, although it should be mentioned that the
29 actual statistics are relatively close to the 10% critical values. By contrast, the results
30 were more in accordance with economic theory for the case related to short-run
31 fluctuations. The cyclical component of the U.S. real output is better represented by two
32 cyclical movements with periods 5.75 years and 11 years, respectively. Consequently, it
33 has been found that the periodicity of the cyclical component of the two series is very
34 similar one to another.

16
17
18 This work examines the presence of unobserved components in the time series of
19 Total Factor Productivity, which is an idea central to modern Macroeconomics. The main
20 approaches in both the study of economic growth and the study of business cycles rely on
21 certain properties of the different components of the time series of Total Factor
22 Productivity. In the study of economic growth, the Neoclassical growth model explains
23 growth in terms of technical progress as measured by the secular component of Total
24 Factor Productivity. While in the study of business cycles, the Real Business Cycle
25 approach explains short-run fluctuations in the economy as determined by temporary
26 movements in the production function, which are reflected by the cyclical component of
27 the time series of the same variable. The econometric methodology employed in the
28 estimation of these different components is the structural time series approach developed
29 by Harvey (1989), Harvey and Shephard (1993), and others. An application to the time
30 series of Total Factor Productivity for the 1948-2002 U.S. private non-farm business
31 sector is presented.

1. Introduction

The seminal work of Solow's (1957), which derives a methodology to measure technological progress, has been of major importance in Macroeconomics. First, in the growth literature it has become the basis for an extensive theoretical body on growth accounting that tries to quantify the sources of economic growth. Second, the main approach in the study of business cycles, the Real Business Cycle approach, assumes technological innovations (measured by Solow's procedure) as the main driving force of short-run fluctuations in the economy, and employs it in the simulations of quantitative models. And third, as it is believed that technological progress is an important source of economic growth many researchers have attempted to explain it as the endogenous outcome of economic decisions, which has served as the basis of a new body of literature on endogenous economic growth.

Although the main approach in both the study of economic growth and business cycles relies on the time series behaviour of the same variable, technological progress, their interest is focused on different components of the series. Hence, in the study of economic growth the attention is centred on the pattern described by the non-stationary part of the series (which can keep steady, speed up or slow down), while in the study of business cycles, the interest is on the stationary part of this series. This distinction is commonly ignored in the empirical estimation of technical progress, which sometimes could have important effects on our conclusions about the pattern displayed by the secular component of the variable over time.

In this work the presence and characterisation of unobserved components in the time series of Total Factor Productivity is examined. The structure given to the paper is the following: in Section 2 a brief description of the methodology derived by Solow (1957) is presented, and some changes to the specification of the production function are introduced in order to give an explicit account of the different components of the series in accordance with the main approaches in the study of economic growth and the business cycle. In Section 3 the econometric methodology employed to get the estimates of the different components of the time series of technological progress is described. Section 4 shows the empirical results obtained in the analysis of Total Factor Productivity in the U.S. economy under this methodology. Finally, Section 5 presents the conclusions of the paper.

2. Theoretical Background

In the Growth Accounting literature, observed economic growth is partitioned into components associated with factor accumulation and a residual that reflects technical progress and other elements. This breakdown of the rate of growth of aggregate output into different components has its foundation in the pioneering work of Solow (1957). In this work, he derives a measure of technical progress, and shows how to employ it to correct the estimation of the production function. Solow considers the Neoclassical production function¹

$$Y(t) = F(K(t), L(t), A(t)) \quad (2.1)$$

¹ By Neoclassical production function, we mean that the function is concave, twice continuously differentiable, satisfies the Inada (1964) conditions and that both factors are essential in production.

where $Y(t)$ is the flow of output produced at time t , $K(t)$ is the physical capital stock accumulated at time t , and $L(t)$ is the labour input at time t . The production function also depends on $A(t)$, the level of technology, and the notation makes it explicit that it varies with time. Then, by assuming both technological change to be Hicks-Neutral and that each input is paid its (social) marginal products, he obtains an expression for the rate of technological progress as²

$$\hat{g} = \frac{\dot{Y}}{Y} - s_K \cdot \frac{\dot{K}}{K} - s_L \cdot \frac{\dot{L}}{L} \quad (2.2)$$

Equation (2.2) suggests that the rate of technical progress (\hat{g}) can be obtained as residual from the rate of growth of real output (\dot{Y}/Y), once the growth rates of capital (\dot{K}/K) and labour (\dot{L}/L), weighted by their respective income shares, have been deducted. In the literature, \hat{g} is often described as an estimate of Total Factor Productivity (TFP) or the Solow residual.

Solow made it explicit that in applied work the residual would pick up any factor shifting the production function. However, he labelled it technical progress under the presumption that technological change would be the main influence being captured by it.

²By assuming Hicks-Neutral technological change, as stated by Solow (1957, p. 312), shifts in the production function “leave marginal rates of substitution untouched but simply increase or decrease the output attainable from given inputs”.

1
2
3 He found some ground for this assertion in his estimates of the factor $A(t)$ for the US
4
5
6 economy, which showed a strong upward trend during the period 1909-1949.³
7
8
9

10
11 The production function specified by Solow (1957) to measure technological
12
13 progress is the same specification given to the production function in the Solow-Swan
14
15 model or Neoclassical model of economic growth. In this model the factor $A(t)$ is
16
17 introduced in the production function in order to enable the modelled economy to
18
19 reproduce the observed pattern of some macroeconomic variables that register growth in
20
21 per capita terms over the years. Therefore, the specification of the production function is
22
23 intended to pick up those driving forces that bring about economic growth under the
24
25 Neoclassical model of economic growth. It is important to notice, however, that such a
26
27 specification for the production process does not provide an explicit account of any other
28
29 forces that drive short-run fluctuations in the economy as those ones claimed by the Real
30
31 Business Cycle approach. From this perspective, a more appropriate specification for the
32
33 production process seems to be one that explicitly distinguishes those forces that drive
34
35 economic growth from those associated with business cycles.
36
37
38
39
40
41
42
43

44 In modern Macroeconomics the production function is specified in such terms
45
46 that it is allowed to pick up forces that drive both economic growth and business cycles,
47
48 and it is described as follows
49
50
51
52

$$Y(t) = \lambda(t)F(K(t), L(t), A(t)) \quad (2.3)$$

53
54
55
56
57 ³ A negative trend in $A(t)$ would imply the unreasonable case of technical regress, something that would
58 have discouraged Solow from writing his paper (see, Solow 1957, p.316).
59
60

1
2
3
4
5
6 Here the production process is similar to that one specified in equation (2.1)
7
8 except that there is an explicit account of *temporary* changes in the production function
9
10 through a random variable $\lambda(t)$, while *secular* improvements in technology are measured
11
12 by $A(t)$. Hence, the production function establishes a clear distinction between forces that
13
14 drive economic growth from those that drive short-run fluctuations.⁴
15
16
17
18
19

20
21 In the economic growth literature the specification given to the production
22
23 process ignores the term $\lambda(t)$, while in the business cycle literature growth is omitted or it
24
25 is simply started with a transformed economy.⁵ Therefore, $\lambda(t)$ and $A(t)$ stand for
26
27 processes whose driving forces are completely different, and consequently they require
28
29 different specifications. In the business cycle literature $\lambda(t)$ is commonly described as a
30
31 stationary process, which displays considerable serial correlation, with first-differences
32
33 nearly serially uncorrelated, while in the economic growth literature $A(t)$ is usually
34
35 specified as a non-stationary process that can be expressed either as a trend-stationary
36
37 process or a difference-stationary process. Even though economists have considered it
38
39 appropriate to separate these different processes according to the subject of study (i.e.
40
41 economic growth or short-run fluctuations), it seems clearly inappropriate to ignore them
42
43 in an empirical estimation of technological progress. For that reason, if equation (2.3) is
44
45
46
47
48
49
50
51
52

53
54 ⁴ This specification is found in papers such as King, Plosser and Rebelo (1988) and King and Rebelo
55 (1999).

56
57 ⁵ In the analysis of business cycles, models with steady state growth are transformed into stationary
58 economies. This transformation is introduced to the Neoclassical growth model by scaling all the trending
59 variables by the growth component $A(t)$.
60

employed and the same reasoning is carried out as before, we arrive at an expression for TFP for the particular case of Hicks-Neutral technological change given by

$$\hat{g} = \frac{\dot{\lambda}}{\lambda} + \frac{\dot{A}}{A} = \frac{\dot{Y}}{Y} - s_K \cdot \frac{\dot{K}}{K} - s_L \cdot \frac{\dot{L}}{L} \quad (2.4)$$

Equation (2.4) establishes an explicit distinction between fluctuations of the production function that occur in the short-run from those of a more permanent nature such as technological progress. This discrepancy between TFP and changes in technology, which is commonly ignored in the growth accounting literature, is the one that will be addressed in this paper by employing the structural time series approach.

3. Econometric Methodology

The econometric methodology employed in this paper is the structural time series approach developed by Harvey (1989) and Harvey and Shephard (1993), which build on early work such as Nervole, Grether and Carlvalho (1979). The essence of this approach is to set up a model, which regards the observation as being made up of a trend (or permanent) component and an irregular (or temporary) component. Consequently, structural time series models are nothing more than regression models in which the explanatory variables are functions of time and the parameters are time varying. The estimation is conducted by setting the model in state space form, with the state of the system representing the various unobserved components. In the case of linear models, the

Kalman filter is employed, which provides the means of updating the state as new observations become available.⁶

The simplest structural time series model, usually referred to as the *local level model*, is given by a trend component and an irregular term, which is a white noise process. The model can be written in the following way,

$$y_t = \mu_t + \varepsilon_t \quad t = 1, 2, \dots, T \quad (3.1)$$

where y_t is the observed value, μ_t is a trend and ε_t is a white noise disturbance term, that is, a sequence of serially uncorrelated random variables with constant mean, in this case zero, and constant variance, σ_ε^2 . The trend component, μ_t , may take a variety of forms, the simplest being a level that fluctuates up and down according to a random walk

$$\mu_t = \mu_{t-1} + \eta_t \quad t = \dots, -1, 0, 1, \dots \quad (3.2)$$

where η_t is a white noise disturbance with variance σ_η^2 , which is uncorrelated with the stochastic term ε_t . No starting value needs to be specified for μ_t since it is assumed to have started at some point in the remote past.

An alternative specification for the trend component is the following

⁶ A thorough discussion of the methodological and technical ideas underlying this approach is found in Harvey, A. (1989).

$$\mu_t = \mu_{t-1} + \beta_{t-1} + \eta_t \quad (3.3)$$

$$\beta_t = \beta_{t-1} + \zeta_t \quad t = \dots -1, 0, 1, \dots$$

where η_t and ζ_t are mutually uncorrelated white noise disturbances with zero means and variances σ_η^2 and σ_ζ^2 , respectively. Together, (3.1) and (3.3) form what is often referred to as the *local linear trend model*. The effect of η_t is to allow the level of the trend to shift up and down, while ζ_t allows the slope to change. The longer the variances the greater are the stochastic movements in the trend. We should notice that the trend specification given in (3.3) nests different processes such as, the random walk with drift trend ($\sigma_\zeta^2 = 0$) and the deterministic linear trend ($\sigma_\eta^2 = \sigma_\zeta^2 = 0$).

A cycle can be introduced to (3.1) in order to formulate a model more in line with economists' traditional view that the movements of an annually recorded time series for a macroeconomic variable are determined by a trend component, a cyclical component and a noise component. Formally,

$$y_t = \mu_t + \psi_t + \varepsilon_t \quad t = 1, \dots, T \quad (3.4)$$

where ψ_t is the cyclical component that is a function of time, and the other components have been specified above. Modelling the cyclical process takes the form

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho \begin{bmatrix} \cos \lambda & \sin \lambda \\ -\sin \lambda & \cos \lambda \end{bmatrix} \begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} \omega_t \\ \omega_t^* \end{bmatrix} \quad (3.5)$$

where ω_t and ω_t^* are uncorrelated white noise disturbance terms with variance σ_ω^2 and $\sigma_{\omega^*}^2$, respectively, and ψ_t^* appears by construction in order to form ψ_t . The disturbance terms make the cycle stochastic rather than deterministic. The parameter $0 \leq \lambda \leq \pi$ is the frequency of the cycle, which is measured in radians. The period of a cycle corresponding to a frequency of λ is $2\pi/\lambda$ years. The coefficient $0 < \rho \leq 1$ is a damping factor on the amplitude of the cycle. If $0 < \rho < 1$ the process is a damped sine or cosine, wave. While if $\rho = 1$ the process is again a sine or cosine wave, but no damping movement is present. A single equation for ψ_t can be obtained by writing the model as

$$\psi_t = \frac{(1 - \rho \cos \lambda L)\omega_t + (\rho \sin \lambda L)\omega_t^*}{1 - 2\rho \cos \lambda L + \rho^2 L^2} \quad (3.6)$$

where L is the lag operator and ρ is assumed to be in the range $0 < \rho < 1$. Equation (3.6) shows that the process described by ψ_t is an ARMA(2,1), which becomes an AR(2) whenever $\sigma_{\omega^*}^2 = 0$. A final point to note is that the stochastic cycle collapses to an AR(1) process when $\lambda = 0$ or π .

In the model described by equation (3.4) the cycle is introduced by adding it to a trend component and an irregular component. Such a model is usually referred to as the *trend plus cycle model*. An alternative way of introducing a cycle is by incorporating it

into the trend. This specification is usually known as the *cyclical trend model*. In this case, trend and cycle are not separable, and the model can be formally written as

$$y_t = \mu_t + \varepsilon_t \quad t = 1, 2, \dots, T \quad (3.6)$$

$$\beta_t = \beta_{t-1} + \zeta_t \quad t = \dots, -1, 0, 1, \dots$$

$$\mu_t = \mu_{t-1} + \psi_{t-1} + \beta_{t-1} + \eta_t$$

The trend plus cycle model (3.4) and the cyclical trend model (3.6) are the most important formulations of structural time series models that exhibit cyclical process.

4. Empirical Results

In this section the empirical results of the paper will be presented. The time series to be analysed is the widely cited measure of Total Factor Productivity for the U.S. economy produced by the Bureau of Labour Statistics (BLS).⁷ Figure 1 shows the annually recorded TFP series in logarithmic terms for the period 1948-2002.

FIGURE 1

The series computed by the BLS uses for real output the national accounting data from the Bureau of Economic Analysis (BEA). The private non-farm business sector includes all of gross domestic product except the output of general government, government enterprises, non-profit institutions, the rental value of owner-occupied real

⁷ Series Id: MPU750023 (K)

1
2
3 estate, the output of paid employees of private households, and farms from the private
4 business sector, but includes agricultural services. The output index, which is supplied by
5 BEA, is computed as chained superlative index (Fisher Ideal Index) of components of
6 real output, and then adjusted by the BLS. Labour input is obtained by Tornqvist-
7 aggregation of the hours at work by all persons, classified by education, work experience,
8 and gender with weight determined by their shares of labour compensation. Finally, the
9 capital input measures the services derived from the stock of physical assets and
10 software. The assets included are fixed business equipment, structures, inventories and
11 land. The BLS produces an aggregate input measure obtained by Tornqvist aggregation
12 of the capital stock of each asset type using estimated rental prices.⁸

29 The U.S. TFP series has been widely analysed and a growing body of
30 research has emerged around it. Among the most salient and well-known features of the
31 series are the patterns of productivity slowdowns after 1973, which has been associated
32 by some researchers with the oil price shocks of the 1970s, and rebounds after 1995.
33 Additionally, it has been recognised that TFP tends to move pro-cyclically; in periods of
34 economic expansion, TFP is unusually large, while during recessions, it is low or even
35 negative.
36

41
42
43
44
45
46
47

48 In the economic literature there are very few cases of an explicit treatment of the
49 presence of different components in the TFP series. An exception to this is found in King
50 and Rebelo (1999), where the productivity series is specified in terms of two components;
51
52
53
54

55
56
57 ⁸ More detailed information on methods, limitations, and data sources is provided BLS Bulletin 2178
58 (September 1983), "Trends in Multifactor Productivity, 1948-81".
59
60

1
2
3 a trend which is assumed to be linear and deterministic, and a cyclical component which
4 follows an first-order autoregressive process, AR(1). Employing quarterly data of TFP
5 for the U.S. economy during the period 1947 (first quarter) to 1996 (fourth quarter) they
6 fit a linear trend to the series, and then use the residuals to estimate an AR(1) model –the
7 resulting point estimate of the persistence parameter is 0.979. It is this decomposition of
8 the TFP series that is addressed in this work, but by employing a formal econometric
9 methodology in the specification process in order to get estimates of the different
10 components of the series and to determine their main characteristics.

39
40

41 To determine whether or not the U.S. TFP series is characterised by having a unit
42 root in their autoregressive representations, a modified Augmented Dickey-Fuller test
43 (hereafter ADF-GLS^t) developed by Elliot, Rothenberg and Stock (1996), which has
44 difference-stationary [or I(1)] as the null hypothesis will be employed. An important
45 property of this test is that it has more power than the original ADF tests, and is
46 approximately uniformly most power invariant. Similarly, a second test that is a version
47 of the Kwiatkowski, Phillips, Schmidt and Shin (1992) tests developed by Leybourne and
48

McCabe (1994), which has trend-stationary [or I(0)] as the null hypothesis [hereafter KPSS(LM)] will be conducted.

The KPSS(LM) results will be used to corroborate the information obtained by applying the ADF-GLS^τ test, and vice versa. Consequently, if the ADF-GLS^τ test rejects the unit root hypothesis and the KPSS(LM) test fail to reject the stationary null hypothesis then, these results will be considered as strong evidence in favour of a trend-stationary process. By contrast, if the ADF-GLS^τ test fails to reject the null hypothesis but the KPSS(LM) rejects it, we will consider this as strong evidence supporting the view of the presence of a difference-stationary process. If both tests fail to reject their respective null hypothesis then, it will be considered that the data does not contain sufficient information to discriminate between these two kinds of processes.⁹

Null specific critical values for the ADF-GLS^τ tests using a preferred difference-stationary specification following the approach specified by Cheung and Chinn (1997) have been generated.¹⁰ Similarly, for the KPSS(LM) tests null specific critical values using a preferred trend-stationary specification following the procedure suggested in Leybourne and McCabe (1996) have been computed.¹¹ In Table 1 the ADF-GLS^τ statistic

⁹ In cases where both tests reject their respective null hypothesis, as argued by Cheung and Chinn (1997), it might be an indication that the data generating mechanism is more complex than that captured by standard linear time series models.

¹⁰ Cheung and Chinn (1997) generate null specific critical values using a selected difference-stationary specification, which is chosen from models with lag parameters p and q ranging from 0 to 5 using the BIC statistic.

¹¹ Leybourne and McCabe (1996) generate null specific critical values by fitting an ARIMA (p,1,1) model with p set initially at 5, and then reducing it to 4 if the statistic $z(p=5) = |T^{1/2} \hat{\varphi}_5 \hat{\theta}| < 1.645$, and so on. Once the value of p has been determined a preferred trend-stationary description is obtained by re-estimating an ARIMA (p,0,0) model with a time trend.

1
2
3 and the KPSS(LM) statistic together with their associated 10%, 5% and 1% critical
4
5 values for the U.S. TFP series are presented.
6
7

8
9
10
11 **TABLE 1**
12
13
14

15 In the first row of Table 1 the results obtained from applying the ADF-GLS^τ test
16 is shown. It is possible to see that the actual statistic is well below the rejection area of
17 the null hypothesis of a unit root. Additionally, in the second row of the table the results
18 of the KPSS(LM) tests is presented. According to this result there is a clear rejection of
19 the null hypothesis of a trend-stationary process as it is rejected at a 1% significant level.
20 Based on the results obtained in both the ADF-GLS^τ tests and the KPSS(LM) tests we
21 find strong evidence to disregard the possibility of having a deterministic linear trend in
22 the times series of the TFP series for the U.S. economy.
23
24
25
26
27
28
29
30
31
32
33
34
35
36

37 It is known that unit root tests are sensitive to the presence of structural breaks in
38 a series. Perron (1989) demonstrated that when there are structural changes in a series the
39 standard tests for unit root hypothesis against the trend-stationary alternatives are biased
40 towards the non-rejection of a unit root. Considering this possibility structural change
41 tests following the methodology suggested by Perron (1997) have been conducted.
42
43
44
45
46
47
48
49
50

51 Perron's technique consists of examining the likelihood of three different kinds of
52 changes in the structure of a series: one that permits an exogenous change in the level of
53 the series (Model A), one that allows an exogenous change in the slope (Model B), and
54
55
56
57
58
59
60

1
2
3 finally one that considers changes in both level and slope (Model C).¹² Table 2 shows the
4
5 results obtained by conducting structural break tests on the time series of the U.S. TFP.
6
7
8
9

10 11 **TABLE 2**

12
13
14
15 The table above shows those years in which the t-statistics of the null hypothesis
16
17 of a unit root were found to be the highest in absolute value. For both models, the one
18
19 that allows a change in level and the one that allows a change in level and slope, the
20
21 suggested time break was at the early 1960s, while for the model with an exogenous
22
23 change in slope the time break was at the beginning of the 1970s. The critical values were
24
25 obtained from Perron's tables (1997) with a sample size selected according to the one that
26
27 is closest to the size of the series under study. As can be seen from the table the tests fail
28
29 to reject the null hypothesis of a unit root at 10% significant level for all the
30
31 specifications. Consequently, these results seem to corroborate the absence of a
32
33 deterministic linear trend in the time series of TFP in the U.S. economy.
34
35
36
37
38
39
40

41
42 In order to evaluate the possibility of the presence of a cyclical component in the
43
44 U.S. TFP series some descriptive statistics such as the correlogram and the power
45
46 spectrum can provide useful information. Figure 2 presents the estimates of these
47
48 statistics for the series in first-differences (i.e. the U.S. TFP rate of growth).
49
50
51
52

53 54 **FIGURE 2**

55
56 ¹² Perron's (1997) methodology involves estimating the regressions for the three models for all possible
57
58 break points, and selecting that point where the t-statistic of the null hypothesis of a unit root is the highest
59
60 in absolute value.

1
2
3
4
5
6 The correlogram shows small individual autocorrelations not providing strong
7
8 evidence of the presence of cyclical movement in the series, although there seems to be
9
10 some evidence of cyclical movement buried with noise. However, a much clearer
11
12 message emerges from the examination of the power spectrum, which shows what
13
14 appears to be a cycle with a period between 6 to 7 years, and the possibility of additional
15
16 cyclical movements.¹³

17
18
19
20
21
22 Based on the information gathered by conducting unit root tests and the
23
24 descriptive statistics employed to evaluate the presence of cyclical movements in the
25
26 series, some likely specification for the trend and the cyclical components of a structural
27
28 time series model for the data have been estimated.¹⁴ Table 3 shows some basic
29
30 diagnostic and goodness-of-fit statistics for these different structural time series models.

TABLE 3

All these models assume the presence of a trend, two cycles and an irregular component. The table shows diagnostic and goodness-of-fit statistics for three structural time series models with different specifications for the trend or secular component of the series. The first statistical specification assumes that the trend component follows a random walk with drift, which is specified by employing equation (3.3) and a deterministic slope (i.e. $\sigma_{\zeta}^2 = 0$). The second statistical specification for the long-run

¹³ On this graph the period is obtained as 2 divided by the frequency.

¹⁴ Structural time series models were estimated using the econometric software Stamp 5.0.

1
2
3 component is a variant of the local linear trend model, which introduces a somewhat
4 smoother trend by employing equation (3.3) with a deterministic level (i.e. $\sigma_{\eta}^2 = 0$) and a
5
6 stochastic slope. Finally, the last specification for the long-run component is the local
7
8 linear trend model, which stipulates the level and the slope to be stochastic (i.e. equation

3.3).

Diagnostic checking tests are conducted by computing the Box-Ljung $Q(p,q)$ statistic for serial correlation, which is based on the first p residual autocorrelations and tested against a χ^2 distribution with q (i.e. $p + 1$ minus the number of estimated parameters) degree of freedom. A simple diagnostic test for heteroskedasticity $H(h)$, which is the ratio of the squares of the last h residuals to the squares of the first h residuals, where h is set to the closer integer of $T/3$. This statistic is compared with the appropriate significant point of an F distribution with (h,h) degrees of freedom.

The Prediction Error Variance (P.E.V.), the coefficient of determination (R_D^2) and the information criteria (Akaike Information Criterion, AIC, and Bayesian Information Criterion, BIC) provide the goodness-of-fit statistics. The Prediction Error Variance is the variance of the one-step-ahead prediction errors in the steady state. These statistics have been employed to compute the information criteria, which are the appropriate statistics to compare models that have different numbers of parameters.¹⁵ The coefficient of determination, R_D^2 , is the statistic recommended by Harvey (1989, chapter 5), which

¹⁵ The information criteria have been computed using the procedure suggested in Harvey (1989), pp.269-270.

1
2
3 enables the fit of the estimated model to be compared directly to a random walk with
4
5 drift. For $0 < R_D^2 \leq 1$ the model is giving a better fit than the random walk with drift; for
6
7
8 $R_D^2 = 0$ the fit is the same; while for $R_D^2 < 0$ the fit of the model is worse than the random
9
10 walk with drift. Table 1 also presents information related to the Log-Likelihood.
11
12
13
14
15

16 The structural time series model that registers better goodness-of-fit based on both
17
18 information criteria is the smooth trend plus cycle and irregular components. The
19
20 diagnostic tests of this model indicate that the fit is fine. Figure 3 shows the different
21
22 components of the structural time series model for the TFP series of the U.S. economy.
23
24
25
26
27

28 **FIGURE 3**

29
30
31
32 From the figure above it can be seen how the secular component of technological
33
34 progress has evolved over the years. The estimates of this component suggest that
35
36 technological progress slows down in the U.S. economy long before the oil price shocks
37
38 of the 1970s. Technological progress seems to have reached a peak at the beginning of
39
40 the 1960s when it starts to slow down until early 1980s to rebound then after. The
41
42 estimated standard error of the disturbances driving the slope ($\hat{\sigma}_\zeta$) is 0.0026. For the
43
44 cyclical component the model suggests the presence of two cycles with frequencies
45
46 $\lambda_1 = 0.979$ (6.42 years period) and $\lambda_2 = 0.535$ (11.74 years period). The estimate of ρ
47
48 for the first cycle is 0.810, while for the second cycle it is 0.998, which is very close to 1
49
50 indicating the presence of a deterministic cycle. The estimated standard errors of the
51
52 disturbances driving these two cycles are 0.0068 and 0.0006, respectively. Finally, the
53
54
55
56
57
58
59
60

1
2
3 irregular component seems to be the most volatile part of the model with an estimated
4
5 standard deviation of 0.0075.
6
7

8
9
10 An important issue to address at this stage is to compare the results
11
12 obtained in the study of the U.S. TFP series with those of the U.S. real output series. If
13
14 business cycles are mainly driven by short-run fluctuations in the production function, as
15
16 it is claimed by the Real Business Cycles approach, then we should expect close
17
18 similarities between the cyclical movements shown by the TFP series with those shown
19
20 by the real output series. Similarly, if the secular component of the TFP series drives
21
22 economic growth, then it should be found that both the TFP series and the real output
23
24 (per labour) series share a single common trend. In order to compute the correlogram and
25
26 the spectrum of the real output series it is important to determine the main characteristic
27
28 of the trend to conduct the proper de-trending procedure. In Table 4 the ADF-GLS[†]
29
30 statistic and the KPSS(LM) statistic together with their associated 10%, 5% and 1%
31
32 critical values for the U.S. real output series are presented.¹⁶
33
34

54
55
56
57

TABLE 4

58
59
60 In the table above it is possible to observe that the ADF-GLS[†] statistic is below
the rejection area as it is not possible to reject the null hypothesis of the presence of a unit
root in the real output series at 5% significant level. Additionally, the results obtained by
conducting the KPSS(LM) test does not allow the rejection of the null hypothesis of a

¹⁶ The real output series is the same employed by BLS in the computation of the U.S. TFP series.

1
2
3 trend stationary process either. Therefore, we should conclude that for the time series of
4
5 real output in the U.S. economy the data does not contain sufficient information to
6
7 discriminate between a difference-stationary process and a trend-stationary process.
8
9

10
11
12 As in the U.S. TFP series, structural change tests have been conducted on the U.S.
13
14 real output series. Table 5 shows the results obtained from these tests.
15
16

17
18
19
20 **TABLE 5**
21

22
23
24 Interestingly, the results shown by the table above indicate likely time breaks
25
26 similar to those obtained in the examination of the U.S. TFP series. However, as in the
27
28 case of the U.S. TFP series, the tests fail to reject the null hypothesis of a unit root at 10%
29
30 significant level for all possible specifications.
31
32

33
34
35
36 Based on the previous results it is necessary to establish an assumption in relation
37
38 to the kind of process described by the trend of the series in order to render stationarity in
39
40 the series and compute both the correlogram and the spectrum. In Figure 4 estimates of
41
42 these descriptive statistics for the de-trended U.S. real output series under the assumption
43
44 of a trend-stationary process are shown.

The information provided by the correlogram shows clear cyclical movements in the stationary component of the series. The data generating mechanism seems to be that of a second order autoregressive process, AR(2), with complex roots. Nevertheless, the message given by the power spectrum suggests the presence of a cycle with a very long period (λ is close to zero), which is not in accordance with the evidence of cyclical fluctuations observed in the economy. By contrast, under the assumption of a difference-stationary process for the U.S. output series the results are more in accordance with the empirical evidence on business cycles. In Figure 5 the correlogram and the power spectrum for the U.S. real output growth are shown.

FIGURE 5

The figure above shows the correlogram and power spectrum for the first-differences of the U.S. real output (i.e. the growth rate of real output). Similarly to the case of the TFP series, the autocorrelations are small providing weak evidence of cyclical movement in the series. However, an examination of the spectrum indicates a clear cycle with a period between 5 to 6 years, and the possibility of an additional cycle of longer periodicity. It is interesting to notice the close similarity between the power spectrum of the first-differences of TFP and the one obtained for the real output series. Based on these results, it seems reasonable to disregard the presence of a deterministic linear trend in the U.S. real output series. Table 6 shows some basic diagnostic and goodness-of-fit statistics for suitable structural time series models for the U.S. real output series.

TABLE 6

As in the case of the U.S. TFP series all these models assume the presence of a trend, two cycles and an irregular component. The structural time series model with the best goodness-of-fit based on both information criteria is the random walk with drift plus cycle and irregular components. The diagnostic tests indicate no problem with the fit of the model. Figure 6 displays the different components of the structural time series model for the real output series of the U.S. economy.

FIGURE 6

Figure 6 shows the significant differences that exist between the long-run components of the TFP series and the real output series of the U.S. economy. For the latter the trend is better described as a random walk with a drift of 0.036. The standard error of the disturbances of the level (σ_η) is 0.0149 making this component the most volatile part of the model. The cyclical component, on the other hand, shows strong similarities with those found for the U.S. TFP series. The model suggests the presence of two cycles with frequencies $\lambda_1 = 1.093$ (5.75 years period) and $\lambda_2 = 0.564$ (11.14 years period). The estimate of ρ for the first cycle is 0.817, while for the second cycle it is 1, indicating the presence of a deterministic cycle. The estimated standard deviation of the disturbances for the first cycle is 0.0103. The correlation between the cyclical component of the U.S. TFP and the cyclical component of the real output series is 0.86. Finally, the irregular component shows an estimated standard error of 0.0095.

In order to evaluate the existence of a single common trend between the time series of TFP and real output (per labour) for the U.S. economy, as suggested by the Neoclassical growth model, cointegration tests have been conducted.¹⁷ The econometric investigation of this topic is based on the concept of cointegration introduced by Engle and Granger (1987). Its aim is to determine the number and shape of stationary linear combinations -named cointegrating relations- of time series which are themselves non-stationary. In order to conduct the cointegration tests the methodology developed by Johansen (1988, 1991, 1995) will be employed, which is based on maximum-likelihood estimation within a Gaussian vector autoregression. Table 7 shows the results of applying Johansen cointegration tests for the series under study.

TABLE 7

The unrestricted vector autoregressive (VAR) model for the variables in level was set with two lags as suggested by the BIC. The diagnostic tests for this model did not show problems of autocorrelation, heteroscedasticity or normality in the residuals. The specification given to the deterministic components of the model was that of unrestricted intercepts and restricted trend in the cointegration space. The results show that both statistics, the λ_{trace} and the λ_{max} statistic, fall in the non-rejection area of the null-hypothesis of no cointegration. Consequently, the results obtained do not provide evidence of the presence of a single common trend for the series of TFP and real output

¹⁷ The BLS series Id number is MPU750021.

1
2
3 of the U.S. economy as it is suggested by economic theory. Although, it should be said
4
5 that both statistics are relatively close to the 10% significant level suggesting the
6
7 presence of one cointegrating relation.
8
9

10 11 12 13 **5. Conclusions**

14
15 In this work the presence of unobserved components in the time series of Total
16
17 Factor Productivity is considered. This idea is central to modern Macroeconomics as the
18
19 main approach in both the study of economic growth and the business cycle relies on
20
21 certain features of the different components belonging to the time series of this variable.
22
23 The econometric methodology employed in order to get the estimates of the different
24
25 components of Total Factor Productivity is the structural time series approach developed
26
27 by Harvey (1989) and Harvey and Shephard (1993) that build on early works such as
28
29 Nervole, Grether and Carlvalho (1979).

58
59
60

36 In the examination of the 1948-2002 annually recorded U.S. Total Factor
37
38 Productivity series computed by the Bureau of Labour Statistics the results indicate the
39
40 presence of different unobserved components (i.e. trend, cycle and irregular component)
41
42 as economic theory suggests. The secular component of the series seems to be better
43
44 represented as a smooth trend, that is, a process given by a deterministic level and a
45
46 stochastic slope. The estimates of this component suggest that technical progress in the
47
48 U.S. economy reached a peak at the beginning of the 1960s when it started to decline
49
50 until the early 1980s, to rebound afterward. This result contradicts the idea that
51
52 technology in the U.S. economy slowed down in the 1970s as a result of the oil price
53
54
55
56
57
58
59
60

1
2
3 shocks during this decade. Similarly, evidence supporting the view of the presence of a
4
5 deterministic linear trend as it is sometimes assumed in the business cycles literature was
6
7 strongly rejected. In relation to the cyclical component of the series, it seems to be best
8
9 represented by two cycles with a period of 6.42 years and 11.74 years, respectively.
10
11
12
13
14

15 The results obtained in the analysis of the Total Factor Productivity series were
16
17 compared with those obtained from a similar analysis of the U.S. real output series.
18
19 Economic theory suggests that both the secular component of Total Factor Productivity
20
21 and real output (per labour) should be the same. In addition, if shifts in the production
22
23 function are the main driving forces generating short-run fluctuations in the economy,
24
25 then the cyclical components of Total Factor Productivity and real output should share
26
27 some of their main characteristics. The empirical results for the U.S. economy seem to
28
29 suggest different secular components for the two series, as there is no evidence of the
30
31 existence of cointegration between the series, although it should be mentioned that the
32
33 actual statistics are relatively close to the 10% critical values. By contrast, the results
34
35 were more in accordance with economic theory for the case related to short-run
36
37 fluctuations. The cyclical component of the U.S. real output is better represented by two
38
39 cyclical movements with periods 5.75 years and 11 years, respectively. Consequently, it
40
41 has been found that the periodicity of the cyclical component of the two series is very
42
43 similar one to another.
