What Enhances Mathematical Ability? Inter- and Intra-Country Inequality in Test Scores of 15-year Olds

Mark Bailey^{*} and Vani K Borooah⁺
University of Ulster

July 2007

Abstract

This paper examines the mathematical abilities of 15-year olds in a range of countries which participated in the 2003 cycle of the OCED's Programme for International Student Assessment (PISA). Utilising information on the scores obtained by individual students in the mathematical part of the PISA assessment, we use a range of indicators from the literature on inequality and poverty to evaluate the "mathematical performance" of participating countries. Since data from PISA contained a wealth of information on the circumstances of the students, in terms of their home and school environment, we identify, and examine the relative influence of, factors which serve to enhance the mathematical performance of students in the PISA assessment.

1. Introduction

Economists are concerned with the levels of mathematical ability that individuals have because the mathematical ability of individuals affects economic performance. At a macroeconomic level, studies making use of international school test score data have found a link between mathematical ability and the economic growth of the state (Hanushek and Kimko, 2000). This linkage has been recognised by policy makers. For example, Alan Greenspan giving testimony before the Committee on Education and the Workforce of the U.S. House of Representatives in March 2004 noted that:

“Research on wealth creation in both emerging and developed nations strongly suggests that it is the knowledge and the skill of our population interacting under our rule of law that determine our real incomes”

And this was partly due to the fact that:

“Many of our students languish at too low a level of skill, and the result is an apparent excess of supply relative to a declining demand. ... The hypothesis that we should be able to improve upon the knowledge that our students acquire as they move from kindergarten to twelfth grade gains some support from international comparisons. A study conducted in 1995 revealed that, although our fourth-grade students were above average in both math and science, by the time they reached their last year of high school they had fallen well below the international average.” (Greenspan (2004))

At a microeconomic level, studies have found positive wage returns for individuals to mathematical ability (Kenny et. al., 1979, Dolton and Vignoles, 2000, McIntosh and Vignoles, 2000). Dolton & Vignoles (2000) refer to the returns to an individual due to the possession of Mathematics ‘A’-level (a Mathematics qualification taken at post-16 level); interestingly they find that that the return is not

evident at the start of a person's career but occurs later; Dolton and Vignoles (2000) argue that the return is due to employers observing that employees with A-level mathematics had higher levels of productivity compared to those who did not have this qualification. In a similar vein, Wolf (2002) argues that "even allowing for other factor imaginable, people who took A-level mathematics earn substantially more – around 10 per cent more- than those who did not" (p. 35).

Jenkins et al (2003), looking at life-long learning, found that mathematical ability for women was particularly important in determining which of them would undertake lifelong learning that lead to a qualification – an important consideration given the emphasis on lifelong leaning in recent UK government policy thinking such as the "new skills agenda".

Furthermore, whilst papers such as Murnane et al (1995) and Ingram & Neumann (2006) support this claim, they also present evidence that, for the United States, the possession of mathematical skills and their level have become increasingly important in the determination of wage rates in recent years. To quantify these results, Ingram & Neumann (2006) find that the return to mathematical and verbal ability has nearly doubled between 1980 and 1998.

The OCED's Programme for International Student Assessment (PISA) is one of a range of trans-national tests of student ability; discussion of how it compares to other assessments can be found in Hansen & Vignoles (2005) and Brown et al (2007). PISA is a collaborative effort, involving all OECD countries and a significant number of partner countries, to measure how well 15 year students "are prepared to meet the challenges of today's knowledge society". The PISA 2003 assessments consist of paper-and-pencil tests and the following domains are tested: (i) mathematical literacy; (ii) reading literacy; (iii) scientific literacy.

On the basis of these tests, each of 276,150 students in 41 countries was assigned a score for mathematics, reading, and science. In addition to this information about how well students fared in their assessments, the PISA data contains a wealth of information on the circumstances surrounding a student. These relate to inter alia: (i) his/her personal circumstances, living arrangements etc; (ii) parental attributes relating to education, class; (iii) home possessions and environment relating to books, computers, internet, place to study; (iv) school circumstances relating to amount of instruction, relationship with teachers, type of school etc.

Against this background, this paper examines the mathematical abilities of 15-year olds in a range of countries which participated in the 2003 cycle of PISA. Utilising information on the scores obtained by individual students in the mathematical part of the PISA assessment, we use a range of indicators from the literature on inequality and poverty to evaluate the “mathematical performance” of participating countries. Since, as noted above, data from PISA contained a wealth of information on the circumstances of the students, particularly in terms of their home and school environment, we identify, and examine the relative influence of, factors which serve to enhance the mathematical performance of students in the PISA assessment.

2. Equity Sensitive Indicators of Student Assessment Scores

In a paper prepared for the 1995 *Human Development Report*, Anand and Sen (1997) pointed out that a country's non-economic achievements were likely to be unequally distributed between subgroups of its population: for example, in terms of gender equality, which was the focus of their concern, the female literacy rate, or female life expectancy, was often lower than that for males. In the face of such inter-group inequality, they argued that a country's achievement with respect to a particular outcome should not be judged exclusively by its mean level of achievement (for example, by the average literacy rate for a country) but rather by the mean level *adjusted to take account of inter-group differences in achievements*.

Anand and Sen (1997) proposed a method, based on Atkinson's (1970) seminal work on the relation between social welfare and inequality, for making such adjustments and they termed the resulting indicators *equity sensitive indicators*. They further suggested that assessments of country achievements should be made on the basis of such equity sensitive indicators rather than, as was often the case, on the basis of its mean level of achievement. This would, then, allow a comparison between two countries, one of which had a lower mean achievement level, but a more equitable distribution of achievement, than the other.¹ In this section we apply these ideas to the student assessment scores (SAS) - hereafter, simply, "scores" – in the PISA data.

Suppose that \bar{X} is the average score in a country where X_i is the score of student i ($i=1\dots N$). We know that, because of inequality in the distribution of scores between students, the average score of a country will not be achieved by all its students.

¹ Anand and Sen (1997) compared the Honduras (with an average literacy rate of 75%, distributed between men and women as 78%, 73%) with China (with an average literacy rate of 80%, distributed between men and women as 92%, 68%) and asked which country should be regarded as having the "better" achievement with regard to literacy: China with a higher overall rate or the Honduras with greater gender equality?

1
2
3 Therefore, in assessing the SAS achievement of a country, by how much should we
4 reduce its average SAS to take account of inequality in scores?
5
6

7
8 The answer to this question depends on how *averse we are to inequality*. In his
9 seminal paper on income inequality, Atkinson (1970) argued that we (society) would
10 be prepared to accept a reduction in average income, *provided the lower income was*
11 *equally distributed*, from a higher average income which was unequally distributed.²
12
13 The size of this reduction depended upon our degree of "inequality aversion" which
14 Atkinson (1970) measured by the value of a (inequality aversion) parameter, $\varepsilon \geq 0$.
15
16 When $\varepsilon = 0$, we are *not at all* averse to inequality implying that we would not be
17 prepared to accept even the smallest reduction in average income in order to secure an
18 equitable distribution. The degree of inequality aversion increases with the value of
19 ε : the higher the value of ε , the more averse we would be to inequality and, in order
20 to secure an equitable distribution of income, the greater the reduction in average
21 income we would find acceptable.

23
24
25
26
27
28
29
30
31
32
33
34
35

36 These ideas can, equally well, be applied to student assessment scores. We
37 can reduce the average score, \bar{X} , of a country by the amount of inter-student
38 inequality in scores to arrive at X^e , a "group equity sensitive" score for the country,
39 $X^e \leq \bar{X}$. We refer to X^e as the *equally distributed equivalent score*. The size of this
40 reduction (as given by the difference, $\bar{X} - X^e$) depends upon our aversion to
41 inequality: the lower our aversion to inequality, the smaller will be the difference and,
42 in the extreme case in which there is no aversion to inequality ($\varepsilon = 0$), there will be
43 no difference between the average and the equity sensitive scores. Three special cases,
44 contingent upon the value assumed by ε , may be distinguished:

² In the language of economics, the two situations would yield the same level of social welfare, i.e. be 'welfare equivalent'.

1. When $\varepsilon = 0$ (no inequality aversion), X^e is the *arithmetic mean* of the student scores: $X^e = \bar{X}$

2. When $\varepsilon = 1$, X^e is the *geometric mean* of the student scores: $X^e = \left[\prod_{i=1}^N (X_i) \right]^{1/N} < \bar{X}$.

3. When $\varepsilon = 2$, X^e is the *harmonic means* of the student scores:

$$X^e = \left[\sum_{i=1}^N \frac{N}{X_i} \right]^{-1} < \bar{X}.$$

Table 1 shows the equity sensitive scores for each of the 41 countries in the PISA data, contingent upon the amount of inequality in the distribution of scores between *all* the 15 year olds in (the sample for) that country.

3. Inequality Decomposition

Suppose that the N students are sub-divided into K mutually exclusive groups (indexed $k=1..K$) where group k has N_k students and a score vector, \mathbf{S}_k . An interesting question is how much of the observed difference between students in their assessment scores is the result of differences *between* groups and how much is the result of differences *within* groups? We answer this question using additively decomposable inequality indices.

An inequality index $I(\mathbf{S}; N)$ is said to be additively decomposable if:

$$I(\mathbf{S}; N) = \sum_{k=1}^K I(\mathbf{S}_k; N_k) w_k + \mathbf{B} = \mathbf{A} + \mathbf{B}$$

where: $I(\mathbf{S}; N)$ represents the *overall* level of inequality defined over the vector of all the scores, \mathbf{S} ; $I(\mathbf{S}_k; N_k)$ represents the level of inequality *within* group k ; \mathbf{A} – expressed as the weighted sum of the inequality in each group, w_k being the weights – and \mathbf{B} represent, respectively, the *within-group* and the *between-group* contribution to overall inequality.

If, indeed, inequality can be ‘additively decomposed’ along the above lines then, as Cowell and Jenkins (1995) and Jenkins (1995) have argued, the proportionate contribution of the between-group component (**B**) to overall inequality is the income inequality literature’s analogue of the R^2 statistic used in regression analysis: the size of this contribution is a measure of the amount of inequality that can be ‘explained’ by the factor (or factors) used to subdivide the sample which, in this case, is country.

Only inequality indices which belong to the family of *Generalised Entropy Indices* are additively decomposable (Shorrocks (1980)). These indices are defined by a parameter θ and, when $\theta=0$, the weights are the population shares of the different groups (that is, $w_k = N_k / N$); since the weights sum to unity, the within-group contribution **A** is a weighted average of the inequality levels within the groups. When $\theta=0$, the inequality index takes the form:

$$I(\mathbf{S}; N) = \left(\sum_{i=1}^N \log(S_i / \bar{S}) \right) / N$$

where: $\bar{S} = \sum_{i=1}^N S_i / N$ is the mean score over the entire sample of students. This inequality index is Theil’s (1967) Mean Logarithmic Deviation (MLD) index and, because of its attractive features in terms of the interpretation of the weights, it was the one we used to decompose inter-student inequality in scores by various grouping of students.

The value of the MLD index, for the 276,150 students living in 41 different countries, was 0.024 and the within-country contribution (the value of **A**, above) to this value was 0.017 – thus, 28 percent of inequality in the distribution of the S_i between the students was due to differences *between* the countries in the mean values of their scores and 72 percent was due to inequality *within* the countries.

Another division of students which we analysed was the highest occupational class of a parent: white collar, high skilled (49 percent of students); white collar, low skilled (22 percent of students); blue collar, high skilled (15 percent of students); blue collar, low skilled (14 percent of students). The value of the MLD index, for the 266,329 students whose parental occupational status was recorded, was 0.024 and the within-country contribution (the value of A , above) to this value was 0.021 – thus, 13 percent of inequality in the distribution of the S_i between the students was due to differences in the mean values of scores *between* the occupational classes and 87 percent was due to inequality in student scores *within* the classes.

Another partition we examined was by the level of parental education. The PISA data also provided information on the level of parental education in terms with the highest level of educational attainment of a parent converted into “years of schooling” – the values of this variable ranged from 0, in steps of one year, to 17. From information on parental “years of schooling” we classified students according to whether their parents’ educational level was: low (0-6 years, corresponding to the lowest decile of “years of schooling”); medium (7-15 years, corresponding to 10th-75th percentile); and high (>15 years, corresponding to the top quartile). Of the 267,511 students whose parental “years of schooling” was recorded, 11 percent had parents with “low” education; 66 percent had parents with “medium” education; and 23 percent had parents with “high” education.

The value of the MLD index, for these 267,511 students whose parental educational level was recorded, was 0.024 and the within-country contribution (the value of A , above) to this value was 0.022 – thus, 9 percent of inequality in the distribution of the S_i between the students was due to differences *between* the mean

student scores for the different parental educational levels and 91 percent was due to inequality in student scores *within* the parental educational levels.

4. Mathematical Proficiency

Pisa (2003) defined seven levels of proficiency in mathematics: *level 1*, for $SAS \leq 357.77$; *level 2*, for $357.77 < SAS \leq 420.07$; *level 3*, for $420.07 < SAS \leq 482.38$; *level 4*, for $482.38 < SAS \leq 554.68$; *level 5*, for $554.68 < SAS \leq 606.99$; *level 6*, for $606.99 < SAS \leq 669.3$; *level 7*, for $SAS > 669.3$. The number of students, and the proportion of the total number of students, in each of these categories is shown, for every country, in Table 2.

This table shows that Tunisia (52 percent), Brazil (51 percent), Indonesia (50 percent), Uruguay (30 percent), Mexico (26 percent), Turkey (26 percent), and Serbia (18 percent) had the largest proportion of students at the lowest level of proficiency in mathematics. In all the other countries, less than one in ten students – and, in many countries, less than one in twenty students – were at the lowest proficiency level. At the other extreme, Hong Kong (10 percent), Belgium (8 percent), Japan, Korea, and the Netherlands (all 7 percent) had the largest proportion of students at the highest level of proficiency in mathematics. From these seven levels of proficiency, we conducted a more detailed analysis of students who were “mathematically weak” and those who were “mathematically strong”.

Suppose that a student (i) is regarded as *mathematically weak* if his/her SAS in mathematics is lower than (or equal to) some threshold value represented by z , the “weakness line”, and as *mathematically strong* if his/her SAS in mathematics is greater than (or equal to) some threshold value represented by w , the “strength line”. Then, an aggregate measure of mathematical weakness is provided by any of the following indices:

1
2
3
4
5
6
7
8
9
10
11
12

1. The *Headcount Ratio* (H), which is the proportion of students who are mathematically weak: $H = M / N$, where N and M are, respectively, the total number of students and the total number of mathematically weak students.

13
14
15
16
17

2. The *Weakness Gap Ratio* (P) is the mean distance of the SAS of mathematically weak students from the weakness line, expressed as a

18
19
20
21
22

proportion of the weakness line: $P = \frac{\sum_{i=1}^M (z - X_i)}{Mz} = 1 - \frac{\mu^W}{z}$, where: μ^W is the

23
24

mean score of the mathematically weak students..

25
26
27
28
29
30
31

3. The *Achievement Gap Ratio* (Q) is the mean distance of the outcomes of all the students from the weakness line - the non-weak being assigned a distance of zero - expressed as a proportion of the deprivation line:

32
33
34
35
36

$$Q = \frac{\sum_{i=1}^M (z - X_i)}{Nz} = \frac{\sum_{i=1}^M (z - X_i)}{Mz} \frac{M}{N} = P \times H$$

37

40
41
42
43
44
45
46
47
48
49
50
51
52

4. The *Sen (1976) Measure*: $S = H \times [P + (1 - P) \times G^W]$, where: G^W is the Gini coefficient computed over the scores of mathematically weak students³. If there was no inequality between mathematically weak students in respect of their SAS (i.e. $G^W = 0$) then $S = H \times P = Q$. But, if there was inequality between mathematically weak students in their SAS (i.e. $G^W > 0$), then the Sen index would exceed the Achievement Gap Ratio by the amount:

53
54
55
56
57

$H \times (\mu^P / z) \times G^P$. The Sen index, therefore, represents an *equity sensitive*

58
59
60

³ It is important to emphasise three aspects of Sen's measure: it takes account of the *number* of mathematically weak students, relative to the total number of students, through H , the headcount ratio; it takes account of the *depth* of their weakness through P , the weakness gap ratio; it takes account of *relative weakness* through G^W , the Gini coefficient calculated on the scores of mathematically weak students.

weakness index in the sense that, in addition to taking account of the proportion of mathematically weak students and the depth of their weakness, it also takes account of inequality in scores between mathematically weak students or, as Sen (1976) would have termed it, “relative weakness”.

In a manner analogous to that described above we can define aggregate measures of mathematical strength: the head count ratio; the strength gap ratio; the achievement gap ratio; and the Sen index. Tables 3 and 4 show the values of the mathematical weakness and mathematical strength rates for each of the 41 countries in the sample, where a student was regarded as “mathematically weak” if he/she was placed at the lowest level of proficiency (level 1) and as “mathematically strong” if he/she was placed at the highest two proficiency levels (levels 6 and 7).

Table 3 shows, under the column “head count ratio”, that 12.2 percent of all students were mathematically weak, their scores placing them in the lowest proficiency level; the “Weakness Gap Ratio” shows that the average score of these weak students was 13 percent below the level 1 threshold score of 357.77; the “Achievement Gap Ratio” shows that the mean distance of all students (weak and non-weak) from the level 1 threshold was 1.6 percent; lastly, the Sen ratio bumps up the Achievement Gap Ratio by the amount of inequality between weak students, as measured by the Gini coefficient, to arrive at a figure of 2.3 percent.

Mathematical weakness, as measured by the Sen Index, was lowest (below 0.5%) in Finland, Korea, Netherlands, Canada, The Czech Republic, Macao, and Ireland and highest (above 5%) in Uruguay, Indonesia, Tunisia and Brazil. These results broadly mirror the ranking provided by the head count ratio: countries which have high/low head count ratios for mathematical weakness also have high/low values on the Sen

Index. However, there are some exceptions to this rule: Mexico, Turkey, and Serbia have high head count ratios but the mean scores of their weak students are not far below the level 1 threshold and, further, in these countries, there is not much inequality in the scores of their mathematically weak students: consequently, in spite of having a high head count ratio, these countries have a low value on the Sen Index.

Table 4 shows, under the column “head count ratio”, that 11.8 percent of all students were mathematically strong, their scores placing them in the two highest proficiency levels, levels 6 and 7; the “Strength Gap Ratio” shows that the average score of these weak students was 6.9 percent above the level 6 threshold score of 606.99; the “Achievement Gap Ratio” shows that the mean distance of all students (strong and not-strong) from the level 6 threshold was 0.82 percent; lastly, the Sen ratio bumps up the Achievement Gap Ratio by the amount of inequality between strong students, as measured by the Gini coefficient, to arrive at a figure of 1.2 percent. Mathematical strength, as measured by the Sen Index, was greatest (2 percent or higher) Australia, Belgium, Czech Republic, Hong Kong, Japan, Korea, Netherlands, and New Zealand and least (less than 0.5 percent) in *inter alia* Brazil, Indonesia, Mexico, Portugal, Thailand, Tunisia, Uruguay.

5. Explaining Mathematical Proficiency

Table 5 details the results of a regression which seeks to explaining the predicted Scores in Mathematics by using the socio-economic characteristics of the student and their family along with information about their education (both inside and outside the school environment) and a county-type control variable.

The socio-economic characteristic explanatory variables for the student and the family comprise

- The age of the student: we would expect an older student to perform better in tests, *ceteris paribus*; however, it is worth pointing out that given that the students in the survey are fairly tightly clustered in terms of age with a standard deviation for age in the full sample of 3½ months so we may not find this to be statistically significant.
- The type of family: single parent, a nuclear family (mother, father and children), mixed family or other. The traditional view would be that students who are members of a nuclear family would perform better in education.
- The level of parental education converted into years of schooling. Here we would expect that more schooling for the parent should improve the educational performance of the student..
- Whether the language used by the family at home is the same as the language used for the test. It is plausible that those students using a language at home other than the test language would under-perform in a test conducted in the test language but it is also possible that such students may have a predisposition to working harder to overcome this disadvantage which will outlay the expectation of underperformance.

- Students with parents who are white collar workers (i.e. non-manual) should perform better than students whose parents who are blue collar workers (i.e. manual). Within these two groups, students with parents who are high skilled workers should perform better than students with parents who are low skilled workers.

The information about their education (both inside and outside the school environment) comprise:

- The minutes of mathematical instruction at School, categorised by us into four quartiles ranging from lowest to highest, with the highest quartile taken as the residual or base category. We would expect that the test score would rise as the amount of instruction increased.
- The interest in Mathematics, categorised by us into four quartiles ranging from lowest to highest, with the highest quartile taken as the residual or base category. We would expect that the test score to rise as the interest in Mathematics increased.
- The availability of computing resources at home categorised by us into four quartiles ranging from lowest to highest, with the highest quartile taken as the residual or base category. We would expect that the test score rises as the availability of computing resources increases; this is both due to computers being of use for improving educational attainment and the presence of computers being a partial proxy for higher household income.
- The availability of other resources at home such as a quiet place to study, categorised by us into four quartiles ranging from lowest to highest, with the highest quartile taken as the residual or base category. We would

1
2
3 expect this test score to rise as the availability of other resources at home
4
5
6 increasesd.

- 7
8
9
- 10 • The level of motivation, categorised by us into four quartiles ranging from
11 lowest to highest, with the highest quartile taken as the residual or base
12 category. We would expect that the test score to rise as the level of
13 motivation increased.
14
15
 - 16 • The level of discipline in the classroom, categorised by us into four
17 quartiles ranging from lowest to highest, with the highest quartile taken as
18 the residual or base category. We would expect that the test score to rise as
19 the level of discipline in the classroom increased.
20
21
 - 22 • The use of different learning strategies. Here we are comparing the use of
23 *elaboration* learning strategies (which is the residual category - an
24 example being to understand new concepts in mathematics by relating
25 them to things already known) with *memorisation* learning strategies
26 (example: learn the answers to problems off by heart) and *control* learning
27 strategies (example: self testing as the students studies to see if they
28 remember the work already done). Our *a priori* belief was that elaboration
29 and control learning strategies which were more conducive to a higher test
30 score compared to memorisation strategies.

45
46
47

48 Focusing on the statistically significant results, our main findings were:
49

- 50
- 51 • A student from a nuclear family or a mixed family was predicted to score
52 approximately 6 more points than a student from a single parent family.
53
 - 54 • A student with 17 years of parental schooling (approximately Masters level if
55 education is continuous) was predicted to score approximately 13 more points
56
57
58
59
60

1
2
3 than a student with 10 years of parental schooling (approximately equivalent
4 to leaving at age 16).
5
6

- 7
8 • Students whose parents were high skilled white collar workers were predicted
9 to score 31 more points than students whose parents were low skilled blue
10 collar workers; students whose parents were low skilled white collar workers
11 were predicted to score 17 more points than students whose parents were low
12 skilled blue collar workers; students whose parents were high skilled blue
13 collar workers were predicted to score 6 more points than students whose
14 parents were low skilled blue collar workers.
15
16
- 17 • Students for whom the language used by the family at home was different
18 from the language used for the test scored 11 points less than students for
19 whom the language used by the family at home was the same as the language
20 used for the test scored.
21
22
- 23 • Students in the lowest 2 quartiles for minutes of mathematical instruction at
24 School scored approximately 12 points less than students in the highest
25 quartile; students in the 3rd quartile scored approximately 7 points fewer than
26 students in the highest quartile.
27
28
- 29 • Students in the lowest quartile for the availability of computing resources at
30 home scored approximately 47 points fewer than students in the highest
31 quartile; students in the second quartile for the availability of computing
32 resources at home scored approximately 19 points less than students in the
33 highest quartile.
34
35
- 36 • Students in the lowest quartile for the availability of other resources at home
37 scored approximately 37 fewer points than students in the highest quartile;
38 students in the second quartile for the for the availability of other resources at

home scored approximately 16 fewer points than students in the highest quartile; students in the third quartile for the for the availability of other resources at home scored approximately 10 fewer points than students in the highest quartile.

- Students in the lowest quartile for their interest in Mathematics scored approximately 25 points less than students in the highest quartile; students in the second quartile for their interest in Mathematics scored approximately 16 fewer points than students in the highest quartile; students in the third quartile for their interest in Mathematics scored approximately 8 fewer points than students in the highest quartile.
- Students in the lowest quartile for their level of motivation scored approximately 2 points fewer than students in the highest quartile as did students in the third quartile (the coefficient for the second quartile was not statistically significantly different from zero)
- Students in the lowest quartile for the level of discipline in the classroom scored 31 fewer points than students in the highest quartile; students in the second quartile for the level of discipline in the classroom scored approximately 22 fewer points than students in the highest quartile; students in the third quartile for the level of discipline in the classroom scored approximately 11 fewer points than students in the highest quartile.
- Students mostly making use of a memorisation learning strategy scored 2 points less than those mostly making use of elaboration learning strategies; Students mostly making use of a control learning strategy scored 5 points less than those mostly making use of elaboration learning strategies.

- Students in english-speaking OECD countries scored 19 points more than students in OECD partner countries; students in non-English speaking OECD countries scored 18 points more than students in OECD partner countries;
- Students in a higher grade (or year) score 27 points more for each grade.
- The high level of significance for the constant term suggests that there are some omitted variables from the analysis, but this was always likely to be the case when analysing such a complex area.

For Peer Review

6. Conclusion

Looking at the aggregate measures of mathematical strength, the value of the Sen index for mathematical weakness – remembering that this index took into account the proportion of students who were weak, the depth of their weakness, and inequality between mathematically weak students - was lowest (below 0.5%) in Finland, Korea, Netherlands, Canada, The Czech Republic, Macao and Ireland and highest (above 5%) in Uruguay, Indonesia, Tunisia and Brazil. At the other end of the scale, the value of the Sen index for mathematical strength – remembering that this index took into account the proportion of students who were strong, the height of their strength, and inequality between mathematically strong students – was highest in Australia, Belgium, Czech Republic, Hong Kong, Japan, Korea, Netherlands, and New Zealand and least (less than 0.5 percent) in *inter alia* Brazil, Indonesia, Mexico, Portugal, Thailand, Tunisia, Uruguay.

In terms of the determinants of the point score, the strongest influences (defined as effecting an at least 10 point increase in the point score) on mathematical performance – and in which where policy could play little or no role - were social class (where students with parents who were high skilled white collar workers being predicted to score 31 points more than students whose parents were low skilled blue collar workers) and students being non-native language speakers (with students, whose language in the family home was different to the language used for the test, scoring 11 points less than students whose home language was also the test language)

The areas in which policy could have an effect were the amount of mathematical instruction at school (students in the lowest two quartiles by time spent on mathematical instruction at School scored approximately 12 fewer points than students in the highest quartile), computer availability at home (students in the lowest

1
2
3 quartile for the availability of computing resources at home scored approximately 47
4
5 fewer points than students in the highest quartile), the availability of other educational
6
7 resources at home (students in the lowest quartile for the availability of other
8
9 resources at home scored approximately 37 fewer points than students in the highest
10
11 quartile), developing an higher level of interest in Mathematics (students in the lowest
12
13 quartile of interest in Mathematics scored approximately 25 fewer points than students
14
15 in the highest quartile), and maintaining an higher level of discipline in the classroom
16
17 (students in the lowest quartile for the level of discipline in the classroom scored 31
18
19 fewer points than students in the highest quartile)
20
21
22
23

24
25 There is, therefore, evidence from this analysis of the PISA data that if policy
26
27 makers wish to improve the level of mathematical ability of their school pupils, then a
28
29 sensible policy regime would be to: (i) increase the amount of mathematical
30
31 instruction at school, (ii) increase the availability of computers at home (such as
32
33 laptop borrowing schemes), (iii) increase the availability of other educational
34
35 resources at home (such as by encouraging the borrowing of library books, CD-
36
37 ROMs, DVD-ROMs and other educational material), (iv) take measures to develop an
38
39 higher level of interest in Mathematics, (v) take measures to maintain an higher level
40
41 of discipline in the classroom.

The numbers in the line against the country name represent student numbers at each proficiency level.
The numbers in italics, below that line, represent student percentages at each proficiency level.

Table 3
Rates of Mathematical Weakness of 15-year olds, by Country*

| Country | Head Count Ratio (%) | Weakness Gap Ratio (%) | Achievement Gap Ratio (%) | Sen Measure (%) |
|-------------------|----------------------|------------------------|---------------------------|-----------------|
| 1. Australia | 4.4 | 10.9 | 0.48 | 0.70 |
| 2. Austria | 4.1 | 8.9 | 0.37 | 0.53 |
| 3. Belgium | 6.1 | 13.0 | 0.79 | 1.1 |
| 4. Brazil | 51.5 | 19.1 | 9.8 | 13.6 |
| 5. Canada | 2.7 | 8.3 | 0.22 | 0.33 |
| 6. Czech Rep | 2.8 | 8.1 | 0.23 | 0.33 |
| 7. Denmark | 3.8 | 10.3 | 0.40 | 0.58 |
| 8. Finland | 1.2 | 8.1 | 0.09 | 0.13 |
| 9. France | 4.4 | 9.3 | 0.41 | 0.59 |
| 10. Germany | 7.4 | 10.9 | 0.80 | 1.16 |
| 11. Greece | 18.4 | 13.2 | 2.4 | 3.5 |
| 12. Hong Kong | 3.0 | 12.2 | 0.36 | 0.52 |
| 13. Hungary | 7.1 | 10.7 | 0.77 | 1.1 |
| 14. Iceland | 3.9 | 9.7 | 0.38 | 0.55 |

What Enhances Mathematical Ability? A Cross-Country Analysis Based on Test Scores of 15-year Olds

Mark Bailey* and Vani K Borooah⁺
University of Ulster

First Version: July 2007

Revised: June 2008

Abstract

This paper examines the mathematical abilities of 15-year olds in a range of countries which participated in the 2003 cycle of the OCED's Programme for International Student Assessment (PISA). Utilising information on the scores obtained by individual students in the mathematical part of the PISA assessment, we use a range of indicators from the literature on inequality and poverty to evaluate the "mathematical performance" of participating countries. Since data from PISA contained a wealth of information on the circumstances of the students, in terms of their home and school environment, we identify, and examine the relative influence of, factors which serve to enhance the mathematical performance of students in the PISA assessment.

1. Introduction

An interesting - but, arguably, not sufficiently appreciated – feature of the labour market is the positive association between a person’s earnings and whether he or she had studied mathematics at school to an advanced level (Kenny et. al., 1979, Dolton and Vignoles, 2000, McIntosh and Vignoles, 2000). Dolton & Vignoles (2000, 2002) measured the returns an individual obtained from having an A-level in Mathematics (a Mathematics qualification taken in British schools at post-16 level) and found that the return became evident at a later, rather than earlier, stage of a person’s career; they argued that the return was due to employers observing that employees with A-level mathematics had higher levels of productivity compared to those who did not have this qualification. They concluded that individuals with an A-level in mathematics earned 7%-10% more than similarly educated workers without this qualification, even after controlling for the initial ability of these individuals.

In a similar vein, Jenkins et al (2003) found that, for women, mathematical ability was particularly important in determining which of them would undertake lifelong learning that would lead to a qualification – an important consideration given the emphasis on lifelong learning in recent UK government policy thinking such as the “new skills agenda”. More recently, Kounine et. al. (2008) have bemoaned the decline of mathematics in the United Kingdom and argued that winning the battle of the “maths economy” will be crucial to the UK’s future economic success.¹

Murnane et al (1995) and Ingram & Neumann (2006) while supporting this claim, also presented evidence that, in the United States, mathematical qualifications had become increasingly important in determining wage rates: Ingram & Neumann (2006)

¹ For a contrary view on the usefulness of mathematics see Jenkins (2008).

1
2
3 found that the return to mathematical and verbal ability nearly doubled between 1980
4
5 and 1998.
6

7
8 What benefits the individual also benefits the economy: at a macroeconomic level,
9
10 studies making use of international school test score data have found a link between
11
12 mathematical ability and the economic growth of the state (Hanushek and Kimko,
13
14 2000). This linkage has been recognised by policy makers. For example, Alan
15
16 Greenspan giving testimony before the Committee on Education and the Workforce of
17
18 the U.S. House of Representatives in March 2004 noted that:
19
20

21
22 “Research on wealth creation in both emerging and developed nations strongly
23
24 suggests that it is the knowledge and the skill of our population interacting
25
26 under our rule of law that determine our real incomes... A study conducted in
27
28 1995 revealed that, *although our fourth-grade students were above average in*
29
30 *both math and science, by the time they reached their last year of high school*
31
32 *they had fallen well below the international average.”* (Greenspan, 2004,
33
34 emphasis added).
35
36
37

38
39 Given the importance of the level of mathematical ability of a country's
40
41 population, in determining both individual life chances and also macroeconomic
42
43 performance, this paper asks two broad questions:
44

- 45
46 (i) How do levels of mathematical ability differ between countries and are
47
48 levels of inter-country inequality in mathematical ability susceptible to
49
50 analysis using the tools of inequality theory?
51
52 (ii) What are the factors that influence such ability and, in exercising such
53
54 influence, what is the relative strength of the relevant factors?
55
56

57
58 We answer these questions using data from the OCED's Programme for
59
60 International Student Assessment (PISA) which is one of a range of trans-national

1
2
3 tests of student ability.² PISA is a collaborative effort, involving all OECD countries
4 and a significant number of partner countries, to measure how well 15 year students
5
6
7
8 “are prepared to meet the challenges of today’s knowledge society”. The PISA 2003
9
10 assessments consist of paper-and-pencil tests and the following domains are tested: (i)
11
12 mathematical literacy; (ii) reading literacy; (iii) scientific literacy.
13
14

15
16 On the basis of these tests, each of 276,150 students in 41 countries was assigned
17
18 a score for mathematics, reading, and science. In addition to this information about
19
20 how well students fared in their assessments, the PISA data contains a wealth of
21
22 information on the circumstances surrounding a student. These relate to *inter alia*: (i)
23
24 his/her personal circumstances, living arrangements etc; (ii) parental attributes
25
26 relating to education, class; (iii) home possessions and environment relating to books,
27
28 computers, internet, place to study; (iv) school circumstances relating to amount of
29
30 instruction, relationship with teachers, type of school etc.
31
32
33

34 The issue of inter-country differences in education achievement has been
35
36 investigated by Maas and Criel (1982) who estimated Gini coefficients based on
37
38 enrolment data for 16 East African countries and, more recently, by Thomas *et. al.*
39
40 (2001, 2002) who studied inequality in educational attainments for 140 countries. The
41
42 latter set of papers developed the concept of education Gini and argued that this could
43
44 be used as an indicator of welfare complementing average educational, health,
45
46 nutritional, and income attainments. In so doing, Thomas *et. al.* (2001, 2002) were
47
48 motivated by Sen’s (1999) observation that concern with equity should not be
49
50 confined to just income inequality but, indeed, should be extended to embrace all the
51
52 dimensions which impinge on a person’s ability to function effectively in society.
53
54
55
56
57
58
59
60

² See Hansen & Vignoles (2005) and Brown et al (2007) for a discussion of how PISA compares to other assessments.

Machin and Vignoles (2004) have studied educational inequality in the UK from the perspective of socio-economic groups. Comparing two cohorts of individuals, born in 1958 and 1970, they found that the links between educational achievement and parental income / social class strengthened over this period so that the labour market success or failure of individuals became more closely connected to their parents income. This work is complemented by that of Galindo-Rueda *et. al.* (2004) who found that in UK higher education, even before the introduction of tuition fees, children from poorer neighbourhoods had become less likely to participate in higher education since 1994-95, as compared to children from richer neighbourhoods.

In this paper we extend the contribution of Thomas *et. al.* (2001, 2002), to the study of educational inequality, in one respect. Following the work of Anand and Sen (1997) we argue that the average achievements of a country with respect to a particular welfare indicator –which in the case of this paper is “mathematical ability” as measured by PISA – should be tempered by considerations of inequality in the distribution of achievements between the individuals in the country’s population. Anand and Sen (1997) referred to the resultant indicators of achievement as being “equity sensitive”. In this paper we construct, for each country in the PISA sample, equity sensitive indicators of mathematical ability.

The heart of the paper lies, however, in answering the latter questions relating to the factors which enhance mathematical ability. Since, as noted above, data from PISA contained a wealth of information on the circumstances of the students, particularly in terms of their home and school environment, we identify, and examine the relative influence of, factors which serve to enhance the mathematical performance of students in the PISA assessment.

1
2
3 The determinants of the factors underlying educational achievement have been the
4
5 subject of several studies. Jenkins *et. al.* (1993) examined the determinants of lifelong
6
7 learning and concluded that those who left school with O-level qualifications or
8
9 higher were much more likely to undertake lifelong learning. Okpala and Onocha
10
11 (1988) examined the factors underlying student achievement in physics in Nigeria and
12
13 examined the role of *inter alia* gender, home, interest in physics in shaping
14
15 achievement in physics.

For Peer Review

2. Equity Sensitive Indicators of Student Assessment Scores

In a paper prepared for the 1995 *Human Development Report*, Anand and Sen (1997) pointed out that a country's non-economic achievements were likely to be unequally distributed between subgroups of its population: for example, in terms of gender equality, which was the focus of their concern, the female literacy rate, or female life expectancy, was often lower than that for males. In the face of such inter-group inequality, they argued that a country's achievement with respect to a particular outcome should not be judged exclusively by its mean level of achievement (for example, by the average literacy rate for a country) but rather by the mean level *adjusted to take account of inter-group differences in achievements*.

Anand and Sen (1997) proposed a method, based on Atkinson's (1970) seminal work on the relation between social welfare and inequality, for making such adjustments and they termed the resulting indicators *equity sensitive indicators*. They further suggested that assessments of country achievements should be made on the basis of such equity sensitive indicators rather than, as was often the case, on the basis of its mean level of achievement. This would, then, allow a comparison between two countries, one of which had a lower mean achievement level, but a more equitable distribution of achievement, than the other.³ In this section we apply these ideas to the student assessment scores (SAS) - hereafter, simply, "scores" – in the PISA data.

Suppose that \bar{X} is the average score in a country where X_i is the score of student i ($i=1\dots N$). We know that, because of inequality in the distribution of scores between students, the average score of a country will not be achieved by all its students.

³ Anand and Sen (1997) compared the Honduras (with an average literacy rate of 75%, distributed between men and women as 78%, 73%) with China (with an average literacy rate of 80%, distributed between men and women as 92%, 68%) and asked which country should be regarded as having the "better" achievement with regard to literacy: China with a higher overall rate or the Honduras with greater gender equality?

1
2
3 Therefore, in assessing the SAS achievement of a country, by how much should we
4 reduce its average SAS to take account of inequality in scores?
5
6

7
8 The answer to this question depends on how *averse we are to inequality*. In his
9 seminal paper on income inequality, Atkinson (1970) argued that we (society) would
10 be prepared to accept a reduction in average income, *provided the lower income was*
11 *equally distributed*, from a higher average income which was unequally distributed.⁴
12
13 The size of this reduction depended upon our degree of "inequality aversion" which
14 Atkinson (1970) measured by the value of a (inequality aversion) parameter, $\varepsilon \geq 0$.
15
16 When $\varepsilon = 0$, we are *not at all* averse to inequality implying that we would not be
17 prepared to accept even the smallest reduction in average income in order to secure an
18 equitable distribution. The degree of inequality aversion increases with the value of
19 ε : the higher the value of ε , the more averse we would be to inequality and, in order
20 to secure an equitable distribution of income, the greater the reduction in average
21 income we would find acceptable.
22
23
24
25
26
27
28
29
30
31
32
33
34
35

36 These ideas can, equally well, be applied to student assessment scores. We
37 can reduce the average score, \bar{X} , of a country by the amount of inter-student
38 inequality in scores to arrive at X^e , a "group equity sensitive" score for the country,
39 $X^e \leq \bar{X}$. We refer to X^e as the *equally distributed equivalent score*. The size of this
40 reduction (as given by the difference, $\bar{X} - X^e$) depends upon our aversion to
41 inequality: the lower our aversion to inequality, the smaller will be the difference and,
42 in the extreme case in which there is no aversion to inequality ($\varepsilon = 0$), there will be
43 no difference between the average and the equity sensitive scores. Three special cases,
44 contingent upon the value assumed by ε , may be distinguished:
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

⁴ In the language of economics, the two situations would yield the same level of social welfare, i.e. be 'welfare equivalent'.

60

1. When $\varepsilon = 0$ (no inequality aversion), X^e is the *arithmetic mean* of the student scores: $X^e = \bar{X}$

2. When $\varepsilon = 1$, X^e is the *geometric mean* of the student scores: $X^e = \left[\prod_{i=1}^N X_i \right]^{1/N} < \bar{X}$.

3. When $\varepsilon = 2$, X^e is the *harmonic means* of the student scores:

$$X^e = \frac{N}{\sum_{i=1}^N (X_i)^{-1}} < \bar{X}.$$

Table 1 shows the equity sensitive scores for each of the 41 countries in the PISA data, contingent upon the amount of inequality in the distribution of scores between *all* the 15 year olds in (the sample for) that country. This table shows three separate rankings for the 41 countries: first, the ranking that resulted entirely from the average score of countries when intra-country inequality was deemed not to matter; second, the ranking that resulted when inequality aversion was measured by $\varepsilon = 1$ or, in other words, the relevant average was measured by the geometric mean; lastly, the ranking that resulted when inequality aversion was measured by $\varepsilon = 2$ or, in other words, the relevant average was measured by the harmonic mean.

Table 1 shows that the rankings changed only slightly from no inequality aversion to inequality aversion: the first 8 places were unchanged; Australia slipped from 11th to 12th place while Canada rose from 12th to 11th place; Germany slipped from 19th to 20th to 21st under successively higher degrees of inequality aversion while Italy slipped from 24th to 25th place. In general, we can conclude that the use of equity-sensitive indicators did not add much to the rankings of countries by their average level of mathematical achievements.

3. Explaining Mathematical Proficiency

Pisa (2003) defined seven levels of proficiency in mathematics: *level 1*, for $SAS \leq 357.77$; *level 2*, for $357.77 < SAS \leq 420.07$; *level 3*, for $420.07 < SAS \leq 482.38$; *level 4*, for $482.38 < SAS \leq 554.68$; *level 5*, for $554.68 < SAS \leq 606.99$; *level 6*, for $606.99 < SAS \leq 669.3$; *level 7*, for $SAS > 669.3$.

Table 2 shows that Tunisia and Brazil (52 percent), Indonesia (51 percent), Uruguay (30 percent), Mexico (26 percent), Turkey (26 percent), Thailand (18 percent), and Greece and Serbia (18 percent) had the largest proportion of students at the lowest level of proficiency in mathematics. In all the other countries, less than one in ten students – and, in many countries, less than one in twenty students – were at the lowest proficiency level.

At the other extreme, Table 3 shows that Hong Kong (32 percent), Netherlands and Belgium (27 percent), Liechtenstein and the Czech Republic (25 percent), and Japan and Korea (24 percent) had the largest proportion of students at the two highest levels of mathematical proficiency.

Table 4 details the results of a regression model which seeks to explaining the predicted Scores in Mathematics by using the socio-economic characteristics of the student and their family along with information about their education (both inside and outside the school environment) and a county-type control variable.

The socio-economic characteristic explanatory variables for the student and the family comprise

- The age of the student: we would expect an older student to perform better in tests, *ceteris paribus*; however, it is worth pointing out that given that the students in the survey are fairly tightly clustered in terms of age with a

1
2
3 standard deviation for age in the full sample of 3½ months so we may not
4
5 find this to be statistically significant.
6
7

- 8 • The type of family: single parent, a nuclear family (mother, father and
9 children), mixed family or other. The traditional view would be that
10 students who are members of a nuclear family would perform better in
11 education.
12
13
- 14 • The level of parental education converted into years of schooling. Here we
15 would expect that more schooling for the parent should improve the
16 educational performance of the student..
17
18
- 19 • Whether the language used by the family at home is the same as the
20 language used for the test. It is plausible that those students using a
21 language at home other than the test language would under-perform in a
22 test conducted in the test language but it is also possible that such students
23 may have a predisposition to working harder to overcome this
24 disadvantage which will outlay the expectation of underperformance.
25
26
- 27 • Students with parents who are white collar workers (i.e. non-manual)
28 should perform better than students whose parents who are blue collar
29 workers (i.e. manual). Within these two groups, students with parents who
30 are high skilled workers should perform better than students with parents
31 who are low skilled workers. This would be consistent with results on
32 socio-economic educational inequality reported by Machin and Vignoles
33 (2004) and Galindo-Rueda *et. al.* (2004).

(vi) The level of discipline in the classroom, categorised by us into four quartiles ranging from lowest to highest, with the highest quartile taken as the residual or base category. We would expect that the test score to rise as the level of discipline in the classroom increased.

(vii) The use of different learning strategies. Here we are comparing the use of *elaboration* learning strategies (which is the residual category - an example being to understand new concepts in mathematics by relating them to things already known) with *memorisation* learning strategies (example: learn the answers to problems off by heart) and *control* learning strategies (example: self testing as the students study, to see if they remember the work already done). Our *a priori* belief was that elaboration and control learning strategies were more conducive to a higher test score compared to memorisation strategies.

With this background, we use the regression estimates shown in Table 4 to highlight the main findings.

Country Effects. One would expect that, after controlling for other variables, the country in which a student lived would influence his/her results. This is because the country of residence would capture the general level of resources available to residents and which would buttress the more specific variables pertaining to the individual students. Ideally, the equations should have been estimated with a dummy for each country. However, given that there were 41 countries, we decided to group the countries as follows:

- (i) OECD English speaking countries (Australia, Canada, Ireland, New Zealand, UK, and USA).
- (ii) OECD Nordic countries (Denmark, Finland, Iceland, Norway, Sweden).

(iii) OECD West European countries (Austria, Belgium, France, Germany, Greece, Italy, Luxembourg, Netherlands, Portugal, Spain, Switzerland).

(iv) OECD East European countries (Czech Republic, Hungary, Poland, and Slovakia).

(v) Other OECD countries. (Japan, Korea, Mexico, and Turkey).

(vi) OECD Partner countries (Brazil, Hong Kong, Indonesia, Leichtenstein, Latvia, Macao, Russia, Thailand, Tunisia, Uruguay, and Serbia).

The results show that, with the OECD partner countries taken as the residual option, all the following OECD groups had positive coefficient estimates⁵: East Europe (38 points), West Europe (29 points), Nordic countries (23 points), English-speaking countries (22 points). However, the other OCED countries (which contained mathematically weak countries like Mexico and Turkey) reported a negative coefficient estimate of 16 points.

Family Type and Parental Occupation. The results showed very clearly that both family structure and parental occupation exercised a significant influence on student performance: *ceteris paribus* a student from a nuclear family was predicted to score approximately 6 more points, on average, than a student from a single parent family while students whose parents were high skilled white collar workers were predicted to score an average of 29 more points than students whose parents were low skilled blue collar workers.

This parental advantage persisted for students whose parents were lower down the occupational ladder: students whose parents were low skilled white collar workers were predicted to score 12 more points than students whose parents were low skilled blue collar workers while students whose parents were high skilled

⁵ Meaning that, *ceteris paribus*, their average scores were higher than the OCED partner average by the coefficient estimate.

1
2
3 blue collar workers were predicted to score 2 more points than students whose
4
5
6 parents were low skilled blue collar workers.
7

8 Both these results are consistent with received wisdom: Machin and Vignoles
9
10 (2004) have drawn attention to the links between educational achievement and
11
12 parental class; Gordon (1996) has argued that the current rates of success in
13
14 the GCSE exams in Britain (taken at the age of 16) are associated with locations
15
16 away from inner cities and the reason for this is the high concentration of lone
17
18 parent families in inner cities.
19

20
21
22 **Years of Schooling and Language at Home.** The effect on scores of how
23
24 well educated students' parents were was significant, but weak. A student, one of
25
26 whose parents had received 17 years of parental schooling (approximately
27
28 equivalent to a Master's degree) was predicted to score approximately only two
29
30 more points than a student with 10 years of parental schooling (approximately
31
32 equivalent to leaving at age 16). This suggests that, once parental occupational
33
34 class was controlled for, there was not much additional role for the influence of
35
36 parental educational.
37
38
39

40
41 Similarly, the language spoken at home did exert a large and significant effect
42
43 on student scores: students, for whom the language used by the family at home
44
45 was different from the language used for the test, scored an average of 16 fewer
46
47 points compared to students for whom the language used by the family at home
48
49 was the same as the language used for the test.
50
51

52
53 **The School Environment.** The environment at school affected student
54
55 performance in a number of ways:
56

57
58 1. First, and most obvious, was the time which the school devoted to instruction
59
60 in mathematics. There was a very clear correlation between student

1
2
3 performance and the time spent on mathematics. For example, compared to the
4
5 average score of students in the highest quartile with respect to instruction
6
7 time: *ceteris paribus* the average score of students in the lowest quartile of
8
9 instruction time was 18 points lower; the average score of students in the
10
11 second quartile of instruction time students was 10 points lower, and the
12
13 average score of students in the third quartile of instruction time was 8 points
14
15 lower.
16
17
18
19

20 2. Second, our results clearly showed that classroom discipline mattered. The
21
22 effective learning of mathematics depended not just on the time devoted to is
23
24 study but also on classroom management which sought to create a good
25
26 learning environment in the classroom through high standards of discipline.
27
28 *Ceteris paribus* compared to the average score of students who enjoyed the
29
30 highest level of classroom discipline, students in the lowest quartile for the
31
32 level of discipline in the classroom scored, on average, 31 fewer points. Nor
33
34 was this poorer performance confined to the lowest level of discipline:
35
36 students in the second quartile for the level of discipline in the classroom
37
38 scored approximately 21 fewer points than students in the highest quartile,
39
40 while students in the third quartile for the level of discipline in the classroom
41
42 scored approximately 11 fewer points (compared to students in the highest
43
44 quartile).
45
46
47
48
49

50 3. Third, the school could have been instrumental in making students interested
51
52 in mathematics and motivating them to do well.⁶ Of these two factors, once
53
54 interest in mathematics had been controlled for, motivation did not have much
55
56 of a role. Compared to the average score of students with the highest level of
57
58
59
60

⁶ Though, in addition to the school, several factors –including, home, friends – could influence interest and motivation.

1
2
3 interest in mathematics, the average score of students with lowest level of
4
5 interest was 27 points lower but, compared to the average score of students
6
7 with the highest level of motivation to study mathematics, the average score of
8
9 students with lowest level of motivation was only 4 points lower.
10
11

12
13 4. Fourth, the school had an influence on student scores through the choice of
14
15 appropriate teaching and learning strategies. However, it must be admitted that
16
17 after controlling for the other school factors, 1-3 above, the influence of
18
19 learning strategies on student performance was weak.
20
21

22 The results relating to school environment have obvious implications for the
23
24 efficiency with which schools are run. In this connection, Bee and Dolton (1985)
25
26 offer evidence that there may be economies of scale to be reaped from having
27
28 larger schools.⁷
29
30

31 **The Home Environment:** The results clearly pointed to the importance of
32
33 computing resources at home as an aid to proficiency in mathematics. Students in
34
35 the lowest quartile for the availability of computing resources at home scored, on
36
37 average, approximately 47 points fewer than students in the highest quartile while
38
39 students in the second quartile for the availability of computing resources at home
40
41 scored approximately 23 points less than students in the highest quartile.
42
43 Interestingly, there was hardly any difference in the average scores of students in
44
45 the third and fourth quartiles of computing facilities thus suggesting that the
46
47 marginal benefit of better facilities diminished very rapidly.
48
49
50
51

52 Non-computing resources - for example, in the form a quiet, separate place to
53
54 study - were also important in influencing student scores. Students in the lowest
55
56 quartile for the availability of other resources at home scored approximately 31
57
58
59
60

⁷ See also Dolton (1991) for a study of the efficient provision of computing services in UK universities.

1
2
3 fewer points than students in the highest quartile; students in the second quartile
4
5 for the availability of other resources at home scored approximately 15 fewer
6
7 points than students in the highest quartile. With respect to non-computing
8
9 resources, there was a 10 point difference in the average scores of students in the
10
11 third and fourth quartiles of non-computing facilities suggesting that the marginal
12
13 benefit of better non-computing facilities did not diminish as rapidly as did the
14
15 marginal benefit of better computing facilities.

6. Conclusion

The proportion of mathematically weak students was lowest (3 percent or less) in Finland, Korea, the Netherlands, Macao, Canada, the Czech Republic, and Hong Kong and highest (over 50 percent) in Tunisia, Brazil, and Indonesia. At the other end of the scale, the proportion of mathematically strong students was highest (25 percent or more) in Hong Kong, the Netherlands, Belgium, Liechtenstein, and the Czech Republic.

In terms of the determinants of the point score, the strongest influences (defined as effecting, at least, a 10 point increase in the point score) on mathematical performance – and in which where policy could play little or no role - were social class) and students being non-native language speakers. The areas in which schooling policy could have an effect were the amount of mathematical instruction at school and the level of classroom discipline. In terms of the home environment, the availability of a computer was important but equally important was the availability of non-computing facilities (quiet place to study, books etc.). Indeed, as the results showed the marginal benefit of computing facilities diminished much more rapidly than the marginal benefit from non-computing facilities.

A very important factor for high mathematical achievement is an interest in mathematics and here a number of factors – employment opportunities, school, home, friends – need to coalesce to create, sustain, and enhance interest in mathematics.

There is, therefore, evidence from this analysis of the PISA data that if policy makers wish to improve the level of mathematical ability of their 15 year olds, then a sensible policy regime would be to: (i) increase the amount of mathematical instruction at school and classroom discipline in general, (ii) increase the availability of computers at home (such as laptop borrowing schemes), (iii) increase the

1
2
3 availability of other educational resources at home (such as by encouraging the
4
5 borrowing of library books, CD-ROMs, DVD-ROMs and other educational material),
6
7
8 (iv) take measures to develop an higher level of interest in Mathematics.

| Liechtenstein | 4.2 |
| New Zealand | 4.2 |
| Austria | 4.1 |
| Iceland | 3.9 |
| UK | 3.9 |
| Denmark | 3.8 |
| Ireland | 3.8 |
| Hong Kong | 3 |
| Czech Rep | 2.8 |
| Canada | 2.7 |
| Macao | 2.6 |
| Netherlands | 2.5 |
| Korea | 2.2 |
| Finland | 1.2 |
| All Countries | 12.2 |

* Proportion of students at the lowest level of mathematical proficiency.

Table 3
Rates of Mathematical Strength of 15-year olds, by Country*
By Descending Order

| Country | Head Count Ratio (%) |
|----------------------|----------------------|
| Hong Kong | 32.4 |
| Netherlands | 27.4 |
| Belgium | 26.9 |
| Liechtenstein | 25.3 |
| Czech Rep | 25.1 |
| Korea | 23.8 |
| Japan | 23.6 |
| Finland | 22.3 |
| New Zealand | 20.7 |
| Australia | 19.3 |
| Macao | 17.2 |
| Switzerland | 17.1 |
| Germany | 16.1 |
| Canada | 16 |
| France | 15.1 |
| UK | 15.1 |
| Sweden | 14.8 |
| Iceland | 14.7 |
| Denmark | 14.6 |
| Austria | 14.5 |
| Slovakia | 12.9 |
| Ireland | 10.8 |
| Italy | 10.7 |
| Norway | 10.7 |
| Hungary | 9.7 |
| Luxembourg | 9.7 |
| Poland | 8.9 |
| USA | 8.6 |
| Spain | 8.1 |
| Latvia | 7.7 |
| Russian Fed | 6.8 |
| Portugal | 4.8 |
| Turkey | 4.7 |
| Greece | 3.1 |
| Uruguay | 2.6 |
| Thailand | 2 |
| Serbia | 2 |
| Brazil | 0.9 |
| Mexico | 0.36 |
| Indonesia | 0.11 |
| Tunisia | 0.11 |
| All Countries | 11.8 |

* Proportion of students at the highest two levels of mathematical proficiency.

Table 4
Regression Estimates for Explaining Predicted Scores in Mathematics

| | |
|--|-----------|
| Family Type (residual- other type): | |
| Single parent family | 13.24*** |
| | (11.56) |
| Nuclear Family | 18.65*** |
| | (17.08) |
| Mixed Family | 15.02*** |
| | (11.48) |
| Highest Occupational Class of Parent (residual blue collar low skilled): | |
| White Collar, high skilled | 28.60*** |
| | (42.87) |
| White Collar, low skilled | 12.15*** |
| | (17.70) |
| Blue Collar, high skilled | 1.70** |
| | (2.34) |
| Highest Educational Attainment of parent: | |
| Years of Schooling | 1.75*** |
| | (8.29) |
| (Years of Schooling) ² | 0.007 |
| | (0.77) |
| Language at home if different from test language | -15.61*** |
| | (15.89) |
| Minutes of Mathematical Instruction at School (residual – fourth quartile): | |
| Minutes: lowest quartile | -17.85*** |
| | (32.59) |
| Minutes: second quartile | -9.54*** |
| | (14.14) |
| Minutes: third quartile | -7.62*** |
| | (13.66) |
| Computing facilities at home (residual – fourth quartile): | |
| Facilities: lowest quartile | -46.91*** |
| | (66.05) |
| Facilities: second quartile | -22.83*** |
| | (31.05) |
| Facilities: third quartile | -1.51** |
| | (3.15) |
| Low home Educational Resources: | -2.92*** |
| | (6.20) |
| Home Resources (residual – fourth quartile): | |
| Resources: lowest quartile | -30.86*** |
| | (38.45) |
| Resources: second quartile | -14.46*** |
| | (24.27) |
| Resources: third quartile | -9.68*** |
| | (15.95) |

| | |
|---|-----------|
| <i>Interest in mathematics (residual – fourth quartile):</i> | |
| Interest: lowest quartile | -27.26*** |
| | (49.91) |
| Interest: second quartile | -17.28*** |
| | (35.60) |
| Interest: third quartile | -8.95*** |
| | (14.52) |
| <i>Motivation (residual – fourth quartile):</i> | |
| Motivation: lowest quartile | -4.13** |
| | (6.16) |
| Motivation: second quartile | -2.19 |
| | (4.17) |
| Motivation: third quartile | -2.57*** |
| | (4.20) |
| <i>Learning Strategies (residual – elaboration learning strategies):</i> | |
| Memorisation/rehearsal learning strategies | 1.01** |
| | (2.37) |
| Control learning strategies | 3.57*** |
| | (7.95) |
| <i>Discipline in classroom (residual – fourth quartile):</i> | |
| Discipline: lowest quartile | -31.20*** |
| | (53.26) |
| Discipline: second quartile | -20.74*** |
| | (40.89) |
| Discipline: third quartile | -10.78*** |
| | (18.91) |
| <i>Student's grade:</i> | 29.66*** |
| | (93.32) |
| <i>Country-specific variables (residual – OECD partner countries):</i> | |
| OECD country: english speaking | 22.23*** |
| | (35.25) |
| OECD Nordic countries | 23.12*** |
| | (29.18) |
| OECD Western Europe | 28.92*** |
| | (48.55) |
| OCED Eastern Europe | 38.49*** |
| | (51.75) |
| OECD Others | -16.19*** |
| | (22.49)) |
| <i>Intercept</i> | 502.18*** |
| | (271.93) |
| <i>Observations</i> | 186612 |
| <i>R-squared (adjusted)</i> | 0.346 |

Absolute value of t statistics in parentheses

* significant at 10%; ** significant at 5%; *** significant at 1%
