ABSTRACT

Various syndromes of the Ras-MAPK pathway, including the Noonan, Cardio-Facio-Cutaneous, LEOPARD and Costello syndromes share the common features of craniofacial dysmorphisms, heart defect and short stature. In a subgroup of the patients severe muscle hypotonia, central nervous system involvement and failure to thrive occur as well. Here we report on five children diagnosed initially with classic metabolic and clinical symptoms of an oxidative phosphorylation disorder. Later in the course of the disease the children presented with characteristic features of Ras-MAPK pathway related syndromes, leading to the re-evaluation of the initial diagnosis. In the five patients, additional to the oxidative phosphorylation disorder, disease causing mutations were detected in the Ras-MAPK pathway. Three of the patients also carried a second, mitochondrial-related genetic alteration which was asymptotically present in their healthy relatives.

Did we miss the correct diagnosis at the first place or is mitochondrial dysfunction directly related to Ras-MAPK pathway defects? The Ras-MAPK pathway is known to have various targets, including proteins in the mitochondrial membrane influencing mitochondrial morphology and dynamics. Prospective screening of eighteen patients with various Ras-MAPK pathway defects detected biochemical signs of disturbed oxidative phosphorylation in three additional children. We concluded that only a specific, metabolically vulnerable subpopulation of patients with Ras-MAPK pathway mutations present with mitochondrial dysfunction and a more severe, early onset disease. We postulate that patients with Ras-MAPK mutations have an increased susceptibility, but a second metabolic hit is needed to cause the clinical manifestation of mitochondrial dysfunction.

KEYWORDS: Cardio-Facio-Cutaneous syndrome, *HRAS*, *PTPN11*, mitochondrial encephalomyopathy, 3-methylglutaconic aciduria, ethylmalonic aciduria

ABBREVIATIONS: CFC = Cardio-Facio-Cutaneous, CS = Costello syndrome, FTT = failure to thrive, MAPK = mitogen-activated protein kinase, MDC = mitochondrial disease criteria, mtDNA = mitochondrial DNA, NS = Noonan Syndrome, OXPHOS = oxidative phosphorylation, SCAD = short-chain acyl-CoA dehydrogenase

INTRODUCTION

It is well established that heterozygous germline mutations in genes encoding participants of the Ras-MAPK pathway cause Noonan syndrome (NS) and the related disorders Cardio-Facio-Cutaneous (CFC), LEOPARD and Costello (CS) syndrome.¹ These are clinically characterised by distinctive facial appearance, heart defects, ectodermal abnormalities, variable cognitive defects, motor delay and susceptibility to certain malignancies. Mutations in *PTPN11*, *RAF1* and *NF1* have been identified in patients with NS/LEOPARD syndrome and neurofibromatosis type 1. *HRAS* mutations have been identified in 80-90% of patients with CS and *BRAF* and *MEK1/2* mutations were found in CFC patients. *KRAS* mutations have been identified in NS and CFC. *SOS*, *SHOC2*, *NRAS* and *RAF1* mutations were found in 10-30% of NS patients without *PTPN11* and *KRAS* mutations respectively. Loss-of-function mutations in *SPRED1* were identified in neurofibromatosis type I-like syndrome. All molecules regulate the Ras-MAPK cascade.²

Mitochondrial dysfunction is the most common inborn error of metabolism in children, the diagnosis is based on characteristic clinical symptoms of multisystem involvement and the presence of metabolic markers. The clinical diagnosis is possible using a validated scoring system (Mitochondrial disease criteria, MDC score) considering clinical signs and symptoms as well as biochemical abnormalities (e.g. lactic acidemia, elevated serum alanine and urinary excretion of certain organic acids and Krebs-cycle intermediates).³ The ultimate diagnosis is based on the measurement of abnormal ATP production from substrate oxidation and the presence of oxidative phosphorylation (OXPHOS) enzyme complex deficiency in muscle specimen or cultured fibroblasts.⁴

Recently it was shown that the clinical presentation of congenital myopathy with excess of muscle spindles (CMEMS) and hypertrophic cardiomyopathy is caused by *HRAS* germline mutations.⁵ Moreover, mitochondrial dysfunction with multiple enzyme deficiencies

of the OXPHOS system has been described in one patient with CFC syndrome carrying a *BRAF* mutation and demonstrating muscular Coenzyme Q deficiency. This suggests a functional connection between the Ras-MAPK pathway and mitochondrial function.⁶

Interestingly the role of mitochondrial DNA (mtDNA) mutations have been implicated before in a patient with NS, not carrying *PTPN11* mutations, but a heterozygous 3 bp deletion in the beta myosin heavy chain (beta-MHC) gene associated with seven mtDNA alterations. Unfortunately familiarity and functional assays in that patient were not available. The authors raised the possibility, however, that the mitochondrial DNA mutations might play a role in the phenotypic presentation.⁷ Another recent study underlines these findings by showing evidence that the mtDNA haplogroup 'R' is associated with NS in South India. In seven patients with the typical clinical picture of NS, mutation analysis of *PTPN11* failed to show alterations. In contrast a total of 146 mtDNA mutations, five of which were novel and exclusively observed in NS patients were found.⁸ Furthermore another study could show lower mitochondrial membrane potential and lower ATP content as well as higher levels of reactive oxygen species (ROS) in mouse fibroblast cell lines with constitutively active SHP2 (as found in NS patients) compared with wild type.⁹

We encountered several patients presenting with clinical and metabolic features of OXPHOS dysfunction, encephalomyopathy and lactic acidemia in infancy, who later developed clinical features suggesting defects in Ras-MAPK genes. In order to collect information about the association of mitochondrial dysfunction and Ras-MAPK pathway defects we systematically studied the clinical, biochemical, histological and molecular features in five patients diagnosed with both an OXPHOS disorder and Ras-MAPK gene defect. To further evaluate the effect of Ras-MAPK pathway mutations on mitochondrial function we prospectively screened 18 additional patients carrying Ras-MAPK gene mutations for clinical and biochemical signs of OXPHOS dysfunction.

1. MATERIAL AND METHODS

2.1. Patients

We evaluated the clinical, biochemical and molecular genetic data of five children who were referred to our center for mitochondrial disorders under suspicion of a primary disorder of the OXPHOS. They all underwent a standard diagnostic protocol including the assessment of organ function, imaging and laboratory studies. The patients demonstrated a MDC score > 6, indicating probable to definite mitochondrial disease, and therefore underwent a combined open muscle/skin biopsy.³ During the further course of disease all five children developed variable clinical features suggestive for a syndrome diagnosis caused by a mutation in the Ras-MAPK signalling pathway, leading to critical reassessment of the initial diagnosis and further molecular genetic investigations. Moreover, we prospectively screened 18 patients with known mutations of the Ras-MAPK pathway, referred for additional metabolic investigations due to feeding and swallowing difficulties, hypotonia, growth delay and failure to thrive (FTT). These routine clinical investigations were performed based on standard protocols for patients with a suspected mitochondrial dysfunction with the approval of the regional ethical commission (CMO number 2007/295).

2.2. Biochemical analysis in blood, fibroblasts and urine

Serum amino acids, serum acyl-carnitine profile and very long chain fatty acids analysis, serum transferrin isoelectric focusing were performed by standard methods^{3,10-15}. Measurement of short-chain acyl-CoA dehydrogenase (SCAD) activity, 3-methylglutaconyl-CoA hydratase activity and cardiolipin analysis were performed in blood or fibroblasts by standard methods^{13,14}. Organic acids in urine were analyzed by gas chromatography/mass spectrometry (GC-MS) with standard methods or by using NMR spectroscopy as described elsewhere.^{10,12}

2.3. Laboratory analysis in muscle and fibroblast samples

Both an open muscle and skin biopsy were performed in all cases using standard methods.

Musculus quadriceps samples were obtained by open muscle biopsy under general anesthesia and obtaining the adjacent skin sample during biopsy³. The samples were used for histological, histochemical (hematoxylin eosin, SDH, COX, NADH immune-staining and electronmicroscopy) and detailed biochemical investigations.

After biopsy, muscle tissue was immediately put in ice-cold SETH buffer (0.25 mol/L sucrose, 2 mmol/L EDTA, 10 mmol/L Tris, 5×10^4 IU/L heparin, pH 7.4) and transported to the laboratory within 15 minutes. Fat and connective tissue were removed. Muscle tissue was minced with a Sorvall TC2 tissue chopper, homogenized in SETH buffer, and centrifuged at 600g. A portion of the 600g supernatant was used for measuring oxidation rates and ATP production rates. The remaining 600g supernatant was frozen in 100- μ L aliquots in liquid nitrogen and kept at -80°C for enzymatic measurements⁴.

The OXPHOS was evaluated by determining the ATP production rate from pyruvate oxidation in fresh muscle and the activity of the enzyme complexes I-V of the respiratory chain by spectrophotometric assays in frozen muscle and under standard condition-cultured fibroblasts.^{3,4,10}

Incubations were performed at 37°C in 20-mL glass incubation vials for 20 min. The vials for measuring ^{14}C -labeled substrate oxidations contained a small plastic tube with 0.2 mL of hyamine. Incubation volume was 0.5 mL, containing 30 mmol/L potassium phosphate, 75 mmol/L potassium chloride, 8 mmol/L Tris, 1.6 mmol/L EDTA, 5 mmol/L MgCl_2 , 0.2 mmol/L p^1, p^5 -di(adenosine-5') pentaphosphate (myo-adenylate kinase inhibitor). To regenerate ADP by creatine kinase in the 600g supernatant, 20 mmol/L creatine was added to all ADP-containing incubations⁴.

ATP and phosphocreatine (CrP) were measured in the supernatant. Samples were thawed, put on ice for 5 min, and centrifuged (2 min at 14 000g and 2 °C) in an Eppendorf 5402 centrifuge.

Oxidation rates of [U-¹⁴C]malate were measured in the presence of malonate [inhibitor of succinate dehydrogenase (SDH)] to prevent the oxidation of [2,3-¹⁴C]malate to proceed beyond 1 TCA cycle. ATP production was measured in incubations containing pyruvate, malate, creatine, and ADP, in both the absence and presence (blank reaction) of arsenite. Incubations were started with 50 µL of 600g supernatant and stopped by addition of 0.2 mL of 3 mol/L perchloric acid through the rubber septum via a hypodermic syringe. Incubations were kept on ice for 1 h to trap the ¹⁴CO₂ in the hyamine⁴. Incubations for ATP production measurements were kept on ice for 15 min and then centrifuged (5 min at 14 000g and 2 °C) in an Eppendorf 5402 centrifuge, after which 0.5 mL of the supernatant was neutralized with 0.6 mL of ice-cold 1 mol/L KHCO₃. The mixtures were kept on ice for 15 min and frozen at –20 °C^{3,4,10}.

2.4. Genetic Analysis

Mitochondrial and nuclear DNA was extracted from muscle. Mitochondrial DNA mutations were evaluated using a standard mitochip analysis (GeneChip® Human Mitochondrial Resequencing Array 2.0, Affymetrix, Inc.). Deletions were analyzed by long template PCR. Sequencing of the nuclear coded genes was performed on an ABI 3730 DNA analyzer using BigDye terminator chemistry (Applied biosystems, Lekkerkerk a/d IJssel, The Netherlands). Molecular investigations included sequence analysis of the structural genes of the OXPHOS complex I (*NDUFS1*, *NDUFS2*, *NDUFS4*, *NDUFS7*, *NDUFS8*, *NDUFV1*), and of the *POLG1*, *DGUOK* and *OPA3* genes depending on the biochemical results from the muscle biopsy and fibroblasts.³ Genes within the Ras-MAPK pathway comprising *PNTP11*, *BRAF*,

HRAS, *RAF1*, *SOS1*, *MEK1* and *MEK2* were sequenced by standard methods. Molecular karyotyping (250 k Affymetrix SNP array platform) was performed in all patients.

2. RESULTS

The patient characteristics of the five patients with proven OXPHOS dysfunction are presented in detail (3.1.-3.5.), the data of the prospective screening of 18 patients with known Ras-MAPK disorders are summarized at the end of this section (3.6.).

3.1. Clinical patient characteristics

The characteristic facial profiles and skin abnormalities of the patients are shown in figures 1 and 2, the MRI changes in patient 3 - 5 are shown in figure 3. The clinical features are summarized in table 1.

Patient 1 (fig 1E): The female patient was followed for short stature, mild muscle hypotonia with muscle weakness, delayed motor and speech development and hypertrophic cardiomyopathy with mild left ventricular outflow obstruction at the age of 14 months. Mild dysmorphic features, hypertelorism and prominent ears, were noted. Metabolic investigations were initiated based on a mixed conductive/sensorineural hearing loss and progressive ventricular septal hypertrophy, revealing a chronic ethylmalonic aciduria at the age of four years. Based on a slow clinical progression and the suspicion of a mitochondrial multi system disorder (MDC score 8) the child underwent an open muscle biopsy during a diagnostic cardiac muscle biopsy session at the age of 14 years. Later in the disease course, at the age of 14-16 years multiple lentiges appeared leading to re-evaluation of the initial diagnosis. Current state: stable, at 17 years the speech development is age-appropriate and her IQ measures 72.

Patient 2 (fig 1A,B; fig 2A): The male patient was followed for muscular hypotonia, ptosis and delayed psychomotor development and failure to thrive from the age of four

months. Short stature, bifid uvula, cryptorchidism, long fingers and wrinkled skin of the hands were also noted. He developed seizures at the age of eight months. A small ventriculo-septal heart defect closed spontaneously at the age of 17 months. Due to a suspected encephalomyopathy metabolic screening was initiated, revealing chronic lactic acidemia and lactic aciduria. Muscle biopsy was performed (MDC score 6). At the age of three years the patient developed the characteristic facial features of CFC syndrome.

Current state: stable, at the age of eight years he is still treated for ichthyosiform dermatitis and tonic-clonic seizures, his IQ measures 69.

Patient 3 (fig 1 C,D; fig 2D): The male patient had a severe muscle hypotonia from the age of one month, swallowing problems, recurrent infections and West syndrome. By ten months of age pulmonic stenosis was detected with right ventricular hypertrophy. Due to severe FTT and swallowing problems he got a gastrostomy. Severe developmental delay (he couldn't roll over at the age of 18 months) and chronic lactic acidemia, together with the multi system involvement (MDC score 8), lead to performing a muscle biopsy. Skin biopsy due to wrinkled skin on the hands, around the knees and in the nuchal region showed no structural or histological elastin alterations. From the age of three years the patient started to develop impressively, including eating on his own and reaching the motor milestones of sitting, standing and walking at the age of 4.5 years. His epilepsy became under control from the age of four years. Physical examination initially revealed mild and unspecific dysmorphic features, thick hair and very dry skin. At the age of 4.5 years dysmorphic features characteristic for CFC syndrome became obvious.

Current state: stable, at the age of six years he walks independently and has an IQ of 65.

Patient 4 (fig 1F, fig 2B): In this male patient generalised muscle hypotonia, swallowing problems and a lack of visual contact were apparent at birth. At the age of three months he was diagnosed with West syndrome. Severe FTT and swallowing problems

necessitated a gastrostomy. Mild dysmorphic features comprising coarse facies, cutis laxa of the hands and feet and curly hair were noted (Figure 3). Due to a severe developmental delay (no head control at the age of ten months), progressive spasticity, chronic lactic acidemia and 3-methylglutaconic aciduria he underwent a muscle biopsy (MDC score 8). Physical re-examination a year later revealed evolving dysmorphic facial features, thick hair and erythema/ichthyosiform eczema of the face. From the age of 2.5 years he started to develop, including increasing visual contact, giving noises, starting to eat on his own and reaching the motor milestones of rolling over, head control and sitting with support.

Current state: stable, at the age of four years his epilepsy is still difficult to control and his developmental quotient is appropriate for a child of six months old.

Patient 5 (fig 1 G,H; fig 2C): The male patient was followed for failure to thrive, psychomotor developmental delay, muscular hypotonia, congenital sensorineural deafness, dysmorphic facial features, microcephaly, short stature, cutis laxa at the hands, ichthyosis and progerioid features from the age of four months. He was also diagnosed with left ventricular hypertrophy and mitral valve insufficiency without significant alterations in the cardiac function. Dietary intervention was started to correct severe malnutrition. Facial dysmorphic features at the age of nine months encompassed a prematurely aged-appearance, cutis laxa on the dorsal hand and feet, wrinkled skin axial and nuchal, broad and prominent forehead, hypertelorism, upslanting palpebral fissures, short nose, low set and posteriorly rotated ears, short and webbed neck, thin and curly hair and thin and sparced eyebrows. Due to the severity of the phenotype, elevated lactic acid levels in blood and mild elevation of methylmalonic acid excretion in the urine, a muscle biopsy (MDC score 7) was performed parallel with detailed genetic investigations at the age of 18 months.

Current state: stable, motor development is still severely delayed at the age of 22 months. Since starting to roll over at the age of six months, and sitting with support at 18 month no

additional developmental mile stones were achieved. The patient received a cochlear implant at 21 months of age.

3.2. Neuroradiological patient characteristics

Mild abnormalities were seen by cerebral MRI imaging in three out of five patients (fig 3). Patient 3 shows mild white matter changes at age four years (fig 3A), patient 5 shows delayed myelinisation (fig 3B; aged 19 months). Patient 4 (fig 3C; aged 2 years) and patient 5 (fig 3D; aged 15 months) show hypoplasia of the corpus callosum and frontal atrophy.

3.3. Biochemical patient characteristics

The biochemical features are summarized in table 2.

All patients had elevated lactate and/or alanine levels in blood. Urine organic acid analysis with GC-MS or in vitro NMR spectroscopy showed an increased urinary excretion of ethylmalonic acid in patient 1, methylmalonic acid in patient 3 and 5 and increased excretion of 3-methylglutaconic acid with slight increase of 3-methylglutaric acid and 3-hydroxyisovaleric acid in patient 4. SCAD activity was normal in blood and fibroblasts in patient 1. Urinary propionic acid excretion, blood homocystein and vitamin B12 and folate levels were normal in patients 3 and 5. The disorders including 3-methylglutaconic aciduria type I, type II (Barth syndrome) and type III (Costeff syndrome) were excluded in patient 4 as the activity of 3-methylglutaconyl-CoA hydratase, the cardiolipin levels and molecular analysis of the *OPA3* gene, respectively, showed no abnormalities.

As all our patients scored >6 on the clinical diagnostic scoring system for mitochondrial disorders (MDC, see table 1) the possibility of a respiratory chain defect was further explored.³ Indeed, as shown in table 2, the biochemical analysis of mitochondrial function in the fresh muscle biopsy showed disturbed OXPHOS in four patients with an ATP production from pyruvate oxidation ranging between 24 and 38 nmol ATP/h/mU CS (control range 42 - 81 nmol/h/mU/CS). Patient 2 demonstrated an associated complex I deficiency and patient 3

multiple complex deficiencies. No biochemical abnormality supporting coenzyme Q deficiency was found in either patients. No enzyme deficiency of complex I-V was found in the fibroblasts cell lines of the patients.

3.4. Muscle histology/Electron microscopy

No alterations were found on histology by light microscopy in the patients, except for atrophy of the type II fibers in patient 1 and fiber type disproportion with a slight increase of internal nuclei (3%) in patient 4. Staining with hematoxylin eosin, SDH and COX immune staining were normal. No ragged red fibers were detected. NADH immune-staining was also within normal limits in patients 2 and 3. No significant abnormalities were seen by electronmicroscopy in patient 1, 2, 3 and 5. Histopathologic evaluation in patient 4 detected two giant mitochondria with somewhat abnormal, fragmented membrane structure. No specific alterations pointing to abnormal myogenic differentiation were found in patient 1.

3.5. Genetic studies

The common m.11778G>A *MT-ND1* (*LHON*) mutation was detected in homoplasmic form in patient 1 and her 48 years old mother without any ophthalmologic alterations. No mitochondrial DNA alteration was found in patient 2 and patient 3. A heterozygous *POLG1* mutation was detected in patient 3 (c.2492A>G; p.Tyr831Cys in exon 16). The same heterozygous alteration was found in the healthy mother of the patient at the age of 38 years. Molecular analysis of the mitochondrial DNA detected a homoplasmic alteration (m.6489C>A; pLeu196Ile in *MT-COI*) in patient 4 without COX deficiency. The same alteration was present in homoplasmic form in the healthy mother without any symptoms of epilepsy. Molecular karyotyping by SNP array revealed a 1.4 Mb loss in chromosome Xp22.31 (6.3 – 7.76 Mb) encompassing ~5 genes, including the steroid sulphatase (*STS*) gene causing X-linked recessive ichthyosis in patient 5. The same alteration was seen in the mother.

Several heterozygous *de novo* pathogenic mutations were identified in different genes of the Ras-MAPK pathway in the five children encompassing c.836A>C (p.Tyr279Ser) in *PTPN11* in patient 1, c.721A>C (p.Thr241Pro) in *BRAF* in patients 2 and 3, c.1914T>G (p.Asp638Glu) in *BRAF* in patient 4 and c.124A>G (p.Thr42Ala) in *PTPN11* in patient 5.

3.6. Clinical, biochemical and genetic data of 18 patients with known Ras-MAPK gene mutations, prospectively screened for metabolic features of OXPHOS dysfunction

All patients were previously diagnosed due to suggestive clinical features with a molecularly proven Ras-MAPK defect. Seven children had *BRAF*, six *PTPN11*, three *HRAS*, two children carried *KRAS* mutations.

The majority of patients had the clinical presentation of Noonan syndrome, 5 children had CFC, 1 patient had LEOPARD syndrome and 1 patient had Costello syndrome.

In 15 patients metabolic screening did not show any abnormalities, two patients had recurrent lactic acidemia (one also elevated serum alanine levels), and one patient had elevated urinary excretion of ethylmalonic acid. Only one of these three patients had a MDC score >6, receiving nutritional intervention and awaiting an open muscle/skin biopsy. (The other two patients are under follow up, but haven't underwent muscle biopsy due to ethical considerations).

The three patients with the biochemical abnormalities were screened with Mitochip analysis for possible mtDNA alterations in DNA extracted from leucocytes, but did not show abnormalities.

3. DISCUSSION

Here we describe five patients with the initial diagnosis of mitochondrial encephalomyopathy based on the early infantile presentation of multisystem disease, chronic lactic acidemia and the presence of abnormal organic acids in the urine. The diagnosis was

also supported by significant OXPHOS abnormalities measured in muscle biopsy of all children. Though three patients carried alterations in (or related to) the mitochondrial genome, the functional consequence of these alterations on mitochondrial function were not evident, since these were segregating in healthy family members as well. During the clinical course of disease evolving dysmorphic features lead to reinvestigation of the initial diagnosis and investigation of the Ras-MAPK pathway. All of the five patients carried *de novo* Ras-MAPK related mutations.

One should note, that although the common m.11778G>A *LHON* mutation has no significant biochemical effect on muscular function in most carriers, it might have important clinical relevance in patient 1. This mutation has a highly variable penetrance and the patient might develop visual loss during young adulthood. The mother, who carries the same alteration, has no ophthalmological complaints at the age of 48 years.

In patient 3 a heterozygous missense change in *POLG1* (c.2492A>G; p.Tyr831Cys) was detected. Although this heterozygous alteration has been described once as pathogenic in one adult patient, the same alteration was present in the healthy mother of that patient at the age of 38 years as well.¹⁶ A homoplasmic alteration (m.6489C>A; pLeu196Ile in *MT-COI*) was found in patient 4 without COX deficiency. This alteration has been described as pathogenic in severe epilepsy in association with fibrillar COX deficiency, however the same alteration was homoplasmic present in the healthy mother without any symptoms of epilepsy.¹⁷

In patient 5, a 1.5 Mb deletion on Xp22 including the *STS* gene was identified. This deletion has been frequently reported in literature and occurs due to recombination between low copy repeats. Though individuals with this deletion usually show normal development, some also present with intellectual disability and susceptibility to ADHD, autism and social communication deficits.^{18,19} Therefore we can not exclude that beside the ichthyosis, this

deletion additionally contributes to the developmental and behavior phenotype. One should note, that **the mother** of the patient carries the same deletion without features of ichthyosis.

Interestingly, parallel with a spontaneous clinical improvement in the patients 2-4 there was an evolving syndromic appearance: early clinical presentation with severe neurological symptoms, including intractable epilepsy and the predominance of muscle disease, turning into an unexpected improvement from the age of two to three years with the development of classic facial and skin features facilitating the correct syndrome diagnosis in these patients. In patient 1 the occurrence of lentiginosities around the age of 15 years lead to the correct syndrome diagnosis. In patient 5 parallel with the diagnosis of NS, the severe phenotype with muscular hypotonia and cardiomyopathy as well as lactic acidosis and methylmalonic aciduria lead to further evaluation and confirmation of mitochondrial disease. In patient 4 the severe phenotype with multi-system disease, the lactic acidemia and especially the 3-methylglutaconic aciduria, a known marker for mitochondrial dysfunction, lead us to perform a muscle biopsy, and later on, based on the dysmorphic features, the mutation analysis of the genes of Ras-MAPK pathway.

Intrigued by these findings and the growing evidence for a functional connection between the Ras-MAPK pathway and mitochondria, we prospectively screened 18 patients with known mutations in the Ras-MAPK-pathway for signs of OXPHOS dysfunction.⁶ Metabolic abnormalities, comparable to possible mitochondrial dysfunction were detected in three out of eighteen patients. Only one patient, who was severely malnourished, had a MDC score >6 indicating probable mitochondrial dysfunction. No additional mtDNA alteration was found. One should also consider that the abnormal metabolic markers are secondary to malnutrition. Primary and secondary mitochondrial dysfunction remains a challenging issue in metabolic pediatrics; several patients have been previously reported with secondary mitochondrial dysfunction diagnosed with chromosomal abnormalities and various classic

genetic syndromes.³ We hypothesize that the OXPHOS dysfunction in our patients is a consequence of the metabolic susceptibility due to mutations in Ras-MAPK pathway related genes. This is of high importance for further counselling and disease management.

Recently a study revealed a direct correlation of this pathway to mitochondrial function.²⁰ The control of mitochondria dynamics is regulated by A-kinase anchor protein (AKAP) complexes. Protein kinases and phosphatases are assembled by AKAPs within transduction units, providing a mechanism to control signalling events at mitochondria and other targeted organelles.²¹ Interestingly, it was shown that a distinctive property of the RAF kinases is not only their ability to interact with cellular membranes, but also their presence on mitochondria and subsequent involvement in these AKAPs. The existence of target proteins for RAF kinases on the surface of mitochondria, suggests that these kinases could control directly some important aspects of the physiology of these membrane organelles. Indeed, activation of a specific isoform of the RAF family, C-RAF (= RAF1) through its functional coupling with mitogen-activated protein kinase/ERK kinase (MEK), resulted in a dramatically change of morphology and subcellular distribution of mitochondria.²² The hypothesis that abnormal signalling of RAS/RAF/MEK can result in mitochondrial dysfunction or lead to an increased susceptibility are underlined by another study in mouse fibroblast cell lines with constitutively active SHP2 activity, showing decreased mitochondrial membrane potential and ATP, with an increase in reactive oxygen species (ROS) compared to wild type.⁷ Another recent study underlines these findings by showing evidence that the mtDNA haplogroup 'R' is associated with NS in South India. In seven patients with the typical clinical picture of NS, mutation analysis of *PTPN11* failed to show mutations. In contrast a total of 146 mtDNA mutations, five of which were novel and exclusively observed in NS patients were found.⁸

Therefore, the severe mitochondrial dysfunction observed in our patients with NS, CFC and LEOPARD syndrome, might be explained by this pathophysiologic mechanism and

merits the clinician to search for mutations in the Ras-MAPK genes in patients presenting with mitochondrial encephalomyopathy with additional features that could fit with CFC, NS, CS or LEOPARD syndrome. Mutations in the Ras-MAPK pathway could lead to increased vulnerability of the mitochondria to further, mitochondria related biochemical or genetic alterations. One might speculate that although the single mitochondrial alterations in the three families do not appear to be significant in the pathogenesis, but in association with a second alteration (MAPK mutation), could lead to further deterioration of mitochondrial function. Unfortunately the biochemical defects of the OXPHOS were not expressed in the fibroblasts of the patients, delaying further functional studies on pathogenesis. One point has to be considered critically. The ATP-production as a maker of overall mitochondrial function is measured in intact mitochondria of fresh muscle specimen. Upon extraction from the patient the muscle specimen is directly cooled, brought to the laboratory and worked up for measurements within 10 minutes. It is possible that the phosphorylation state of the OXPHOS complexes is not maintained during transport of the tissue specimens and subsequent mitochondria isolation, because no phosphatase inhibitors were included in our buffers and isolation media. Therefore, possible changes due to alterations in cell signaling caused by mutations in the RAS-MAPK pathway may have been overlooked, and data presented in table 2 related to OXPHOS enzyme activities have to be viewed with some caution. In addition, the diminished activity of the OXPHOS complexes in patients 2 and 3, measured consecutively in frozen muscle might be partly influenced by unspecified phosphorylation. This has to be investigated in the future in more details.

Based on the obvious clinical variability in Ras-MAPK patients, especially with regards to muscle involvement, and the normal biochemical screening in 15 out of 18 prospectively screened patients with classic, molecularly characterized Ras-MAPK syndromes we concluded that only a specific subgroup of these patients presents with a

“mitochondrial phenotype”. This could be expressed due to a second genetic hit (mitochondrial related genetic alteration/polymorphism), another polymorphism in a related metabolic pathway increasing mitochondrial vulnerability, or malnutrition, explaining the more severe clinical presentation in some of the patients of the Ras-MAPK spectrum.

Clinicians should continue to critically review their diagnosis during the course of disease, particularly if there are incongruities between the clinical severity and the genetic diagnosis obtained. The finding of mitochondrial dysfunction in syndromic, Ras-MAPK pathway mutation carriers is also highly relevant both for the correct diagnostic procedure and interpretation of the results. The detection of an underlying signalling pathway mutation in children with mitochondrial dysfunction is essential for genetic counselling, future prognosis assessment and possible therapy.

FIGURE LEGENDS

Figure 1: Clinical pictures of patient 2 (A, B; aged three years), patient 3 (C, D; aged three years), patient 4 (F; aged 3.5 years) and patient 5 (G, H; aged 1.5 years). Patient 1 (E; aged 14 years): note multiple lentiges in the clavicular region.

Figure 2: Wrinkled skin of the hands in patients 2 (A) and 4 (B), and 5 (C). Wrinkled, loose skin in the nuchal region in patient 3 (D). Note dry, ichthyosiform skin abnormalities in patient 3 (D) and 5 (C). Skin histology in patients 3 and 5 showed no histological alterations of the elastin fibers.

Figure 3: Mild abnormalities on MRI imaging of three patients. Cerebral MRI of patient 3 shows mild white matter changes on T1-weighted images (A; aged 4 years). Cerebral MRI of patient 5 shows delayed myelination (B; aged 19 months) on T1-weighted images. Cerebral MRI of patient 4 (C; aged 2 years) and patient 5 (D; aged 15 months) show hypoplasia of the corpus callosum and frontal atrophy on T2-weighted images.

Table 1: Clinical patient characteristics.

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
Muscle hypotonia	+	+	+	+	+
Developmental/speech delay	+/+	+/+	+/+	+/+	+/+
Epilepsy	+	-	+	+	-
Deafness	-	+	-	+	+
Cardiomyopathy	-	+	-	-	+
Pulmonal stenosis	+	+	+	-	-
Short stature	+	+	+	+	+
Swallowing problems	+	-	+	+	+
Failure to thrive	+	-	+	+	+
Dysmorphic facial features (at time of syndrome diagnosis)	+	+	+	+	+
Hair/skin abnormalities	+	+	+	+	+
MDC score prior to muscle biopsy*	6	8	8	8	7
Age at muscle biopsy	14 y	2 y	2.5 years	14 m	18 m
Syndrome diagnosis (age at diagnosis)	CFC (15 y)	LEOPARD (3 y)	CFC (4.5 y)	CFC (2 y)	NS (18 m)

*MDC score 6: mitochondrial disease probable, MDC score 8: mitochondrial disease definite³,

m= months, y= years

Table 2: Biochemical patient characteristics and details on genetic findings.

	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5
Serum lactate (0.4-2.0 mmol/l)	1.2-2.2	2.4-3.2	2.8-7.2	1.7-3.0	1.8-3.2
Blood alanine (120-460 mmol/l)	412-484	820	680	190-634	410
Urinary ethylmalonic acid (0-16 µmol/mmol creatinine)	120	N	N	N	N
Urinary methylmalonic acid (0-18 µmol/mmol creatinine)	N	N	62	N	42
Urinary 3-methylglutaconic acid (0-20 µmol/mmol creatinine)	N	N	N	45-46	N
ATP production (42-81 nmol.h.mU/CS)	38	ND	24	28.5	30
Complex I (70-250 mU/mU CS)	N	61	52	N	N
Complex II (335-749 mU/mU CS)	N	N	310	N	N
Complex III (2200-6610 mU/mU CS)	N	N	2039	N	N
Complex IV (810-3120 mU/mU CS)	N	N	N	N	N
Complex V (169-482 mU/mU CS)	N	N	N	N	N
Pathogenic mutation (<i>de novo</i> , heterozygous)	<i>PTPN11</i> c.836A>C	<i>BRAF</i> c.721A>C	<i>BRAF</i> c.721A>C	<i>BRAF</i> c.1914T>G	<i>PTPN11</i> c.124A>G
Second genetic alteration (asymptomatic maternally present)	<i>LHON</i> m.11778G> A	Not found	<i>POLG1</i> c.2492A>G	<i>MTCO1</i> m.6489C>A	1.4 Mb loss in Xp22.31 encompassing the <i>STS</i> gene*

N: normal, ND: not determined, *present in mother with isolated lamellar ichthyosis
