Abstract

While structural change and regional differences in the pattern of employment specialisation are widely perceived to be significant factors in accounting for disparities in the labour market performance of regions in the United Kingdom, there have been relatively few recent attempts to gather detailed evidence on this issue. The current study aims to fill this gap by examining the effects of structural change and associated changes in the pattern of employment specialisation on three key indicators of regional labour market performance: the rate of employment growth, the unemployment rate and the rate of non-employment. The findings indicate that while industry structure has statistically significant effects on regional labour market performance, the quantitative significance of these effects is relatively small.

Keywords: Structural change Specialisation Regional labour markets

JEL codes: J64; R12

1. Introduction

The past thirty-five years have seen significant changes in the structure of the United Kingdom economy, in particular the decline of many traditional manufacturing and primary sector industries and the emergence of a number of new flourishing fields of activity, mainly in the service sector. The causes of these structural shifts have been widely debated. Explanations that have been put forward include the effects of changes in the composition of demand due to rising consumer incomes, competition from low-wage developing economies, and the crowding out of private sector activities as a result of the growth in the size of the non-market public sector (Bacon and Eltis, 1976).¹ The process of structural change has generated significant upheaval in the labour market as jobs have been reallocated from declining to growing sectors, and led to significant changes in the pattern of industrial specialisation at both the national and regional level (Wren and Taylor, 1999; Robson, 2006).

Inherited differences in industry structure mean that the impact and effects of structural change have been different for different regions. In the United Kingdom, regions such as Wales and the North East of England are often perceived to have suffered because of their traditional concentration of employment in industries such as coal mining and iron and steel production, in which the UK has experienced a long-term decline in its share of world markets.² In contrast, London and the South East of England are perceived to have benefited as a result of their specialisation in thriving service sector activities, such as financial and business services.

¹ For a useful textbook summary of competing explanations see chapter 1 of Griffiths and Wall (2004).

² See, for example, Erdem and Glyn (2001) and O'Leary et al, (2005).

Evidence produced by Wren and Taylor (1999), and supported in the main by findings reported in Robson (2006), suggests that as a result of structural change, regions in the United Kingdom have become increasingly similar in terms of the extent to which employment is specialised in particular industries. In particular, employment in all regions is becoming increasingly concentrated in the service sector. Furthermore, within the service sector itself, an increasing share of the total number of jobs is located within a relatively small number of industries.

While structural change and regional differences in the pattern of employment specialisation are widely perceived to be significant factors in accounting for disparities in the labour market performance of UK regions, there have been relatively few recent attempts to gather detailed evidence on this issue.³ The current study aims to fill this gap in the literature by carrying out a detailed investigation of the effects of structural change and associated changes in the pattern of employment specialisation on three key indicators of regional labour market performance: the rate of employment growth, the unemployment rate and the rate of non-employment.

There are a number of ways in which the labour market performance of a region could, in principle, be influenced by its prevailing industry structure. Firstly, in the short-run, the industry composition of employment within a region may have a significant effect on the region's vulnerability to the effects of aggregate shocks. Other things equal, regions in which there is a relative

³ Taylor and Bradley (1994) find that, other things equal, the impact of the 1990-2 recession in the UK economy was weaker in areas with a relatively high proportion of employment in the primary sector. Other studies that have investigated the role of industry mix in contributing to an explanation for UK regional unemployment disparities include Cheshire (1973), Dixon and Thirlwall (1975), and Taylor and Bradley (1983).

1
2
3 concentration of employment in ‘cyclically sensitive’ industries will tend to
4
5 experience wider cyclical variations in employment and unemployment than
6
7 regions that are specialised in more cyclically stable industries. Secondly,
8
9 structural changes resulting from longer-term shifts in the pattern of labour
10
11 demand across industries may generate ‘reallocation shocks’ that lead to
12
13 increases in regional unemployment as labour that is displaced from declining
14
15 industries takes time to be absorbed into the new growing sectors of the economy
16
17 (Lilien, 1982). Finally, evidence from a number of studies suggests that a
18
19 region’s labour market performance may be influenced by the degree of
20
21 specialisation or diversity in the region’s industry mix (e.g. Diamond and Simon,
22
23 1990; Neumann and Topel, 1991). For example, a region that is characterised by
24
25 a diverse industry employment mix may be less vulnerable to the effects of
26
27 adverse shocks to aggregate demand than one in which employment is
28
29 concentrated within a relatively small number of related industries.

31
32
33
34
35

36 To examine the effect of industry structure on regional labour market
37
38 performance this study makes use of annual data on employment in 30 industries
39
40 for each of the 12 Government Office Regions for the period 1975-2001.⁴ For
41
42 each region, we construct measures of the effects of aggregate industry
43
44 employment shocks, the effects of reallocation shocks, and the degree of
45
46 diversity or specialisation in regional employment. These measures are used as
47
48 explanatory variables in panel data regressions for, in succession: the rate of
49
50 growth of regional employment; the regional unemployment rate; and the rate of
51
52 non-employment. The latter is important as changes in rates of labour force

1
2
3 participation in recent years, particularly amongst prime-age men, mean that a
4 focus on regional unemployment rates alone may give a misleading impression
5 of the extent of regional disparities in the number of individuals without work
6 (Erdem and Glyn, 2001; Fothergill, 2001; O’Leary et al, 2005). The results of
7 these panel data regressions may be used to gain insights into the contribution
8 that changes in industry employment structures have made to the performance of
9 individual regional labour markets.

19
20 The pattern of the remainder of the paper is as follows. In Section 2 we
21 discuss the data on the industry composition of employment by region,
22 highlighting the key structural shifts that have taken place over the past 30 years.
23 In addition, this section presents data on the key indicators of regional labour
24 market performance that are the focus of the paper’s analysis, i.e. the rate of
25 growth of employment, the rate of unemployment and the non-employment rate -
26 where the latter is defined as the proportion of the population of working age that
27 is either economically inactive or unemployed. Section 3 provides details of the
28 measures we use to examine the effects of industry structure on regional labour
29 market performance and reports the results of the study’s econometric analysis.
30 The effects of structural change are then illustrated through an assessment of the
31 contribution made by changes in the industry composition of regional
32 employment to the pattern of regional unemployment disparities in the UK.

53 **2. Changes in the Industry Composition of Employment and** 54 **Regional Labour Market Performance.** 55

56 Table 1 highlights the key changes that have taken place in the period
57 since 1975 in the sectoral distribution of employment at the regional level. The
58 Table shows the percentage of employment in each Government Office Region
59
60

1
2
3 in each of six main industry groups for the years 1975 and 2001. As noted above,
4 the main feature of this data is the remarkable decline in the share of employment
5 in manufacturing experienced in each region and the rise in the importance of the
6 service sector. Also notable, however, is the collapse in employment in the
7 Mining and Quarrying sector, which has had a particular impact on employment
8 in the North East, Wales, the East Midlands and Yorkshire and Humberside.
9

10
11 In absolute terms, the decline in the share of manufacturing employment
12 has been greatest in the regions in which the initial share of manufacturing was
13 highest – the West and East Midlands, the North West, Yorkshire and
14 Humberside, and the North East. However, in proportionate terms the experience
15 of manufacturing decline has been similar across all regions: in general, by 2001,
16 the share of employment in manufacturing was about a half of its level in 1975.⁵
17
18 In contrast to the experience in manufacturing, the growth of the share of
19 employment in the service sector has been greatest in both absolute and
20 proportionate terms in the regions that initially had the lowest service sector
21 employment shares. The implication is that over the period since 1975 there has
22 been a degree of convergence in the sectoral distribution of employment across
23 regions, driven by the growth in service sector employment.

38
39
40
41
42
43
44
45

46 More detailed evidence on the extent of convergence in regional
47 employment structures is presented in Table 2 and Figure 1, which show the
48 patterns and trends in the Coefficient of Regional Specialisation (CRS) for the 12
49 Government Office Regions using data on employment in 30 industries.⁶ CRS is
50 calculated as one-half of the sum of absolute deviations of the share of total
51
52
53
54
55
56
57

58
59 ⁵ Notable exceptions to this trend are the cases of Wales and London. In the former, the share of
60 manufacturing employment in 2001 was approximately 65% of its level in 1975; while in London
the share of employment in manufacturing had declined to almost one-third of its 1975 level.

⁶ The industries are defined in Appendix Table A.

1
2
3 regional employment in industry i from the industry's share of total national
4 employment; i.e. as:
5
6

$$7 \quad CRS = (1/2) \sum_{i=1}^n |(x_{ir} / x_r) - (x_i / x_N)| \quad (1)$$

8
9
10
11
12 where x denotes employment and the i , r and N subscripts denote the industry,
13 region and national economy, respectively. A value of CRS equal to zero
14 implies that the structure of employment in a region is identical to that of the
15 national economy. Higher values of the index imply an increasingly divergent
16 regional employment structure.
17
18
19
20
21
22
23
24

25
26 The data in Table 2 and Figure 1 indicate that over the period 1975-2001,
27 with the exception of the London region and to a lesser extent Scotland, there has
28 been a tendency for regional employment structures to become increasingly
29 similar to that of the UK economy as a whole. From the mid-1990s onwards,
30 however, the tendency towards convergence appears to have flattened out and in
31 some cases to have been at least partially reversed. In absolute terms, the greatest
32 decline in the level of employment specialisation has occurred in Northern
33 Ireland, which traditionally has been the region that has deviated furthest from
34 the national employment pattern but which recently has yielded this distinction to
35 London.

52 *Regional Labour Market Performance*

53
54 The pattern of regional labour market performance in the United
55 Kingdom is often characterised in terms of a 'north-south divide', with regions in
56 the south of the country tending to perform relatively well while those in the
57 north - broadly defined to include both Wales and Northern Ireland - tend to
58
59
60

1
2
3 exhibit a weaker performance (see e.g. Blackaby and Murphy, 1995; Rowthorn,
4
5
6 2000). Evidence in support of this general characterisation is apparent in Figures
7
8
9 2 and 3, which show, respectively, data on levels of employment and the
10
11 claimant count rate of unemployment for the 12 Government Office Regions.⁷
12

13
14 For the most part, the data are supportive of the view that there is a north-
15
16 south divide in regional labour market performance. In particular, in the period
17
18 under consideration, levels of employment growth were strongest in the South
19
20 East, South West and East of England, while these regions experienced
21
22 unemployment rates that were persistently below the average for the UK as a
23
24 whole.⁸ In contrast, the North East and North West have experienced declining
25
26 levels of employment (relative to the start of the period) and relatively high rates
27
28 of unemployment. Exceptions to the general view are apparent, however. Most
29
30 notably, employment growth in London has been relatively stagnant throughout
31
32 most of the period under consideration - except until the mid 1990s - while
33
34 Northern Ireland, despite its high rates of unemployment, has experienced
35
36 significant growth in employment.
37
38
39
40

41
42 Trends in rates of economic inactivity, in particular amongst prime-age
43
44 males, have led to an increasing recognition that a focus on rates of
45
46 unemployment alone may give a misleading impression of the extent of regional
47
48 disparities in the extent of joblessness in the UK economy. In general, economic
49
50 activity rates amongst prime-age males have been declining since the 1970s and
51
52 since the mid-1980s this decline has been particularly pronounced in the regions
53
54 characterised by relatively high average rates of unemployment (Erdem and
55
56
57
58

59
60 ⁷ The employment data are from Cambridge Econometrics, while the source for the claimant
count data is the website of the Office for National Statistics (ONS), www.statistics.gov.uk.

⁸ An exception occurred in the recession of the early 1990s, when the unemployment rate in the
South East rose to a level equal the UK average. However, this period proved to be short lived.

1
2
3 Glyn, 2001; Fothergill, 2001; Faggio and Nickell, 2005). Any assessment of
4 regional labour market performance needs therefore to consider developments in
5
6 the rate of non-employment rather than focussing simply on the rate of
7
8 unemployment.
9
10

11
12
13 Figure 4 shows data on rates of non-employment amongst members of
14 the working age population (aged 15-64 for males, 15-59 for females) for the 11
15 Government Office Regions of Great Britain, for the years 1981-2001.⁹ It should
16 be noted that the employment data used to calculate these figures are compiled
17 from workplace data, while the population figures are based on place of
18 residence. The high level of commuting inflows into London (mostly from the
19 South East) means that the data give a misleading impression of the extent of
20 non-employment amongst households in the London Government Office Region
21 (GOR). Labour Force Survey data indicate that the rate of non-employment
22 amongst households in London is on average roughly comparable to that of a
23 typical 'northern' region.¹⁰ Despite this caveat, it is clear that the data on non-
24 employment rates reinforce the view that there are significant north-south
25 disparities in regional labour market performance.

Structural differences between regions in the industry composition of employment are likely to have implications for the way in which labour market performance in different regions is influenced by the effects of aggregate shocks to the economy. It is well known, for example, that industries vary in their sensitivity to the effects of aggregate shocks, such as fluctuations in the level of aggregate demand. Regions in which there is a relatively high concentration of employment in such industries will therefore tend to exhibit greater vulnerability to the effects of aggregate shocks than other regions and this is likely to be reflected in their labour market performance. If regions have become increasingly similar in the extent of their exposure to ‘high shock’ industries then, for example, this would be expected to lead to a decline in the dispersion of regional rates of employment growth and unemployment.

Studies of the effect of industry structure on regional labour market performance have traditionally been based on the application of ‘shift-share’ analysis. However, it is recognised that this technique is subject to a number of weaknesses (see Fothergill and Gudgin, 1982). In this study we attempt to capture the effect of a region’s industry structure on its vulnerability to the effects of aggregate shocks by following Neumann and Topel (1991) in defining a variable, $Shock_{rt}$, which measures the predicted impact on region r of disturbances to aggregate industry employment. The variable is constructed as:

¹⁰ In the Labour Force Survey for the spring quarter of 2005, the non-employment rate for the London GOR (30.6%) was the highest amongst the British regions. In the UK as a whole, only Northern Ireland had a higher non-employment rate.

$$Shock_{rt} = \sum_{i=1}^n e_{irt} \hat{v}_{it} \quad (2)$$

where e_{irt} denotes the share of industry i in employment in region r at period t

and \hat{v}_{it} denotes a disturbance to the log of aggregate employment in industry i .

The latter is obtained as the residuals from an autoregressive model of the form:

$$\ln E(L)_{it} = \alpha_i + v_{it} \quad (3)$$

where E_{it} denotes aggregate employment in industry i ($i = 1, \dots, n$) and L is the lag operator.

Table 3 shows values of $Shock_{rt}$ for selected years during the time period covered by the data sample. Note that given the method used to construct the data the reported figures represent percentage deviations of regional employment. The data highlight the impact of the cyclical fluctuations experienced in the UK economy over the past thirty years. In particular, the large negative values recorded for 1981 and 1991 reflect the impact of the severe cyclical recessions which were experienced in the early 1980s and early 1990s as a result of rising interest and exchange rates and – in the case of the former – the sharp OPEC-induced increase in oil prices at the turn of the decade. The data show that relative to other regions the industry composition of employment in the West Midlands has tended to make it particularly sensitive to the effects of industry employment shocks, while for Northern Ireland the opposite is true. The figures provide an interesting insight into the way in which the industry composition of employment contributed to the regional impact of the recessions of the early 1980s and early 1990s. For example, the data suggest that in 1981 the size of the negative shock to employment in the West Midlands would have been reduced by 1.3 percentage points if it had possessed the same industry

1
2
3 employment structure as Northern Ireland, while in 1991 the difference would
4
5 have been 1.2 percentage points.
6
7

8 Changes in the value of $Shock_{rt}$ may be expected to give rise to short-run
9
10 deviations of regional unemployment rates from their long-run equilibrium
11
12 values. The duration of these departures from equilibrium will depend upon the
13
14 speed with which regional adjustment mechanisms - relative wages, inter-
15
16 regional migration and labour force participation rates – act to restore the initial
17
18 pattern of equilibrium unemployment differentials. Relative to the U.S., the
19
20 speed of regional adjustment mechanisms in European labour markets has been
21
22 found to be relatively slow (Decressin and Fatás, 1995). Temporary shocks to
23
24 aggregate industry employment may therefore have quite long-lived effects on
25
26 regional labour market performance.
27
28
29
30
31

32 The above point notwithstanding, disturbances generated by aggregate
33
34 industry employment shocks are essentially a short-run cyclical phenomenon.
35
36 More persistent effects on regional labour market performance may be expected
37
38 to result from permanent shifts in the pattern of labour demand across industries
39
40 that necessitate a reallocation of workers between sectors. In the absence of
41
42 frictionless movements of workers between sectors, such reallocation shocks
43
44 may lead to ‘structural unemployment’ within regions as displaced workers take
45
46 time to adjust to the skills required in growing sectors. For older workers in
47
48 particular, the costs of retraining may outweigh the benefits and therefore with
49
50 little prospect of re-employment some workers may find it optimal to leave the
51
52 labour force altogether. Developing this theme, Lilien (1982) devises an index to
53
54 capture the effects of reallocation shocks, which is based on the standard
55
56 deviation of relative employment growth across industries. Using this index, he
57
58
59
60

1
2
3 presents evidence that appears to show that much of the time-series variation in
4 the U.S. unemployment rate in the period since World War II can be explained
5 by the effects of reallocation shocks. The findings obtained by Lilien have since
6 been subject to criticism by a number of authors (e.g. Abraham and Katz, 1986)
7 – mainly on the grounds that he ignored the potential correlation between his
8 index of reallocation shocks and the effects of aggregate cyclical disturbances.
9 Nevertheless, the index devised by Lilien remains a potentially useful indicator
10 of the effects of reallocation shocks on the economy.
11
12
13
14
15
16
17
18
19
20
21

22 For each region, we calculate Lilien's index as:

$$23 \quad \text{Lilien}_t = \left[\sum_{i=1}^n (x_{it} / x_{rt}) (\Delta \log x_{it} - \Delta \log x_{rt})^2 \right]^{1/2} \quad (4)$$

24
25 where x_i is employment in industry i ($i = 1, 2, \dots, n$) and x_r is total regional
26 employment, with Δ denoting the first difference operator. The data, which are
27 tabulated for selected dates in Table 4, show that over the period 1975-2001 the
28 incidence of reallocation shocks tended to be highest in the North East region,
29 with Wales, Scotland and the East Midlands a little way behind. In contrast, the
30 incidence of reallocation shocks is found to be lowest in the South East.
31

40
41
42
43

44 A number of studies have suggested that the extent of specialisation or
45 diversity in a region's industry mix may have a significant effect on its labour
46 market performance. For example, a specialised industry mix may provide a
47 favourable environment for regional employment growth by presenting
48 opportunities for spillovers between firms of productivity enhancing
49 innovations.¹¹ In contrast, in regions with a diverse employment mix there may
50 be greater scope for the effects of negative shocks to industry employment to be

60

absorbed through inter-industry labour mobility, thus enabling the region to sustain a relatively low rate of unemployment (Simon, 1988).¹²

Building upon earlier search-theoretic models from the macroeconomic literature on unemployment (e.g. Lucas and Prescott, 1974), Neumann and Topel (1991) develop a model in which equilibrium regional unemployment disparities can be explained as a result of differences between regions in their degree of exposure to the risk of industry employment shocks. The essence of their model is that regions that are characterised by a relatively high covariance of labour demand shocks between industries, or in which there is a relatively high variance of within-industry shocks, will tend to exhibit relatively high equilibrium rates of unemployment/non-employment, other things equal. Conversely, in regions in which the covariance structure of labour demands is such that workers are able to counter the effects of local shocks through inter-sectoral mobility the equilibrium unemployment rate will tend to be relatively low. In this context, ‘diversity’ is measured – in inverse form – by the extent of a region’s exposure to the risk of industry-wide labour demand shocks.

The measure that Neumann and Topel use to quantify the extent of a region’s exposure to the risk of labour demand shocks is calculated as:

$$Risk_{rt} = e'_{rt} \hat{\Omega}_r e_{rt} \quad (5)$$

where e_{rt} is the $(n \times 1)$ vector of industry employment shares in region r at time t and

$$\hat{\Omega}_r = T^{-1} \sum_t \hat{V}_{rt} \hat{V}'_{rt} \quad (6)$$

¹¹ This is an example of an agglomeration economy, as described for example by Rosenthal and Strange (2004).

¹² The basic idea here can be traced at least as far as Marshall (1920).

is the estimated variance-covariance matrix of demand disturbances in region r .

The vector

$$\hat{V}_{rt} = (\hat{V}_{1rt}, \hat{V}_{2rt}, \dots, \hat{V}_{nrt})' \quad (7)$$

is the vector of estimated industry employment shocks in year t , the elements of which are derived from a regression equation of the form of equation (2) but estimated specifically for each region. The variable $Risk_{rt}$ therefore allows for the effect of both aggregate and region-specific employment disturbances.¹³

Data on the value of $Risk$ are plotted in Figure 5 and tabulated for selected intervals in Table 5. For most regions, changes in the industry composition of employment since 1975 appear to have led to a small trend decline in the extent of exposure to regional employment shocks. The notable exception is the case of the North East, where structural changes have led to a much more marked decline in the risk of labour demand shocks.

A number of measures of regional economic specialisation or diversity exist in the literature.¹⁴ As an alternative to the Neumann and Topel (1991) measure, we experiment with the inclusion of a second, albeit less sophisticated, measure of specialisation or diversity in a region's industry employment mix, namely the Coefficient of Absolute Regional Specialisation ($CARS$) In contrast to the Coefficient of Regional Specialisation (CRS) tabulated earlier, in which the industry structure of employment within a region is compared with that in the economy as a whole, $CARS$ is an index of *absolute* specialisation in regional

¹³ Note that the specification of equation (6) assumes that the variance-covariance structure of labour demand disturbances within regions is constant over time. Therefore any changes in the value of $Risk$ within a region are due to changes in the industry composition of employment within the region. An alternative, more complex, procedure would be to allow the structure of covariances to change over time but this would require a specification of how Ω evolves, which would be difficult to implement empirically.

employment. It is calculated as the coefficient of variation of employment in each industry, i.e. as:

$$CARS = \left[\sum_{i=1}^n (x_i - \bar{x}_i)^2 / (n-1) \right]^{1/2} / \bar{x}_i \quad (8)$$

where $\bar{x}_i = \sum_{i=1}^n x_i / n$

Higher values of *CARS* indicate an increasing dispersion of employment across industries and hence an increasing degree of specialisation. Values for this index, which are tabulated in Table 6, indicate that over the period under consideration, employment in all regions has become increasingly specialised in a relatively small number of industries, a phenomenon chiefly associated with the increasing importance of service sector employment.

Econometric Analysis

To analyse the effects of changes in the industry composition of employment on regional labour market performance, using our various measures of the potential impact of industry composition effects, we estimate panel data regressions of the basic form:

$$y_{rt} = \alpha + \beta_1 Shock_{rt} + \beta_2 Lilien_{rt} + \beta_3 Specialisation_{rt} + \varphi Z_{rt} + \gamma_i + \varepsilon_{rt} \quad (9)$$

where y_{rt} is our chosen measure of labour market performance, which is either the rate of employment growth, $\Delta \ln e$, the log of the unemployment rate, u (based on the claimant count measure of unemployment), or the log of the rate of non-employment, ner . On the right hand side of equation (9), *Specialisation* is measured either by the Neumann and Topel (1991) measure of regional

¹⁴ For a recent review, see Chandra (2005), who develops a new measure similar in spirit to the measure of *Risk* devised by Neumann and Topel (1991).

1
2
3 employment risks, *Risk*, or the *CARS* index of regional employment
4 specialisation. The vector \mathbf{Z} represents a vector of control variables, the
5 components of which differ according to the specification of the dependent
6 variable but which always includes a set of regional fixed effects. The latter are
7 included to capture the effect of unobserved factors that lead to persistent
8 differences in regional labour market performance that are not picked up by the
9 other terms in the equation. The term γ_t denotes a period effect common to all
10 regions. This captures the influence of common aggregate factors that might be
11 expected to influence regional labour market performance, including aggregate
12 demand and supply shocks (interest rate changes, oil price shocks etc.) and
13 changes in labour market institutional variables such as reforms to the
14 unemployment benefit system (e.g. the replacement of unemployment benefit
15 with Job-seekers' Allowance) and the introduction of the National Minimum
16 Wage.¹⁵ The inclusion of these period effects means that the parameter on the
17 *Shock* variable, β_1 , captures the effect of inter-regional variations in $Shock_{rt}$, that
18 are caused exclusively by differences between regions in the industry
19 composition of employment.¹⁶

43
44 In the estimation, we allow for lags in the effect of changes in the
45 explanatory variables by including up to two lags of each variable in the initial
46 estimated equation. In addition, in some specifications of the equation a lagged
47 dependent variable is included. This necessitates the use of a GMM estimator in
48
49
50
51
52

53
54
55
56 ¹⁵ In addition, the effects of changes to the method of calculating the claimant count – of which
57 there were several during the period under study – should, for the most part, be absorbed by the
58 period effects.

59 ¹⁶ We experimented with a specification in which allowance was made for the effects of
60 spillovers from industry employment shocks in contiguous regions but in none of the estimated
equations did these effects turn out to be statistically significant. Hence, no further reference to
this issue is included in the discussion of the results reported below.

1
2
3 order to overcome the biases that would otherwise result from the estimation of a
4 dynamic panel data model with fixed effects.¹⁷
5
6

7
8 Prior to the estimation of our panel data regressions, we carry out an
9 exploratory exercise to test for the presence of unit roots in the main variables of
10 interest. For this purpose, we use the CIPS test developed recently by Pesaran
11 (2005). This test, which provides a test of the null hypothesis of a unit root
12 against the alternative of stationarity, is an extension to the panel unit root test
13 devised by Im, Pesaran and Shin (2003) that allows for the presence of non-zero
14 correlations between the time-series of the individual cross-section units. The
15 results of this exercise are reported in Table 7.
16
17
18
19
20
21
22
23
24
25

26
27 The test statistics indicate that the rate of employment growth, our
28 measure of industry employment shocks, *Shock*, and the Lilien index are
29 stationary variables, while regional unemployment rates, the rate of non-
30 employment, *Risk* and *CARS* are characterised by the presence of unit roots. The
31 result for the variable *Shock* is as would be expected given the manner in which
32 this variable is constructed, while the finding for *Risk* is consistent with the
33 visual evidence from the plot of this variable in Figure 5. In principle, the log of
34 the rate of unemployment and the log of the non-employment rate should be
35 classed as stationary variables, as they are derived from variables that are
36 bounded to lie between zero and one. The test results for these series are
37 probably best interpreted as indicating that over the period under consideration
38 the variables exhibit a high degree of persistence such that they behave as if they
39 possess a unit root. In turn, the results for the exercise as a whole may be
40 interpreted as providing a preliminary indication of the likelihood that we may

3 expect to find a long-run or simply a short-run relationship between a particular
4 measure of industry structure effects and our chosen indicators of regional labour
5 market performance.¹⁸
6
7
8
9

10 For the main econometric investigation, a general-to-specific modelling
11 approach is adopted in which we start with an initial unrestricted dynamic
12 specification (including, as noted above, up to two lags of the explanatory
13 variables) and test down to give a final reported equation following the deletion
14 of a number of insignificant terms. The dynamics of the relationship between the
15 explanatory variables and the relevant measure of regional labour market
16 performance are modelled flexibly, allowing these to be determined by the data.

24
25
26

27 We begin by reporting results from an analysis of the determinants of the
28 rate of regional employment growth, which are presented in Table 8. Regional
29 population density is included as an additional explanatory variable in the initial
30 specification for regional employment growth, following evidence from a
31 number of studies of an ‘urban-rural shift’ in the spatial distribution of
32 employment in the United Kingdom, most notably in manufacturing industry but
33 also in services (see, for example, Fothergill and Gudgin, 1982; Rowthorn,
34 2000). In addition – though with contrasting implications for the sign of the
35 estimated relationship – rising population density may be associated with higher
36 levels of consumer demand, providing further justification for the inclusion of
37 terms in this variable.¹⁹

48
49
50
51
52
53

54
55 ¹⁸ It is also worth bearing in mind that the power of panel unit root tests depends on the presence
56 of a reasonably long time-series dimension to the data - a minimum of 20 observations as a rough
57 rule of thumb. While for most of our variables the number of observations in the data series is a
58 little above this threshold, in the case of the log of the rate of non-employment it is marginally
59 below.

60 ¹⁹ Population density is defined as number of persons per square kilometre. The regional
population figures are taken from NOMIS, www.nomisweb.ac.uk, while the data on land area
are from *Regional Trends*.

Data for regional population density is available only from 1981, hence the equations for regional employment growth (which include up to two lags of the explanatory variables) are estimated using data for 1983-2001, the latter being the latest date for which data is available. Column (1) of Table 8 shows the results obtained from an equation in which the Neumann-Topel measure, *Risk*, is included to capture the effects of specialisation or diversity in a region's industry mix. The results indicate that, as might be expected, positive shocks to industry employment have a positive effect on the overall rate of regional employment growth, though the effect is partially reversed in the longer term. Moreover, the effects of changes in the value of *Shock* appear to be quite persistent, showing up as significant with a lag of up to two years. The coefficients on the terms in *Risk* indicate that a higher degree of specialisation in employment – and hence a relatively high exposure to the risk of industry employment shocks - has a positive effect on the rate of regional employment growth both in the short-run and in the long-run. While the validity of this finding may be called into question by the evidence from the panel unit root tests, which suggested that while employment growth may be a stationary variable *Risk* may be I(1), the effect seems to be statistically well-determined. The finding that specialisation is associated with a higher rate of employment growth is in contrast to the evidence from other studies, most notably that of Glaeser et al (1992), who find that for cities in the USA, greater diversity rather than specialisation provides a stimulus to employment growth.²⁰ The most likely explanation for the result obtained

56
57
58
59
60

²⁰ Similarly, for Canada, Shearmur and Polèse (2005) report that in general greater initial diversity in local employment structures tends to be associated with greater subsequent employment growth. In contrast, however, for urban areas they find evidence that in the late 1990s increasing specialisation was associated with more rapid employment growth, suggesting that the relationship between diversity and employment growth may be both area and period-specific.

1
2
3 here is that within the UK regions a high degree of employment specialisation
4 provides opportunities for the transmission of spillover effects between firms of
5
6 employment creating innovations.
7
8
9

10 Further down the column, there is evidence – albeit below conventional
11 levels of statistical significance – that changes in the Lilien index of sectoral
12 shifts are associated with relatively low rates of employment growth, suggesting
13 that structural change may act to impede the performance of regional labour
14 markets. In contrast, lagged growth in regional population density has a strong
15 positive effect on regional employment growth, suggesting that rising population
16 density may be associated with growth in local levels of labour demand.
17
18
19
20
21
22
23
24
25

26 In column (2), we investigate the potential effects of industry
27 specialisation a little further by breaking down the measure *Risk* into its two
28 constituent components: the component that is due to the within-industry
29 variance of shocks, *RiskV*, and a second component that is due to the covariance
30 of shocks between industries, *RiskC*. The results indicate that the two
31 components of *Risk* are broadly similar in their effects on regional employment
32 growth, though the covariance component has a slightly stronger positive effect.
33
34
35
36
37
38
39
40
41
42

43 In column (3), the measure of *Risk* is replaced with the *CARS* index of
44 employment specialisation. In this case, the coefficient for the first difference of
45 *CARS* suggests that increasing specialisation has a weakly positive effect on
46 regional employment growth, which is broadly supportive of the results from the
47 previous two columns. The results in this column suggest, in addition, a slightly
48 stronger negative effect on employment growth from changes in the Lilien index.
49
50
51
52
53
54
55
56

57 In Table 9, we shift attention to the unemployment rate as a measure of
58 regional labour market performance and report estimates of equations with the
59
60

1
2
3 natural logarithm of the regional unemployment rate as the dependent variable.
4
5 Two lags of the dependent variable are included in the equations, in order to
6
7 capture the dynamics in the relationship between the regional unemployment rate
8
9 and its determinants. As a consequence of the inclusion of these terms, the
10
11 Arellano-Bond GMM estimator is used to correct for the biases that would
12
13 otherwise result from the correlation between the lagged dependent variable and
14
15 the regional fixed effects. As is well known, the differencing procedure involved
16
17 in the implementation of the Arellano-Bond estimator leads to first order serial
18
19 correlation in the disturbance term of the estimated equation. The validity of the
20
21 estimator hinges on the absence of second order serial correlation from the
22
23 regression disturbances, a condition which the relevant test statistic indicates is
24
25 satisfied in the case of the three equations reported in Table 9.²¹
26
27
28
29
30
31

32 As in the equations for regional employment growth, shocks to industry
33
34 employment appear to be a significant determinant of regional unemployment
35
36 rates, with effects that are quite strongly persistent.²² The coefficient for the
37
38 second lag of the Lilien index is also statistically significant, indicating that
39
40 sectoral shifts are a significant contributor to regional unemployment disparities.
41
42 The evidence on the effects of employment specialisation/diversity indicates that
43
44 in general, a high or rising degree of specialisation has a positive effect on the
45
46 regional unemployment rate, a finding that appears to contradict the evidence
47
48 from the equations for regional employment growth. However, the effects on the
49
50 regional unemployment rate are only weakly determined.²³ Perhaps the most
51
52
53
54
55

56
57 ²¹ The estimation period for these equations is 1978-2001.

58 ²² Note, however, that for each of the three specifications shown in the Table the coefficient for
59 the one-year lag of *Shock* was statistically insignificant and this term was therefore deleted from
60 the equation.

²³ In contrast, Neumann and Topel (1991) find that the level of *Risk* has a strong positive effect
on the rate of unemployment in U.S. states.

1
2
3 interesting finding in this context is the evidence from the estimates reported in
4 column (2), which indicates that the within-industry variance of employment
5 shocks and the covariance of shocks across industries appear, on balance, to have
6 opposite effects on the regional unemployment rate. Again, however, while the
7 coefficient for the contemporaneous value of the covariance of industry shocks
8 has a statistically significant negative value, on the whole these results are not
9 particularly well determined.²⁴

11
12
13
14
15
16
17
18
19
20 Finally, we turn to our third measure of regional labour market
21 performance, the rate of non-employment. As noted in earlier sections, the
22 numerator of the non-employment rate includes individuals who are registered as
23 unemployed plus those outside the labour force, and thus this variable represents
24 a more comprehensive measure of the extent of joblessness within a region than
25 the rate of unemployment alone. In this analysis, we include as additional
26 explanatory variables two demographic control variables: the percentage of the
27 working age population in a region that is male (*PMale*) and the percentage of
28 the working age population aged 25 or under (*PYoung*).²⁵ The former is included
29 in recognition of the fact that while differences in labour force participation rates
30 between males and females in the United Kingdom have tended to narrow over
31 the past twenty years, participation rates nevertheless tend to be higher amongst
32 males than amongst females. The latter variable is included to control for
33 variations in non-employment rates that may be expected to occur across
34 different age groups within the working age population.²⁶

The equations for regional rates of non-employment are estimated using data for 1983-2001, with the absence of data for Northern Ireland meaning that the sample size for these regressions is limited to 209 observations. The results reported in Table 10 indicate that as in the analysis of regional unemployment rates, there is strong evidence that differences in industry structure between regions lead to differences in the effects of industry-wide employment shocks on regional labour markets.²⁷ Regions that, as a result of their industry structure, experience relatively large positive shocks to employment tend to have lower rates of non-employment other things equal. In contrast, for the Lilien index of sectoral shifts, evidence is found only for a short-run effect on the regional non-employment rate and even this is below conventional levels of statistical significance. While evidence of a stronger effect might have been expected, the sign of the estimated relationship is at least consistent with the findings from the equations for the regional unemployment rate and the rate of employment growth.

55
56
57
58
59
60

The evidence on the effects of specialisation or diversity in a region's industry-employment mix indicates that a greater or rising degree of specialisation leads to a lower rate of non-employment – evidence which is consistent with the findings from the analysis of regional rates of employment growth rather than the rate of unemployment. When the effects of the individual components of *Risk* are studied in column (2) the evidence indicates that in the

aged over 50 and, alternatively, the proportion of workers aged over 55. However, while the results for the other variables in the equation were largely unaffected, the coefficients for these age variables turned out to be implausibly signed.

²⁷ It was noted in section 2 above that due to the way in which the figures are constructed the data used for this analysis give a misleading impression of the rate of non-employment in London. However, as long as commuting patterns remain relatively stable over time, the effects of the distortion created by commuting from outside the region should be absorbed by the regional fixed effects that are included in the regression model.

1
2
3 long-run it is the within-industry variance of shocks that matters rather than the
4
5 cross-industry covariance of shocks, though there is a statistically significant
6
7 negative effect from the two year change (i.e. the second difference) in the latter
8
9 variable in the short-run. Finally, the findings for the two demographic variables
10
11 indicate that, other things equal, the rate of non-employment is lower in regions
12
13 with a relatively high percentage of males in the working age population, and
14
15 lower too in regions with a relatively high percentage of members of the
16
17 population of working age aged under 25.²⁸ The latter may seem a somewhat
18
19 surprising result given the tendency towards higher rates of participation in post-
20
21 compulsory education in the United Kingdom in recent years but may reflect the
22
23 effect of relatively high rates of employment amongst young workers when they
24
25 do eventually enter the labour market.²⁹
26
27
28
29
30
31

32 In summary, the evidence from the three pieces of analysis above
33
34 indicates that industry structure has statistically significant effects on regional
35
36 labour market performance. Amongst the explanatory variables we use to
37
38 examine the effects of industry structure, the evidence is most consistent in the
39
40 case of the variable *Shock*, which captures the regional impact of industry-wide
41
42 employment shocks. The impact of these shocks differs between regions because
43
44 of regional differences in the industry composition of employment. The findings
45
46 for this variable indicate that positive shocks to industry employment –
47
48 interpreted here as resulting from shocks to labour demand – lead to a faster rate
49
50 of employment growth, a lower unemployment rate and a lower rate of non-
51
52
53
54
55

56
57 ²⁸ Note, however, that the variable for the percentage of males in the population of working age is
58 omitted on grounds of statistical insignificance from the equation reported in the third column
59 and has a coefficient that is not quite significant in column (2).

60 ²⁹ In contrast to this finding, Erdem and Glyn (2001) note the relatively high rate of non-
employment among 16-24 year olds in the UK, in particular among those with low educational
qualifications.

1
2
3 employment. Elsewhere, the evidence for industry structure effects on regional
4 labour market performance is a little more mixed. Evidence is found which
5 shows that regions that are subject to a greater degree of structural change,
6 reflected in a higher variance of employment growth across industries, may as a
7 result experience higher rates of unemployment and, in the short-run at least,
8 lower rates of employment growth and a higher rate of non-employment than
9 other regions. Finally there is evidence that regions that have a high and
10 increasing degree of specialisation in their industry-employment mix may
11 experience a faster rate of employment growth and a lower rate of non-
12 employment. The most likely explanation for this result is that it reflects the
13 effects of industry-specific knowledge spillovers between firms that share a
14 common regional location.³⁰

44
45
46
47
48
49
50
51
52
53 ³⁰ In further, unreported, work we experimented with including the controls for demographic
54 effects, *PMale* and *PYoung*, in equations for regional rates of employment growth and the rate of
55 unemployment. Data on the two demographic variables is unavailable for Northern Ireland,
56 however, hence the sample for these experiments was restricted to data from the regions of Great
57 Britain. The results indicate that the proportion of young workers in the population of working
58 age has a positive short-run effect on the rate of employment growth and a negative short-run
59 effect on the regional rate of unemployment. The results are therefore broadly consistent with the
60 findings reported above for the effects of this variable on the rate of non-employment. The
proportion of males in the population of working age appears to have no effect. The results for

disadvantaged by the effects of structural change. To examine the effect of changes in industrial structure on the unemployment rate in this region we can compute the value of *Shock* that would have prevailed in the region if the share of employment in each of our 30 industries had remained constant at its 1975 value. The results of this exercise indicate that over the five years from 1996-2000 the value of *Shock* would on average have been 0.251 greater in this region had industry shares remained at their 1975 values (i.e. the positive shock to employment would have been 0.251 percentage points higher). Multiplying this figure by the value of the long-run coefficient for *Shock* obtained from column (1) of Table 9 (i.e., -0.262) gives a value of -0.07.³¹ The implication is that by the beginning of the 21st Century, once the dynamic effects had been allowed to work through, changes to industry employment shares will have resulted in the unemployment rate in the North East being around 7 percent (note, not 7 percentage points) higher than it would have been had industry employment shares remained at their 1975 values. In the context of a regional unemployment rate that in the period 2000-03 averaged around 8.3 percent this effect seems relatively small. The impact of structural change on the unemployment rate in the North East appears rather larger once account is taken of changes in the value of the Lilien index. If we compare the average value of the Lilien index for the North East in the period 1996-2001 with its average value in 1975-80 then performing a similar exercise as that for the variable *Shock*, again using the estimates from column (1) of Table 9, we find that the increase in the value of the Lilien index leads to an increase in the region's unemployment rate of 14

the effects of the other variables were broadly unaffected by the inclusion of these terms. The detailed results are available on request from the author.

³¹ This is rounded up slightly. The long-run coefficients from columns (2) and (3) are -0.287 and -0.248, respectively, which produce effects of a similar order of magnitude.

1
2
3 percent in the long-run.³² Overall, however, the effect of changes in industry
4 structure on the evolution of unemployment in the North East region seems
5 relatively small.³³
6
7
8
9

10 To what extent to differences in industry structure appear to be able to
11 account for the disparities in unemployment performance across regions? Again,
12 the figures suggest that the effects in fact are not particularly large. The data on
13 the variable *Shock* indicate that in the second half of the 1990s, for example,
14 differences in industry structure meant that industry employment shocks actually
15 had a more favourable impact on the unemployment rate in the North East than
16 in the South East. In contrast, the higher value of the Lilien index in the North
17 East is estimated to raise the unemployment rate in this region by around 14
18 percent relative to that in the South East but even this effect seems relatively
19 small when set against an average unemployment rate differential of nearly 6
20 percentage points between the two regions during the period 2000-03.

39 **4. Summary and Conclusions**

40
41 In this paper, we have attempted to gauge the extent of structural change
42 and changes in the degree of employment specialisation within regions of the
43 United Kingdom and examine their effects on regional labour market
44 performance. We have analysed the effects of structural change on regional
45 labour market performance by using information on industry employment shares
46 to construct a measure of the regional impact of shocks to aggregate industry
47 employment and by calculating values for each region of the index of sectoral

58
59 ³² For the North East, the increase in the value of the Lilien index in the 1990s may, in particular,
60 reflect the effects of employment decline in the coal industry.

1
2
3 shifts developed by Lilien (1982). The evidence from the latter indicates that
4
5 over the period from 1972-2001 the incidence of sectoral shifts – a measure of
6
7 the pace of structural change – was highest in the North East of England, a region
8
9 that is often perceived as having suffered from the effects of structural change.
10
11 In contrast, the pace of structural change was lowest in the South East.
12
13

14
15 Measures of specialisation and/or diversity in regional employment have
16
17 been constructed, based on the Coefficient of Absolute Regional Specialisation
18
19 (*CARS*), and a measure of a region's exposure to the risk of labour demand
20
21 shocks, due to Neumann and Topel (1991). The evidence from these measures
22
23 indicates that since the 1970s employment in all regions has become increasingly
24
25 specialised within a relatively narrow range of industries, while changes in the
26
27 structure of employment have for most regions led to a modest decline in
28
29 exposure to the risk of labour demand shocks (with a much steeper decline in the
30
31 North East of England).
32
33
34

35
36 The results from panel data regression models in which these various
37
38 measures are used as explanatory variables indicate that differences between
39
40 regions in the industry structure of employment have statistically significant
41
42 effects on regional labour market performance. In particular, differences in
43
44 industry structure give rise to asymmetries between regions in the effects of
45
46 aggregate industry employment shocks, which have significant effects on
47
48 regional unemployment rates, non-employment rates and the rate of regional
49
50 employment growth.
51
52
53

54
55
56
57
58
59
60 ³³ In these calculations, we have ignored the effect of the insignificant variable *Risk*. However, taking the reported coefficient for *Risk* at face value, changes in the value of this variable would have contributed to a reduction in the unemployment rate in the North East.

However, while industry structure effects may be statistically significant, the evidence from this analysis indicates that quantitatively they are of relatively minor importance in accounting either for variations in regional labour market performance over time or for performance disparities between regions. In terms of the econometric models reported in this paper, it seems that most of the performance disparities between regions can only be accounted for by unobserved regional ‘fixed effects’, the sources of which remain to be explained. During the past two decades, a large body of literature has developed that has both highlighted the existence of and sought to find explanations for a trend decline in the relative demand for unskilled labour in the UK and other developed market economies.³⁴ Little attempt has been made to examine the regional implications of this trend but there are reasons to believe that this could be a significant factor in accounting for the observed persistent differentials in regional labour market performance. In particular, Bradley and Taylor (1996) and Green and Owen (2006) have shown that the less prosperous regions in the UK tend to have higher proportions of individuals with relatively low educational qualifications. It is well known that such individuals tend to experience relatively high rates of unemployment and economic inactivity (see Erdem and Glyn, 2001). While skill differentials between regions will to some extent be reflected in differences in industry structure and the incidence of structural change (Bernard et al, 2005), the correspondence between the skill and industry composition of regional employment is unlikely to be unique. Unfortunately, data limitations preclude an investigation of this issue in the current study.

³⁴ See, for example, Machin (1996) and Berman et al (1994).

The findings of this study indicate that the convergence that has taken place over the past thirty years in the industry structures of different regions in the United Kingdom has had only a limited effect in reducing disparities in regional labour market performance. For public policy, the implication is that attempts to stimulate further convergence – e.g. through subsidies to the creation of service sector jobs in areas of traditional manufacturing employment – are unlikely, in themselves, to be of much benefit in tackling these regional disparities. The benefits of such measures are more likely to be felt in terms of their direct job creation effects, which when combined with New Deal-type schemes aimed at improving the employability of workers in under-performing regions, are likely to prove a more effective remedy for tackling disparities in the labour market performance of UK regions.

Acknowledgement

* I am grateful to Katerina Homenidou of Cambridge Econometrics for supplying the data on regional employment by industry used in this study, and to the Royal Economic Society Small Academic Expenses Fund for a grant to cover the cost of purchasing the data. My thanks are due also to Phil Murphy, Ian Stone, participants at a Departmental workshop in Durham and the 2006 WPEG conference in Canterbury, and most of all to an anonymous referee, for their helpful comments on previous drafts. I retain responsibility for any remaining errors in the analysis, interpretation or presentation.

Table 7. Panel Unit Root Tests

Variable	CIPS
$\Delta \ln e$	-2.74*
$\ln u$	-1.82
$\ln ner$	-1.82
<i>Shock</i>	-4.35*
<i>Lilien</i>	-2.93*
<i>Risk</i>	-2.00
<i>CARS</i>	-2.15

Note

The CIPS test is an extension to the IPS test developed for testing for unit roots in panel data by Im, Pesaran and Shin (2003) and is based on estimating regression equations of the form

$$\Delta y_t = \alpha + \beta_i \Delta y_{t-i} - \gamma_{t-1} + \phi_i \Delta \bar{y}_{t+1-i} + \theta \bar{y}_{t-1} + \varepsilon_t$$

for each of the cross-section units in the panel, where y is the variable of interest and \bar{y} is its cross-sectional average value. The inclusion of this term is to take account of any cross-sectional dependence between the individual time-series. The number of lagged difference terms included in the test regression is determined by the need to ensure that the disturbances of the equation are free from serial correlation. The test provides a test of the null hypothesis of a unit root against the alternative of stationarity. The test statistic, which is akin to the ADF test statistic used to test for unit roots in a standard time-series setting, is calculated by taking the average value of the 't-ratio' for the estimated value of γ in the individual time-series regressions. Critical values of the statistic for various values of N , the number of cross-section units, and T , the number of time-series observations, are tabulated in Pesaran (2005).

For all variables except $\ln ner$, the test regressions are estimated using data for the period 1977-2001 for each of the 12 UK regions. For $\ln ner$, the sample period is 1983-2001 and data is available only for the 11 regions of Great Britain, with Northern Ireland excluded. An asterisk denotes that the test statistic is significant at the 5% level.

N	228	228	228

Notes: Estimation is by Least Squares Dummy Variables, with an allowance for regional fixed effects. Absolute t-ratios based on heteroscedasticity-robust standard errors are given in parenthesis. Asterisks denote that the coefficient is statistically significant at the 1% (***), 5% (**) or 10% (*) level on a two-sided test. A full set of time dummies is included in each equation. m_1 denotes a test statistic for first order serial correlation in the equation residuals, which has an asymptotic standard normal distribution.

Table 9. Panel Data Regressions of Regional Unemployment Rates, 1978-2001.The dependent variable is $\ln u_{rt}$

	(1)	(2)	(3)
$\ln u_{rt-1}$	1.252*** (47.0)	1.240*** (57.5)	1.252*** (49.1)

m_2	-0.61	-0.34	-0.59
N	288	288	288

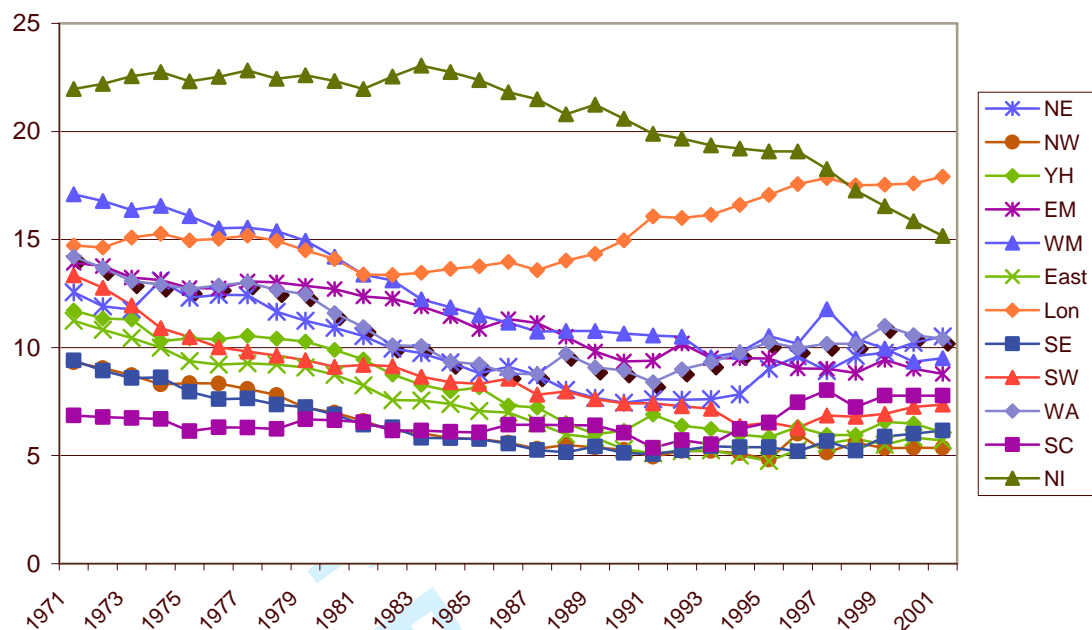

Notes: Estimates are obtained using the GMM in differences estimator of Arellano and Bond (1991). Absolute t-ratios based on heteroscedasticity-robust standard errors are given in parenthesis. Asterisks denote that the coefficient is statistically significant at the 1% (***), 5% (**) or 10% (*) level on a two-sided test. A full set of time dummies is included in each equation. m_1 and m_2 denote test statistics for first and second order serial correlation, respectively, in the residuals of the equation. Each has an asymptotic standard normal distribution. A plus mark + (++) indicates that the test statistic is significant at the 5% (1%) level.

N	209	209	209

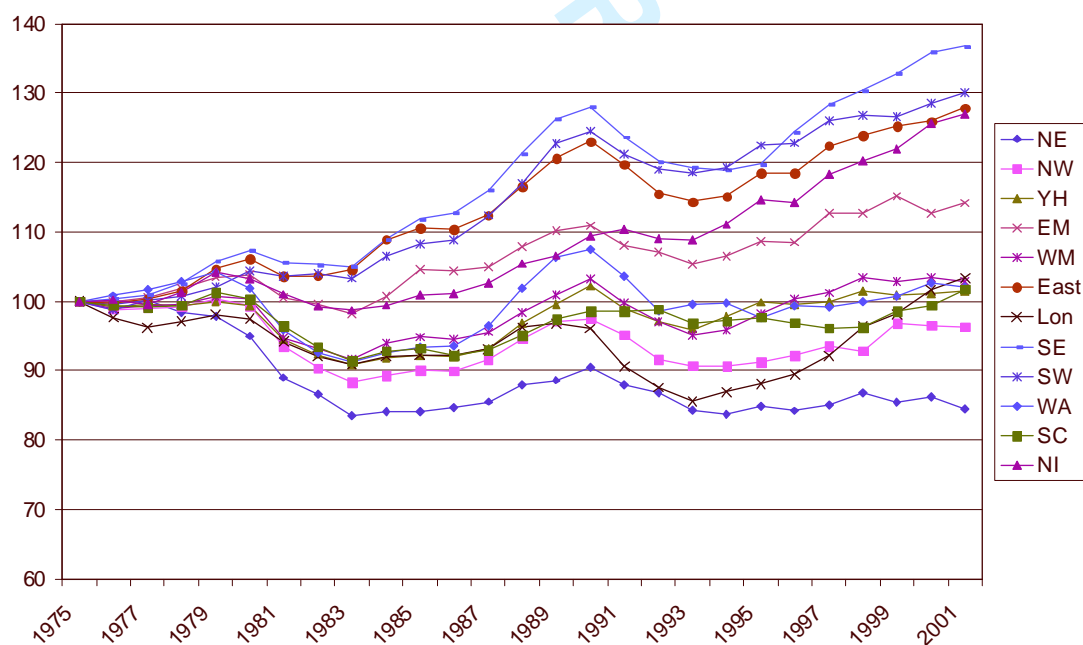

Notes: Estimates are obtained using the GMM in differences estimator of Arellano and Bond (1991). Absolute t-ratios based on heteroscedasticity-robust standard errors are given in parenthesis. Asterisks denote that the coefficient is statistically significant at the 1% (***), 5% (**) or 10% (*) level on a two-sided test. A full set of time dummies is included in each equation. m_1 and m_2 denote test statistics for first and second order serial correlation, respectively, in the residuals of the equation. Each has an asymptotic standard normal distribution. A plus mark ⁺ (⁺⁺) indicates that the test statistic is significant at the 5% (1%) level.

Figure 1. Coefficient of Regional Specialisation

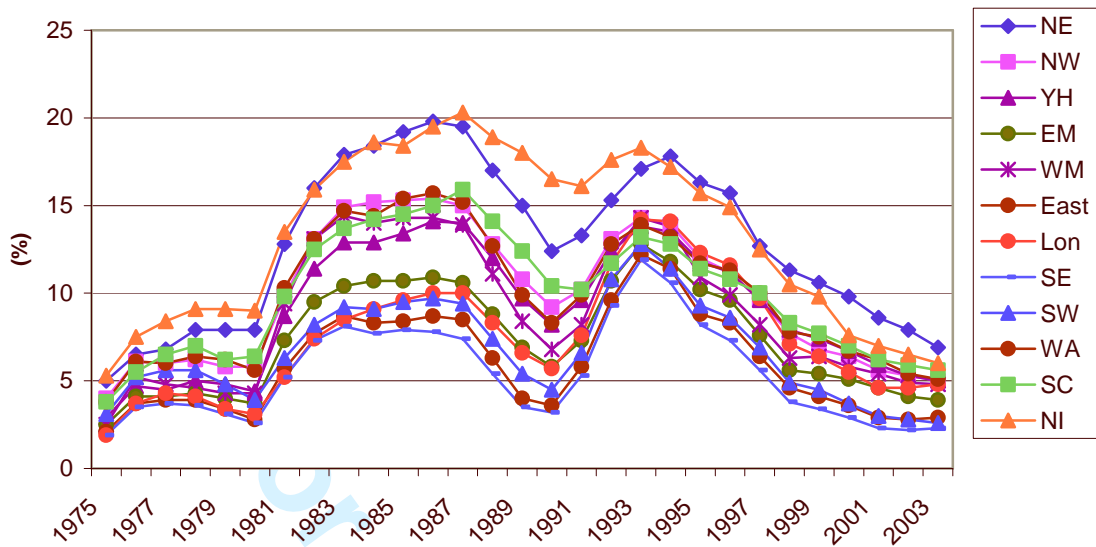

Source: author's calculations based on data from Cambridge Econometrics

Figure 2. Employment in Government Office Regions (1975=100)

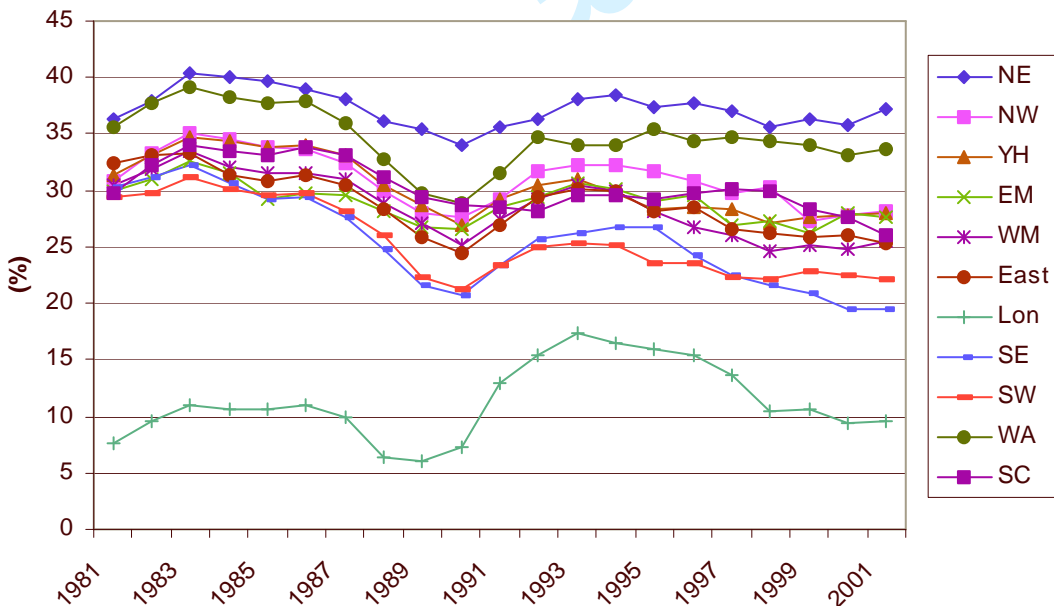

Source: author's calculations based on data from Cambridge Econometrics

Figure 3. Claimant Count Unemployment Rates, 1975-2003

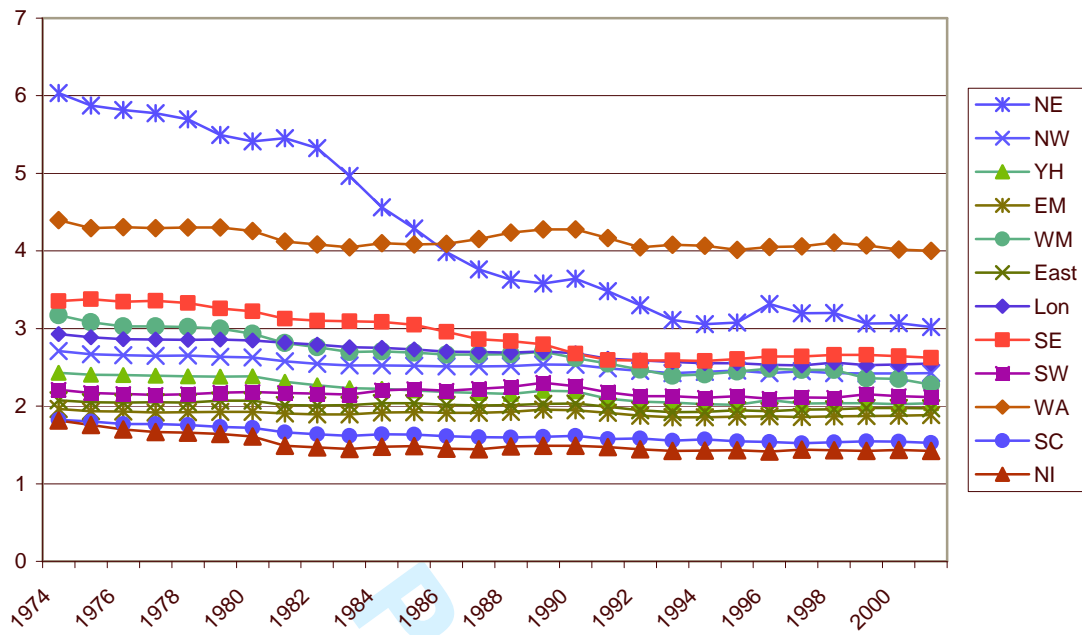

Source: ONS

Figure 4. Rates of Non-employment in UK Government Office Regions

Note: For each region, the non-employment rate in proportionate terms is calculated as one minus the ratio of the number of individuals employed in the region to the size of the population of working age. The resulting figure is then multiplied by 100. The employment data were provided by Cambridge Econometrics, while the figures for the population of working age come from NOMIS.

Figure 5. Employment Risk

Note: variances of log employment disturbances, *Risk*, calculated as described in the text.

Appendix - List of Industries Used in Calculation of the Lilien Index and Employment Specialisation Measures

1. Agriculture etc
2. Electricity, gas & water
3. Construction
- Mining & quarrying**
4. Coal
5. Oil & natural gas etc
6. Other mining
- Manufacturing**
7. Food, drink & tobacco
8. Textiles, clothing & leather
9. Wood & wood products
10. Paper, printing & publishing.
11. Manufactured fuels
12. Chemicals & man-made fibres
13. Rubber & plastic products
14. Non-metal mineral products
15. Basic metals & metal products
16. Mechanical engineering
17. Electronic, electrical and instrument engineering
18. Motor vehicles
19. Other transport equipment
20. Other manufacturing
- Services**
21. Retailing
22. Distribution nes
23. Hotels & catering
24. Transport & communications
25. Banking & finance
26. Insurance
27. Other business services
28. Public administration & defence
29. Education & health
30. Other services

The employment data is supplied by Cambridge Econometrics. The industry aggregates are based on a mapping of Minimum List Headings under the 1968 Standard Industrial Classification (SIC) on to the Activity Headings under the 1980 SIC and on to Divisions under the 1992 SIC (Wren and Taylor, 1999).
