Abstract

Dissolution of large particles in DC-cast 7xxx aluminum alloys is one of the primary objectives of the homogenization process. A mathematical model to describe and predict this complex thermodynamical and kinetical process is of great significance. In this paper, the details of a diffusion limited dissolution model developed based on the thinning, discontinuation and full dissolution (TDFD) mechanism to predict the dissolution of the $Al_{17}(Fe_{3.2},Mn_{0.8})Si_2$ particles are described. The model is capable of predicting the volume fraction and the thickness of the particles during homogenization at different temperatures and time intervals. The predicted results are in good agreement with the measurements using quantitative X-ray diffraction (QXRD) and quantitative field emission gun-scanning electron microscopy (QSEM). The model predictions of the supersaturation parameter, interface position, interface movement rate of the planar surfaces and the cylindrical edges, and the effect of the occurrence of discontinuities on the dissolution extent are presented.

Keywords: Al-4.5Zn-1Mg alloy; modeling; dissolution; intermetallic compounds; analytical methods.

1. Introduction

Homogenization treatment is an important industrial process applied to direct chill (DC) cast aluminum alloys that are subsequently subjected to deformation. It is carried out to improve their final mechanical properties and also to facilitate the subsequent processing towards the final product. It aims at redistributing the alloying elements on a micro scale [1, 2] and dissolving the detrimental particles such as those with low melting points [1, 2] or those which will deteriorate the deformability during hot deformation [3].

In the case of the AA7020 aluminum alloy, more than 70% of the constitutive particles are composed of the $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ phase [4], elongated alongside the grain boundaries (GB). It is well known that the presence of second-phase particles can deteriorate the mechanical properties and hot deformability of the alloy, especially if these are located in the grain boundary regions [5-9]. Therefore, the dissolution of these particles during the homogenization of DC-cast AA7020 aluminum billets is of prime importance. The optimization of the homogenization process in terms of the dissolution of these particles requires a fundamental understanding of the dissolution mechanism, which has recently been proposed and termed thinning, discontinuation and full dissolution (TDFD) [4]. In this mechanism, the dissolution process starts with the thinning of the particles. The thinning process continues until the particles become discontinuous in some regions and finally the full dissolution of particles occurs. It is of interest to develop a model that correlates characteristic parameters of the particles such as concentrations, sizes, shapes and geometries with dissolution temperature and holding time. To author's best knowledge, the dissolution of the $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particles based on the TDFD mechanism has not been mathematically expressed.

In the past, particle dissolution in general has been studied by numerous

1
2
3 researchers using a variety of analytical and numerical techniques [10-32]. For example,
4
5 Aaron and Kotler [10] investigated the effects of the diffusion of the elements in the
6
7 matrix, interfacial reactions and the curvatures of the particles on the dissolution of
8
9 precipitates in binary alloys. It was found that the presence of curvature tended to
10
11 accelerate the dissolution, being particularly important at long times (i.e., when
12
13 precipitate sizes become small) and when the difference between the solute
14
15 concentration at the precipitate/matrix interface and in the depleted matrix was small. It
16
17 was shown, however, that curvature would not affect the dissolution kinetics
18
19 significantly even at long times unless the concentration difference between the
20
21 particle/matrix interface and the matrix was sufficiently small. The interface reaction
22
23 kinetics might produce significant alterations in the dissolution kinetics and increase the
24
25 total time needed for dissolution. It was also found that for the uniform detachment
26
27 mechanism, the interface reaction would have no sensible effect when the kinetics
28
29 coefficient (K_0) was larger than 10^{-3} cm/sec. On the other hand, when $K_0 < 10^{-7}$ cm/sec,
30
31 the particle would be effectively insoluble due to the extremely sluggish kinetics.
32
33 Whelan [11] performed a similar analysis for perfectly spherical precipitates. Both
34
35 Aaron and Kotler [10] and Whelan [11] developed analytical expressions to quantify the
36
37 radius of a spherical dissolving precipitate in a binary alloy in an infinite domain. Nolfi
38
39 et al. [12] used the separation of variables method to solve the kinetic problem of the
40
41 dissolution and growth of a spheroidized, solute-rich stoichiometric precipitate in the
42
43 surrounding matrix. The applicability of this method to solve the dissolution and growth
44
45 problems was demonstrated. Tanzilli and Heckel [13] solved the diffusion equation
46
47 numerically using a finite difference technique for the spherical particles with a constant
48
49 radius. Tundal and Ryum [14, 15] considered the effect of the size distribution of
50
51 particles on their dissolution during homogenization. The results demonstrated that the
52
53
54
55
56
57
58
59
60

1
2
3 distribution of particle sizes was indeed an effective parameter on the model predictions
4
5 and therefore should be considered in the model if an accurate prediction of the
6
7 dissolution kinetics was to be achieved. In addition, Vermolen and Vuik [16, 17]
8
9 presented a mathematical model with nonlinear boundary conditions at the interface and
10
11 compared the numerical solution with the solutions obtained by the analytical methods.
12
13 A better agreement between the numerical solution and experimental results was found.
14
15 Nojiri and Enomoto [18] attempted to reach an exact diffusion controlled dissolution
16
17 solution for spherical precipitates. By applying their formalism the incorporation of the
18
19 influence of capillarity on the dissolution kinetics into the model became possible.
20
21 Aaron et al. [19] compared different mathematical approximations, i.e., interval field
22
23 (Laplace), the invariant size (stationary interface), linearized gradient and the reversed
24
25 growth in diffusion limited phase transformations. They found that the stationary
26
27 interface was the best approximation. Sinder and Pelleg [20] presented the same
28
29 solution as Aaron et al., [19] for planar and spherical particles and compared the results
30
31 related to these different situations. The effect of cross-diffusion in multi-component
32
33 alloys on the dissolution of particles of different geometries; i.e., cylindrical, spherical
34
35 and planar was modeled by Vermolen et al. [21]. In more recent studies, dissolution
36
37 models were extended to multi-component systems in one dimension and to binary
38
39 systems in two dimensions [22-32] and a better agreement between the experimental
40
41 and predicted results was achieved.
42
43
44
45
46
47
48
49

50
51 All of the previously published models are limited to a specific geometry, i.e.,
52
53 spherical, cylindrical or planar geometry. These do not consider a combined mode of
54
55 dissolution from the surfaces and the edges of plate-like particles. However, in the real
56
57 particle dissolution process, the element flux from all free surfaces of particles,
58
59 especially that from edges where there are increases in the concentrations of elements at
60

1
2
3 the particle/matrix interface due to the curvature, is of great importance. Generally, due
4 to the large surfaces of plate-like particles compared with their edges, at the onset of the
5 dissolution process, the fraction of dissolution from the edges relative to that from the
6 planar surfaces is insignificant. Therefore, in a general mode for dissolution from the
7 planar surfaces of a plate-like particle at the beginning of dissolution, neglecting the
8 effect of dissolution from the edges may be allowed. However, as the dissolution
9 proceeds further, the fraction of the dissolution from the edges relative to that from the
10 planar surfaces increases as the radius of the edges decreases and consequently the
11 supersaturation in the vicinity of the particle increases significantly. A larger dissolution
12 rate of particles from the edges than that from planar surfaces was proven by Aaron and
13 Kotler [10] in the case of spherical precipitates dissolving in an infinite matrix. It was
14 found that as time increased, the volume for mass transfer increased, which accelerated
15 the dissolution process. This condition resembles that occurring at the edges of a plate-
16 like particle where the decrease in the thickness of the particle and consequently the
17 decrease in the radius of the edges result in a larger dissolution rate from the edges. This
18 is different from the planar case because the volume of the mass transferred ahead of the
19 moving interface is always constant.

41
42
43
44 Experimental observations [4] have shown that some of the particles dissolve with
45 a mechanisms different than those known in the literature, which makes the modeling of
46 the dissolution process quite complicated. In the case of $\text{Al}_{17}(\text{Fe}_{3.2}\text{Mn}_{0.8})\text{Si}_2$ particles in
47 the AA7020 aluminum alloy, dissolution occurs through the TDFD mechanism [4]. This
48 mechanism is unique and the existing models are not applicable. The TDFD mechanism
49 takes an increase in the number density of the edges of the particles in the structure into
50 account. Therefore, considering the effect of the dissolution from the edges of the
51 particles is essential for the model.

1
2
3 The objective of the research was to develop a model based on the TDFD
4
5 dissolution mechanism, which could be used to predict the volume fraction of the
6
7 $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles dissolved during the homogenization process. The research
8
9 was focused on the dissolution of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in the AA7020
10
11 aluminum alloy which, in spite of its practical importance, has received little attention
12
13 in the research community. The predictions were verified experimentally by using FEG-
14
15 SEM analysis and quantitative XRD analysis.
16
17
18

20 2. The model

23 2.1. The TDFD dissolution mechanism

26 The dissolution mechanism of a $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle at various stages of
27
28 homogenization is schematically illustrated in Fig. 1. Fig. 1 (a-d) shows the overall
29
30 thinning process of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle. In Fig. 1 (e) the formation of
31
32 discontinuities is shown. Assuming that during homogenization an overall decrease in
33
34 the width of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle occurs at a constant rate in different regions
35
36 regardless of the width (Fig. 1 (a-d)), the parts having smaller widths become thinner
37
38 than the other parts and meet each other sooner, as shown in Fig. 1 (d) and (e).
39
40 Therefore, the discontinuities (Fig. 1 (f)) occur as a result of the inherent perturbations
41
42 of the surfaces of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle [4]. At the end of the process, the full
43
44 dissolution of the particles continues with the thinning of the remaining parts and
45
46 theformation of new discontinuities, if there are still remaining perturbations.
47
48
49
50
51

53 2.2. Model setup and assumptions

56 A model based on the TDFD dissolution mechanism [4] has been developed to
57
58 predict the dissolution of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in AA7020 during
59
60 homogenization. This model is capable of predicting the volume fraction and the

1
2
3 thickness of the particles during homogenization at different temperatures and times. In
4
5 this model, the particle is considered to be a two dimensional plate with round
6
7 cylindrical edges and initial perturbations on the planar surfaces located alongside the
8
9 grain boundaries.
10
11

12
13 The dissolution of the particle occurs from surfaces and cylindrical edges into the
14
15 grain interior, as shown in Fig. 2. During dissolution, discontinuities occur at the
16
17 initially thinner parts of the particle, leading to an increase in the number density of the
18
19 cylindrical edges, as shown schematically in Fig. 1 (a) through (f).
20
21

22
23 The application of this modeling framework to the dissolution of
24
25 $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particles requires the following simplifications:
26
27

- 28 • The dissolution of an isolated particle into an infinite matrix in two dimensions is
29
30 considered a diffusion-limited process. The influence of interface reactions on the
31
32 dissolution is neglected. The diffusion rate of the slowest diffusing element, in this case
33
34 Mn [33], is considered the controlling factor of dissolution rate. Moreover, the diffusion
35
36 coefficient is assumed to be independent of composition.
37
38
- 39 • The solute concentrations in the precipitate are constant and equal to their equilibrium
40
41 values [10, 15-20]. The solute concentrations are assumed to be independent of the
42
43 distance from the precipitate/matrix interface and temperature. In other words, there are
44
45 no concentration gradients in the particle [10, 15-20]. Moreover, the diffusion
46
47 coefficients of the elements in the particle are negligibly small compared to the
48
49 diffusion coefficients in the matrix.
50
51
- 52 • Discontinuities in the TDFD dissolution mechanism [4] may occur as a geometrical
53
54 issue as well as due to heterogeneous distributions of solute atoms. From experimental
55
56 observations as presented elsewhere [4], the discontinuities occur mainly due to the
57
58
59
60

1
2
3 initial perturbations on the surfaces of the particles. The heterogeneous distribution of
4
5 solute atoms can accelerate them.
6
7

- 8
9 • The dissolution occurs on the planar surfaces and the cylindrical edges of the particle.
10 The dissolution from the tapered surfaces between the perturbations and the particle
11 bulk (Fig. 3) is neglected.
12
13
- 14
15 • The effect of the initial concentrations of the elements in the structure, before
16 dissolution, is incorporated into the system; however, the effect of solidification
17 segregation is neglected [10, 15-20]. During dissolution, due to the increases in the
18 concentrations of the elements in the surrounding matrix, the dissolution rate decreases.
19 The change in the composition of the matrix due to dissolution is also included in the
20 model by considering an average concentration after each individual time step. The total
21 time of homogenization is composed of small time steps and, at each time step, the
22 increase in the concentration of the matrix due to the dissolution is updated.
23
24
- 25
26 • Diffusion along the grain boundaries is important at low temperatures but not at high
27 temperatures, i.e., $T > 0.5T_m$ [34]. This is due to exponential increase in the number
28 density of vacancies at high temperatures which controls the diffusion rate. Temperature
29 range used in this research, i.e., between 390 and 550 °C, is significantly higher than
30 $0.5T_m$. Therefore, it is reasonable to assume that during homogenization there is no
31 effect of the grain boundaries on the increases of the diffusion rates of the elements,
32 even though the $Al_{17}(Fe_{3.2},Mn_{0.8})Si_2$ particles are located at the grain boundaries.
33
34
- 35
36 • During dissolution, the particle has a finite, nonzero initial width and the cylindrical
37 edge radii are instantaneously equal to its half-thickness, which is a geometrically
38 necessary condition (GNC) as will be discussed later. The particle decreases its size by
39 transferring (or rejecting) solutes into the matrix behind the thinning interface.

2.2. The dissolution process

2.2.1. Dissolution from the planar surfaces

The dissolution from the planar surfaces of the particles may be simplified as the dissolution of a one-dimensional plate-like particle. Assuming the diffusion-limited character for the dissolution of the particle, one arrives at the following equation [10];

$$D\nabla^2 C(x,t) = \frac{\partial C(x,t)}{\partial t} \quad (1)$$

where D is the volume diffusion coefficient in the matrix and $C(x,t)$ the concentration field surrounding the particle. The initial and boundary conditions are described in the following equation [10]

$$\begin{aligned} C(x,t=0) &= C_M & x \geq S_0 \\ C(x=S_0,t) &= C_{Ip} & 0 < t < \infty \\ C(x=\infty,t) &= C_M & 0 \leq t \leq \infty \end{aligned} \quad (2)$$

where x is equal to S_0 at the particle/matrix interface and C_{Ip} and C_M are the concentrations of the elements at the particle/matrix interface and in the matrix, respectively. The term S_0 denotes the value of S at $t=0$. Considering a flux balance at the particle/matrix interface, one can write [10]

$$(C_p - C_{Ip}) \frac{dS}{dt} = D \left(\frac{\partial C}{\partial x} \right)_{x=S} \quad (3)$$

where C_p , the concentration of the diffusing element in the particle, is considered a constant independent of x and t . The analytical solution of Eq. (1) with the initial and boundary conditions presented in Eqs. (2) and (3) for a plate-like particle is known [10, 19]. Using the exact solution to calculate the thickness of the dissolving particle, one may express [10, 19]:

$$S = S_0 - \lambda_p \sqrt{Dt} \quad (4)$$

for

$$\sqrt{\pi} \lambda_p \exp\left(\frac{\lambda_p^2}{4}\right) \operatorname{erfc}\left(\frac{\lambda_p}{2}\right) = k_p \quad (5)$$

where k_p , the supersaturation parameter of the planar surfaces, is defined as

$$k_p = 2 \frac{(C_{1p} - C_M)}{(C_P - C_{1p})} \quad (6)$$

When k is small [10, 19],

$$\lambda_p = \frac{k_p}{\sqrt{\pi}} \quad (7)$$

which can be written as

$$\lambda_p = \frac{2}{\sqrt{\pi}} \frac{(C_{1p} - C_M)}{(C_P - C_{1p})} \quad (8)$$

In this case, the time for full dissolution of the particle (t_f) and for reaching the width of the particle to the half of its initial value (t_h) can be determined as Eqs. (9) and (10) respectively.

$$t_f = \frac{\pi}{4D} \left(S_0 \frac{(C_P - C_{1p})}{(C_{1p} - C_M)} \right)^2 \quad (9)$$

$$t_h = \frac{\pi}{16D} \left(S_0 \frac{(C_P - C_{1p})}{(C_{1p} - C_M)} \right)^2 \quad (10)$$

t_h will be used as a boundary condition for the dissolution from the cylindrical edges which will be explained later.

Using the exact solution, the chemical composition of the matrix can be calculated using Eq. (11) [10]

$$C(x,t) = (C_{Ip} - C_M) \frac{\operatorname{erfc}\left(\frac{(x-S_0)}{2\sqrt{Dt}}\right)}{\operatorname{erfc}(\lambda_p)} + C_M \quad (11)$$

2.2.2. Dissolution from the cylindrical edges

As shown in Fig. 3, the dissolution from the cylindrical edges is, in fact, the dissolution of a cylindrical surface. Therefore, the dissolution has been modeled, considering the dissolution of a one dimensional circle with axial symmetry. In this case, Eqs. (1) through (3) can be written as [35];

$$\frac{\partial C(r,t)}{\partial t} = D \left(\frac{\partial^2 C(r,t)}{\partial r^2} + \frac{1}{r} \frac{\partial C(r,t)}{\partial r} \right) \quad (12)$$

where $C(r,t)$ is the concentration field surrounding the particle subject to the conditions;

$$\begin{aligned} C(r,t=0) &= C_M & r &\geq R_0 \\ C(r=R,t) &= C_{It} & 0 < t < \infty \\ C(r=\infty,t) &= C_M & 0 \leq t \leq \infty \end{aligned} \quad (13)$$

where $r=R$ is at the particle/matrix interface. The term R_0 denotes the value of R at $t=0$. C_{It} is the concentration of the matrix at the particle/matrix interface including the effect of the curvature of the particle. The other parameters have the same definitions as in Eqs. (1) through (3).

The effect of the curvature of the particle on the change in the concentration field can be imported into the model using the Gibbs-Thompson equation modified by Hillert [36] who showed that the composition in the matrix at the curved particle/matrix interface (C_{It}) varied with particle radius, R , as described in Eq. (14)

$$C_{It} = C_1(\infty) \exp\left(\frac{2\gamma V_p}{R_g T R}\right) \quad (14)$$

where $C_1(\infty)$ is the mean matrix composition, γ the specific interfacial energy of the particle/matrix boundary, V_p the molar volume of the particle, R_g the universal gas constant and R the particle radius. Considering the effect of the curvature of the particle, the supersaturation parameter of the cylindrical edges (k_t) should be expressed as [10, 19]

$$k_t = 2 \frac{\left(C_1(\infty) \exp\left(\frac{2\gamma V_p}{R_g T} \frac{1}{S_0 - \lambda_p \sqrt{Dt}} \right) - C_M \right)}{\left(C_p - C_1(\infty) \exp\left(\frac{2\gamma V_p}{R_g T} \frac{1}{S_0 - \lambda_p \sqrt{Dt}} \right) \right)} \quad (15)$$

The dissolution rate from the cylindrical edges of the particles is related to the thermodynamics and kinetics of dissolution and also a geometrical problem that restricts the dissolution rate from the cylindrical edges. Assuming the cross section of the cylindrical edges in two dimensions to be a half-circle, the diameter of the cross section of the cylindrical edge of the particle should be equal to the thickness of the particle as a geometrically necessary condition (GNC) during dissolution. This geometrically necessary condition is schematically shown in Fig. 4. The radius of the cross section of the cylindrical edge during dissolution is restricted by the thickness of the particle and cannot decrease more than that even if the thermodynamic and the kinetics of dissolution would allow.

By applying the GNC, the cylindrical edges of the particles are not allowed to dissolve faster or more slowly than the planar surfaces. It should however be noted that the dissolution from the cylindrical edges and the planar surfaces has been modeled in different mathematical systems. In every specific time step, the dissolution from the cylindrical edge is independent of that from the planar surface. At the end of each time step, the cylindrical edge diameter is artificially assigned to be equal to the particle width. If the dissolution rate from the cylindrical edge is faster than that from the

1
2
3 surface, in a single time step, it will result in a larger decrease in the length of the
4
5 particle, although the diameter should be always equal to the particle width. In this way,
6
7 the increase in the concentration due to the curvature results in a higher dissolution rate
8
9 of the cylindrical edges than that from the planar surfaces and therefore, the length
10
11 decreases faster than the width. Due to the presence of the GNC, a boundary condition,
12
13 presented in Eq. (16), is added to the system. This is necessary to be able to solve Eq.
14
15 (12) with the conditions presented in Eq. (13) and (14).
16
17
18

$$19 \quad C(r = S_0, t_h) = C_{th} \quad 0 < t < \infty \quad (16)$$

20
21 where C_{th} is the concentration at the particle matrix interface at the time the width
22
23 of the particle has reached half of its initial value. It can be obtained by replacing R with
24
25 $S_0/2$ in Eq. (14). There is a particular solution for the problem presented in Eq. (12) as
26
27
28
29
30
31 [35]

$$32 \quad C(r, t) = C_M + (C_{th} - C_M) \frac{t_h}{t} \frac{\exp\left(-\frac{r^2}{4Dt}\right)}{\exp\left(-\frac{S_0^2}{16Dt_h}\right)} \quad (17)$$

33
34
35
36
37
38
39
40 Eq. (3) can also be re-written in the case of a cylindrical particle,

$$41 \quad (C_P - C_{It}) \frac{dR}{dt} = D \left(\frac{\partial C}{\partial r} \right) \quad r = R \quad (18)$$

42
43
44
45
46
47 where C_P is a constant independent of r and t . Having obtained $C(r, t)$ and thus

48
49
50 $\left(\frac{\partial C}{\partial r} \right)$ from Eq. (17), dR/dt may be obtained from Eq. (18) as

$$51 \quad \frac{dR}{dt} = -\frac{R(C_{th} - C_M)}{2(C_P - C_{It})} \left(\frac{t_h}{t^2} \right) \frac{\exp\left(-\frac{R^2}{4Dt}\right)}{\exp\left(-\frac{S_0^2}{16Dt_h}\right)} \quad (19)$$

52
53
54
55
56
57
58
59
60
As discussed above, the radius itself must be equal to one half of the width of the

particle, as a geometrically necessary condition. Therefore, S_0 should be inserted into Eq. (19) for R at the initial time step. Afterwards, R should be replaced by S , which yields that the rate of the decrease in the radius of the cylindrical edge is a function of the rate of the decrease in the width of the particle. In other words, the dissolution rate from the cylindrical edges is a function of the difference between the concentration in the particle and the matrix, the radius of the cylindrical edge (which changes the concentration at the particle/matrix interface) and the rate of the decrease in the width of the particle.

As mentioned earlier, the radius of the cylindrical edge of a particle should be equal to one half of the particle thickness. Therefore, the thickness of the particle during dissolution, shown in Eq. (4) should be inserted into Eqs. (14) and (19), as the instantaneous radius of the particle, which for eq. (19) yields;

$$\frac{dR}{dt} = -\frac{1}{2} (S_0 - \lambda_p \sqrt{Dt}) \frac{(C_{th} - C_M)}{(C_P - C_{It})} \left(\frac{t_h}{t^2}\right) \frac{\exp\left(-\frac{(S_0 - \lambda_p \sqrt{Dt})^2}{4Dt}\right)}{\exp\left(-\frac{S_0^2}{16Dt_h}\right)} \quad (20)$$

In order to determine the effect of the dissolution from the cylindrical edges of the particles, the relationship presented in Eq. (20) should be integrated over the time of dissolution. The integration yields the decrease in the length of the particle, l , as

$$l = -\frac{1}{2} \int_0^t (S_0 - \lambda_p \sqrt{Dt}) \frac{(C_{th} - C_M)}{(C_P - C_{It})} \left(\frac{t_h}{t^2}\right) \frac{\exp\left(-\frac{(S_0 - \lambda_p \sqrt{Dt})^2}{4Dt}\right)}{\exp\left(-\frac{S_0^2}{16Dt_h}\right)} dt \quad (21)$$

Eq. (21) can be used to calculate the decrease in the length of the particle and the dissolution rate from the cylindrical edges.

3. Experimental procedure

1
2
3 Cubic samples of 2 cm on each side were cut from the centre of a direct-chill (DC)
4
5 cast AA7020 billet. The chemical composition of the alloy is shown in Table 1.
6
7 Isothermal homogenization treatments were performed in a salt bath at temperatures of
8
9 390, 430, 470, 510 and 550 °C for 2, 4, 8, 16, 24 and 48 hours. Following the heat
10
11 treatment, the samples were water quenched.
12
13

14
15 The samples were examined using a JEOL 6500 field emission gun-scanning
16
17 electron microscope (FEG-SEM). An optimum operating voltage for resolving the
18
19 particles was found to be 10 kV which ensured sufficient penetration depth of electrons.
20
21 Energy dispersive X-ray analysis (EDX) was also performed with an analyzer attached
22
23 to the FEG-SEM to determine the chemical compositions of the particles.
24
25
26

27
28 The FEG-SEM images of the particles after different homogenization treatments
29
30 were quantitatively analyzed to determine the extent of the dissolution of the particles
31
32 during homogenization whereby 20 particles were analyzed in each case. The thickness
33
34 of the particles was measured and the average value was calculated. During
35
36 homogenization at high temperatures, i.e. 510 and 550 °C, some of the particles were
37
38 completely dissolved in the structure. The dissolved particles were also considered in
39
40 the calculation with a null thickness. The average initial number density of the particles
41
42 in 20 micrographs was counted to be $0.002 \mu\text{m}^{-2}$. The average number density of the
43
44 particles after homogenization was also counted employing the same method and, if it
45
46 was less than the average initial number density which indicated the full dissolution of
47
48 some of the particles, a zero thickness was assumed instead of the vanished ones.
49
50
51
52
53

54
55 A BRUKER-AXS D5005 diffractometer with Cu α_1 wavelength was used to
56
57 identify the phases present in the as-cast and as-homogenized conditions. Quantitative
58
59 XRD (QXRD) analysis was performed using the direct comparison method [37] to
60
estimate the weight percent of the phases in the structure. The application of this

1
2
3 method required the weight percent of the phase of interest in the as-cast structure (i.e.,
4 the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in the present case), as the baseline. To calculate the
5 weight percent of the particles in the as-cast structure, their surface fraction was
6 calculated using FEG-SEM together with EDX which is capable of distinguishing
7 between $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ and other particles and providing a trustworthy initial
8 surface fraction of $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in the as-cast microstructure. The
9 analysis was performed on 20 images at a magnification of 1000 and all the particles
10 present in each image were analyzed. Assuming a uniform distribution of the particles
11 in the structure, the surface fraction was approximated to be equal to the volume
12 fraction. The volume fraction of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles was converted to
13 weight percent using the density of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle (3709 kg/m^3 [38,
14 39]) and the density of AA7020 aluminum alloy (2780 kg/m^3 [40]). The only
15 assumption made was the density of the other particles (a mixture of various phases)
16 other than the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$, being equal to the density of AA7020 aluminum
17 alloy.

38 39 **4. Model inputs**

40 41 42 **4.1. Characteristics of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles**

43
44
45 The thermodynamically stable chemical composition for Al-Fe-Mn-Si compounds may
46 be presented by $\text{Al}_{16}(\text{Fe},\text{Mn})_4\text{Si}_3$ or $\text{Al}_{15}(\text{Fe},\text{Mn})_3\text{Si}_2$ [41]. The crystallography of
47 intermetallic phases containing aluminum, silicon, iron and manganese implies that they
48 should be considered as phases with muledgele sublattices [42]. Therefore, these
49 compounds may be simply considered as a solution of the Al-Fe-Si particles and Mn or
50 vice versa. In that case, their formation and stability at different conditions obey the
51 thermodynamics of solutions. Since Fe and Mn can reside on the same sublattices [42],
52 the Al-Fe-Mn-Si particles can be considered $\text{Al}_{16}(\text{Fe}_{(1-y)},\text{Mn}_y)_4\text{Si}_3$. From the role of the
53
54
55
56
57
58
59
60

1
2
3 RT $((1-y)\ln(1-y)+y\ln y)$ term in the Gibbs free energy of solutions [43], it can be stated
4
5 that a compound with equal values of Fe and Mn has the lowest total free energy.
6
7

8
9 In the DC-cast AA7020 aluminum alloy, the amount of Fe is higher than Mn in the
10
11 grain boundary regions. The larger amount of Fe may be attributed to the partitioning
12
13 coefficients of Fe and Mn which result in severer microsegregation of Fe toward the
14
15 grain boundaries and, therefore, a higher concentration of Fe in these regions [44]. Fe
16
17 has a small solid solubility in aluminum alloys [41]. Therefore, the excess Fe rather than
18
19 what is consumed in Al-Fe-Mn-Si particles, must form other intermetallic compounds.
20
21 In this case, if $y=0.5$, in addition to the thermodynamically stable $\text{Al}_{16}(\text{Fe}_{(1-y)},\text{Mn}_y)_4\text{Si}_3$
22
23 phase, some separate Al-Fe-Si and Al-Fe particles are expected to form to consume the
24
25 remaining insoluble Fe at the grain boundaries. However, as mentioned above, the
26
27 solution formation results in a decrease in the Gibbs free energy of the system
28
29 determined by the $-RT((1-y)\ln(1-y)+y\ln y)$ term. Therefore, in this system, the stable Al-
30
31 Fe-Mn-Si particles dissolve some of the excess Fe and form the meta-stable
32
33 $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles and the remaining Fe incorporate in the formation of other
34
35 intermetallic compounds. The amount of the Fe dissolved in the stoichiometric
36
37 $\text{Al}_{16}(\text{Fe}_{(1-y)},\text{Mn}_y)_4\text{Si}_3$ particles is so much that the total energy of the system is
38
39 minimized by the formation of $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$, Al-Fe-Si and Al-Fe particles. The
40
41 formation of Al-Fe-Si and Al-Fe particles at the grain boundary regions has been
42
43 revealed in the previous investigations of the authors [4, 45]. The same may be valid for
44
45 the replacement of Si atom with exceeding Al in the compound from the stoichiometric
46
47 values.
48
49
50
51
52
53
54
55

56 Low and higher magnification secondary electron FEG-SEM images of the as-cast
57
58 microstructure of the AA7020 aluminum alloy are shown in Fig. 5. The
59
60 $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles elongated along the grain boundaries can be clearly seen.

1
2
3 The perturbations on the surfaces of the particles are illustrated with arrows in Fig. 5
4
5
6 (b).

7
8 Image analysis indicated that the volume fraction of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$
9
10 particles was close to 7%. Therefore, it was possible to determine the identity of these
11
12 phases using XRD [37]. The results, shown in Fig. 6, illustrate that only one phase
13
14 could be detected using XRD analysis, which was $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$. Comparison of
15
16 the XRD results with those from EDX, as given in Table 2, indicates a good agreement.
17
18

19
20 The initial number density of $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles per unit surface is 0.002
21
22 μm^{-2} ($2 \times 10^9 \text{ m}^{-2}$) with an average length of $68 \mu\text{m}$. The average initial thickness of the
23
24 particles was determined to be 640 nm . The average initial number of perturbations on
25
26 the surface was determined to be $0.025 \mu\text{m}^{-1}$ (25000 m^{-1}). To calculate this number, the
27
28 perturbations were considered as the places where the thickness is less than half of the
29
30 average thickness of the particles, i.e. $<320 \text{ nm}$. The measurements were obtained by
31
32 counting the perturbations on 50 particles. The average thickness of the perturbations in
33
34 the initial structure was calculated to be 256 nm .
35
36
37
38
39

40
41 Fig. 7 shows a particle after homogenization at $550 \text{ }^\circ\text{C}$ for 8 hours, demonstrating
42
43 the occurrence of thinning and discontinuation, as described earlier. The occurrence of
44
45 discontinuities during dissolution of the AA7020 alloy was the main reason for
46
47 including the TDFD mechanism in the dissolution model. From this figure, it is clear
48
49 that the distance between discontinuities is proportional to the distance between the
50
51 initial perturbations, indicating that the discontinuities occur as a geometrical issue.
52
53
54

55
56 The experimental observations of the shapes of the particles, presented in Fig. 8,
57
58 show that the cylindrical edges of the particles may initially have rectangular,
59
60 ellipsoidal, needle or circular cross sections (Fig. 8 (a)-(c)). However, as shown in Fig.

1
2
3 8 (d)-(f), during the dissolution, the cylindrical edges have circular cross section.
4
5 Assume the initial shape of the cylindrical edges to be rectangular having two steep
6
7 cylindrical edges at the cylindrical edges. According to the Gibbs-Thompson equation
8
9 (Eq. (14)), a large concentration of the solute at the interface is resulted in which indeed
10
11 increases the dissolution rate significantly. The steep cylindrical edges dissolve sooner
12
13 and therefore a circular cylindrical edge will be produced. The same is valid for an
14
15 ellipsoidal cross section. It should be noted that the transition period from rectangle or
16
17 ellipse to circle has not been considered in the model.
18
19
20
21

22 23 **4.2. The initial constants of the model**

24
25 The general features of the dissolution of particles during homogenization have
26
27 been described by several investigators [10-32]. It is generally accepted that the
28
29 dissolution is a thermally activated process, dependent on the solubility limit and
30
31 diffusion rate of the alloying elements constituting the compound [10-32], mainly the
32
33 element that has the lowest solubility limit and diffusion rate. By comparing the
34
35 thermodynamic data of the three major alloying elements in the $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$
36
37 particles at homogenization temperatures, it is clear that Mn has the lowest diffusion
38
39 coefficient [33]. This indicates that the diffusion of Mn in the matrix is the controlling
40
41 parameter of dissolution kinetics.
42
43
44
45
46

47 48 **5. Model validation**

49 50 **5.1. Volume fraction of the particles**

51
52 Previous investigations [4] showed that during homogenization at temperatures
53
54 lower than 470 °C, spheroidization of $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particles occurred, which
55
56 resulted in a decrease in the area fraction. This might lead to misleading values during
57
58 the validation of the model against the experimental results. Therefore, the validation of
59
60

1
2
3 the model has been made using the results of homogenization treatment only at 470 °C
4
5 and higher.
6
7

8
9 Fig. 9 illustrates a comparison between the model predictions of the volume
10
11 fraction of the particles dissolved at different homogenization temperatures, with the
12
13 experimental FEG-SEM and XRD results. It is clear that in both of the graphs a
14
15 reasonable agreement between the model predictions and the experimental results has
16
17 been achieved.
18
19

20
21 It can be seen that the data from the quantitative FEG-SEM analysis show a better
22
23 agreement. This is because the model presented herein is a two-dimensional model
24
25 which considers the cross section of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle for estimating the
26
27 dissolution. The same procedure was used to calculate the volume fraction and the
28
29 thickness of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles using quantitative FEG-SEM analysis. In
30
31 other words, the cross section of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle has been considered
32
33 and the volume fraction of dissolved particles calculated. However, the QXRD analysis
34
35 works with the bulk of the material which can be considered a three dimensional
36
37 problem.
38
39
40
41

42
43 Another factor which may result in minor discrepancies between the predicted and
44
45 measured values is that in an industrial aluminum alloy, due to the presence of a large
46
47 variety of alloying elements and impurities, a lot of constituent particles and precipitates
48
49 are present, but not considered in this work. Moreover, the dissolution of the mentioned
50
51 particles is a strong function of temperature and time. Some of these particles have
52
53 similar XRD peaks, which may overlap each other and consequently result in
54
55 discrepancies between the experimental results and the model predictions. However,
56
57 such a problem is not valid in the case of QSEM because for each specific particle, the
58
59 EDX analysis was used to ensure that the particle was an $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle.
60

1
2
3 The dissolution of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles into the aluminum matrix is
4
5 dependent largely on the dissolution temperature. This is likely to be due to the strong
6
7 dependence of the diffusion coefficient, the solubility limit of the matrix for the
8
9 dissolving elements and consequently the supersaturation parameter and the volume
10
11 fraction of particles on temperature. With increasing temperature, these parameters all
12
13 increase, which results in an increase in the dissolution rate.
14
15

16 17 18 **5.2. Widths of the particles**

19
20 Fig. 10 shows a comparison between the model predictions for the thickness of the
21
22 particles during homogenization at 470, 510 and 550 °C and the experimentally
23
24 measured values using FEG-SEM. A reasonable agreement between the experimental
25
26 results and model predictions has been reached.
27
28
29

30 31 **6. Model predictions**

32 33 **6.1. The supersaturation parameter at the initiation of dissolution**

34
35 The variations of the concentrations of the elements in the matrix exert influences on the
36
37 dissolution rate by changing the driving force for dissolution. The effect of the changes
38
39 in the concentrations of the elements in the matrix and at the particle/matrix interface is
40
41 incorporated into the model by the supersaturation parameter (k). Since the
42
43 concentrations of the elements at the particle/matrix interface are functions of the shape
44
45 of the interface, two supersaturation parameters may be defined, i.e., (i) for the planar
46
47 surfaces (k_p) and (ii) for the cylindrical edges of the particles (k_t). In the case of the
48
49 planar surfaces, the supersaturation parameter is a function of the concentrations of the
50
51 dissolving elements in the particle, in the matrix and at the particle/matrix interface. In
52
53 the case of the cylindrical edges, however, the supersaturation parameter is dependent
54
55 not only on these variables, but also on the radii of the cylindrical edges, since these
56
57
58
59
60

1
2
3 affect the concentrations of the dissolving elements at the particle/matrix interface. See
4
5 Eq. (14).
6
7

8
9 Fig. 11 illustrates the k_p and k_t values of the particles at different temperatures as a
10 function of the initial width of the particles. It can also be seen that although k_p does not
11 change with the width of the particle, k_t is strongly dependent on the width of the
12 particle. This is expected because for k_p none of the variables are the functions of the
13 width of the particle but for k_t these are. Since an increase in the supersaturation
14 parameter is consistent with an increase in the driving force for dissolution and thus the
15 dissolution rate, it can be concluded that at a given chemical composition, the
16 dissolution rate of the particles with a smaller width is faster than the one with a larger
17 width. The effect of the initial width of the particles is more significant on k_t at smaller
18 widths. Regardless of temperature, when the width of the particles reaches 30 nm, the
19 supersaturation parameter increases sharply. This results in an increase in the
20 dissolution rate of the particles. These observations of k_t agree with the findings of
21 Aaron and Kotler [10] who noted that in the case of spherical particles (in two
22 dimensions, the similar geometrical conditions for the cylindrical edges of the particles),
23 the dissolution rate would increase only if the size of the particles was rather small [10].
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41
42
43

44 The effect of the initial width on the supersaturation parameter indicates that the
45 dissolution rate of a particle having a small width is faster than a larger one such that the
46 overall dissolution rate is dependent on the width of the individual particles. To avoid
47 the complexity of the model, the average values of the initial widths of the particles
48 have been calculated and used. However, since the relationship between the
49 supersaturation parameter and the width is not linear; i.e., k increases sharply as the
50 width reaches a specific value, the discrepancies between the model predictions and the
51 experimental results may be yielded.
52
53
54
55
56
57
58
59
60

6.2. The supersaturation parameter during dissolution

Fig. 12 shows a comparison between k_p and k_t at different temperatures as a function of the width fraction of the particles dissolved, presented by $1-S/S_0$. It is clear that at the start of the dissolution process, i.e., $1-S/S_0=0$, k_t and k_p are close to each other, although at any conditions (at the beginning and during dissolution) k_t is larger than k_p . However, the difference between the k_t and the k_p increases as the width of the particle decreases ($1-S/S_0$ increases toward 1).

K_p decreases during dissolution. This is expected based on the definition of the supersaturation parameter, Eq. (6) since the concentrations of the dissolving elements in the matrix (C_M) increase. However, k_t first decreases when the width of the particles decreases, which, as mentioned earlier, is due to the increases in the concentrations of the dissolving elements in the structure. Afterwards, k_t increases significantly to such an extent that it exceeds the initial k_t value at the beginning of the dissolution process. The reason for this behavior is that when the width of the particle (i.e., the radius of the cylindrical edge) reaches small values, the effect of the radius of the cylindrical edge on the increase of the concentrations of the dissolving elements, C_{It} , dominates the increases in the concentrations of the dissolving elements in the matrix, C_M .

The decreases in k_p and k_t with the initial decreases in the particle width indicate the reductions in the dissolution rate. This trend continues till the end of the process for the planar surfaces of the particles (k_p). However, k_t increases, which indicates that at the finishing stages of dissolution the role of the dissolution from the cylindrical edges becomes more prominent. Based on these findings, it can be concluded that at the initiation of the dissolution process due to the large surfaces of the planar surfaces of the particles relative to their cylindrical edges (68 μm to 320 nm), the effect of the cylindrical edges on the dissolution is insignificant. Therefore, at this stage, the

1
2
3 assumption of neglecting the effect of the cylindrical edges on the dissolution is
4
5 reasonable. However, as dissolution proceeds, the ratio of the dissolution from the
6
7 cylindrical edges to that from the planar surfaces increases sharply, because the radius
8
9 of the cylindrical edges decreases. Aaron and Kotler [10] concluded that for spherical
10
11 precipitates dissolving in an infinite matrix, as time increased, the volume for mass
12
13 transfer increased, thereby speeding up the dissolution rate. This is in fact the conditions
14
15 occurring at the cylindrical edges of the plate-like particles, where with the decrease in
16
17 the thickness of the particles and consequently the radius of the cylindrical edges, the
18
19 dissolution rate from the cylindrical edges intensifies. This is different from the planar
20
21 case, because the volume for mass transport ahead of the moving interface is always
22
23 constant. In this case, k can only decrease as the concentrations of the dissolving
24
25 elements in the matrix increase.
26
27
28
29
30

31 32 **6.3. Interface position and interface movement rate**

33 34 **6.3.1. The effect of dissolution time and temperature**

35
36
37 The dissolution of the particles occurs with the rejection of the constituting
38
39 elements from the particles into the matrix, forcing the interface between the particle
40
41 and matrix to move towards the particle center. Therefore, a study on the position of the
42
43 interface and its movement rate is of importance to understand the extent of dissolution
44
45 and the variations in the dissolution rate.
46
47
48
49

50
51 Fig. 13 shows the interface position of the planar surfaces and the cylindrical edges
52
53 of the particle with respect to dissolution temperature, respectively. In this figure, the
54
55 ratio of the instantaneous half width and half length of the particle (S and L) to the
56
57 initial values (S_0 and L_0) is shown as a function of dissolution time. It is clear that the
58
59 ratio decreases as the dissolution time increases. Both of the graphs show the same
60
trend. The decrease in this ratio is due to the dissolution which forces the boundary to

1
2
3 move toward the particle center. It can be seen that the steep movement of the interface
4
5 occurs at the beginning of the dissolution process (0-8 hours). To ascertain this, the
6
7 interface movement rates for the planar surfaces and the cylindrical edges were
8
9 calculated and presented in Fig. 14. It is clear that the interface movement rate from the
10
11 cylindrical edges (v_t) is larger than that from the planar surfaces (v_p). The interface
12
13 movement rate is directly related to the dissolution rate of the particle. It indicates that
14
15 the dissolution rate from the cylindrical edges is higher than that from the planar
16
17 surfaces.
18
19
20
21

22
23 Readey and Cooper [46] explained the differences between the dissolution kinetics
24
25 of circular and planar particles from a physical point of view. The same explanations
26
27 may be applied to account for the differences in dissolution rate between the cylindrical
28
29 edges and planar surfaces of $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particles. According to Readey and
30
31 Cooper [46], the main difference between the planar and circular geometries is that the
32
33 area available for the transport of the diffusing elements increases along the radial
34
35 distance from the center of a circle, but not from a planar interface. The dissolution rate
36
37 of a circular surface initially decreases, followed by an increase with time as a
38
39 consequence of the following two competing effects: the increase in the concentrations
40
41 of the dissolving elements in the matrix which decreases the dissolution rate and the
42
43 increase in the interfacial area of the sphere with decreasing size of the solute source
44
45 relative to the surrounding area of the diffusion zone, which provides larger space for
46
47 surface flux for the spherical particles. This is consistent with the observations of the
48
49 trend of the k_t curves presented in Fig. 12, which shows that k_t initially decreases and
50
51 then increases during dissolution. According to Readey and Cooper [46], the dissolution
52
53 rate from the planar surfaces of the particle should decrease due to the increases in the
54
55 concentrations of the dissolving elements in the matrix. This is valid for the planar
56
57
58
59
60

1
2
3 surfaces as shown in Fig. 14 (a). However, the dissolution rate from the cylindrical
4
5 edges should first decrease and then increase when the cylindrical edges are small
6
7 enough. As shown in Fig. 14 (b), this does not occur, which is because of the
8
9 introduction of the geometrically necessary condition into the model that restricts the
10
11 decrease in the size of the cylindrical edge.
12
13
14

15
16 The ratio of the interface movement rate of the cylindrical edges to that of the
17
18 planar surfaces (v_t/v_p) is illustrated in Fig. 15. It is clear that the ratio increases as the
19
20 dissolution temperature increases. In addition, with increasing dissolution time the ratio
21
22 increases. Both of these two effects are due to the decrease in the width of the particles;
23
24 i.e, the radius of the cylindrical edges. The increase in the ratio indicating that the
25
26 interface movement rate of the cylindrical edges is higher than that of the planar
27
28 surfaces is consistent with the findings of Readey and Cooper [46] who found that the
29
30 dissolution rate of the spherical precipitates increased at the final stages of dissolution.
31
32
33
34

35
36 As discussed earlier, the reason for the decreasing trend of the dissolution rate from
37
38 the planar surfaces is due to the increase in the concentrations of the dissolving elements
39
40 in the matrix which decreases the driving force for dissolution. However, at the
41
42 cylindrical edges, there are four effective parameters: (i) the increase in the matrix
43
44 concentration, (ii) the geometrically necessary condition, (iii) the increase in the
45
46 concentrations of the dissolving elements at the particle/matrix interface due to the
47
48 effect of the interface curvature and (iv) the increase in the interfacial area of the
49
50 cylindrical edge with decreasing size of the solute source relative to the surrounding
51
52 area of the diffusion zone which provides larger space for surface flux for the circular
53
54 particle. It should be noted that the first two parameters decrease the interface
55
56 movement rate, while the last two increase the interface movement rate.
57
58
59
60

The concentration gradient at the interface of the cylindrical edge initially

1
2
3 decreases with time due to increased solute concentrations in the matrix near the
4 interface. This influence is of major importance at short times when the gradient
5
6 decreases sharply from its original semi-infinite value. As the cylindrical edge becomes
7
8 smaller, the interface movement rate keeps increasing, because the interfacial area of the
9
10 cylindrical edge decreases markedly. This also results in decreasing size of the solute
11
12 source relative to the area of the surrounding diffusion zone. The total flux at the
13
14 cylindrical edge surface is affected by the area available for diffusion throughout the
15
16 diffusion zone and the rate of cylindrical edge shrinkage is equal to the surface flux
17
18 divided by the cylindrical edge surface area. Moreover, with decreasing radii of the
19
20 cylindrical edges, the concentrations of the dissolving elements at the particle/matrix
21
22 interface increase, leading to an increase in the concentration gradient, which in turn
23
24 increases the interface movement rate. However, the geometrically necessary condition
25
26 also prohibits the cylindrical edges to decrease in size significantly. The continuous
27
28 decrease in the interface movement rate indicates that the effective parameters on the
29
30 increase in the interface movement rate do not dominate the influence of increased
31
32 solute concentrations and the physical restriction from the geometrically necessary
33
34 condition. The increase in the ratio of the interface movement rate from the cylindrical
35
36 edges to that from the planar surfaces is evident, which indicates the effectiveness of the
37
38 curvature of the cylindrical edge and the increase in the interfacial area of the
39
40 cylindrical edge in the enhancement of dissolution rate from the cylindrical edges.
41

46
47
48
49
50

51 **6.3.2. The dependence of the interface movement rate on the width of the particles**

52
53
54 Fig. 16 shows the effect of the width fraction of the particles dissolved (presented
55
56 by $1-S/S_0$) on the interface movement rate of the planar surfaces and the cylindrical
57
58 edges, **in logarithmic scale**. The interface movement rates of the planar surfaces and the
59
60 cylindrical edges increase with increasing dissolution temperature. During dissolution,

1
2
3 the highest interface movement rate occurs at the beginning of the process and the
4
5 interface movement rates decrease steeply afterwards.
6
7

8
9 Fig. 17 shows the dependence of the ratio of the dissolution rate from the
10 cylindrical edges to that from the planar surfaces as a function of particle width. It can
11 be seen that the ratio is lower at higher temperatures. This indicates that the only reason
12 for the increase in the ratio at higher temperatures, presented in Fig. 15, is the decrease
13 in the width of the particles due to faster dissolution of the planar surfaces at higher
14 temperatures. This can be confirmed by examining Eq. (14) that illustrates the effective
15 parameters on C_{It} . It can be seen that with increasing dissolution temperature, C_{It}
16 decreases. Therefore, the only role of temperature that intensifies the fraction of
17 dissolution from the cylindrical edges over the planar surfaces is the effect of
18 temperature on the decrease in the width of the particles. This provides a convenient
19 situation for faster dissolution from the cylindrical edges due to the presence of the
20 geometrically necessary condition and also by increasing C_{It} as a result of the
21 decreasing radius of the cylindrical edge.
22
23

25
26
27
28
29
30
31
32
33
34
35
36
37
38
39

40 **6.3.3. The effect of the geometrically necessary condition on the interface** 41 **movement rate of the cylindrical edges** 42 43

44
45 The introduction of the geometrically necessary condition into the model restricts
46 the cylindrical edges from decreasing in diameter more than that allowed by the width
47 of the particle. The reason that the interface movement rate of the cylindrical edges does
48 not increase after the decrease at the beginning of dissolution has been attributed to the
49 presence of the geometrically necessary condition. Fig. 18 shows the effect of the
50 geometrically necessary condition on the interface movement rate of the cylindrical
51 edges. It is clear that, considering that effect, the interface movement rate decreases. In
52 addition, the increase in the interface movement rate at the end of the dissolution
53
54
55
56
57
58
59
60

1
2
3 process, i.e., $1-S/S_0$ close to 1, is clear. This is expected according to the findings of
4
5 Readey and Cooper [46] and also the observations of k_t in Fig. 12. From Fig. 18, it can
6
7 also be concluded that neglecting the effect of the geometrically necessary condition on
8
9 the interface movement rate can cause a significant error in the model predictions.
10
11

12 13 **6.4. The ratio of dissolution from the cylindrical edges to that from the planar** 14 15 **surfaces (the effect of discontinuities)** 16

17
18 Fig. 19 presents the ratio of the volume fraction of the particles dissolved from the
19
20 cylindrical edges to that dissolved from the planar surfaces (f_t/f_p), with and without
21
22 including the effect of the occurrence of the discontinuities. The small value of the ratio
23
24 is because the planar surfaces are much larger than the cylindrical edges and therefore,
25
26 the amount of dissolution from the planar surfaces is much larger than the cylindrical
27
28 edges. The reason for the increase in the ratio has been discussed earlier. It is clear from
29
30 Fig. 19 that the fraction of the dissolution rate from the cylindrical edges becomes larger
31
32 at higher temperatures and longer times when the radii of the cylindrical edges become
33
34 smaller.
35
36
37
38
39

40 The time required for the discontinuities to occur is also shown in Fig. 19. It can be
41
42 seen that due to the occurrence of the discontinuities, the ratio increases sharply.
43
44 Comparing the effect of the occurrence of the discontinuities on the ratio at different
45
46 temperatures to the conditions without the discontinuities shows that regardless of the
47
48 dissolution temperature, by the occurrence of discontinuities, the ratio of the dissolution
49
50 from the cylindrical edges to that from the planar surfaces increases. The ratio is the
51
52 same when the discontinuities do not occur and afterwards, a sudden increase is
53
54 observed due to the occurrence of the discontinuities which is coincident with the
55
56 formation of new cylindrical edges, leading to an increase in the number density of the
57
58 cylindrical edges. This results in a large increase in the ratio of the dissolution from the
59
60

1
2
3 cylindrical edges to that from the planar surfaces.
4
5

6 **7. Conclusions**

8
9 The TDFD dissolution mechanism proposed for the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in
10 the AA7020 aluminum alloy has been mathematically expressed using a diffusion
11 limited dissolution model, taking the dissolution from the planar surfaces and the
12 cylindrical edges of the particles into consideration. The occurrence of the
13 discontinuities which has not been reported previously, has been incorporated into the
14 model which intensifies the dissolution rate by increasing the number density of the
15 cylindrical edges. The dissolution rate from the planar surfaces has been considered
16 dependent on the differences between the concentrations in the particle, in the matrix
17 and at the particle/matrix interface. The dissolution rate from the cylindrical edges has
18 been considered to be dependent on the concentrations of the elements in the matrix and
19 the particle, radius of the cylindrical edge and also the dissolution rate from the planar
20 surfaces. The later has been incorporated into the model applying a geometrically
21 necessary condition. The changes in the concentration of the matrix have been
22 considered in the model by calculating the average values of the dissolved elements in
23 the matrix for the change in the concentration of the matrix in each time step. For a
24 given initial volume fraction and thickness of the particles, this model is capable of
25 predicting the volume fraction and the thickness of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles
26 during homogenization at different temperatures and times. The model predictions of
27 the volume fraction of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles and their thicknesses have been
28 validated with experimental QSEM and QXRD results and a good agreement is found.
29 Based on these results, the following conclusions have been drawn:

- 30
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60
- 1- The dissolution of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles into the aluminum matrix is dependent largely on the dissolution temperature. This is due to the strong

- 1
2
3 dependence of diffusion coefficient, the solubility limit of the dissolving elements in
4 the matrix and consequently the supersaturation parameter (k). With increasing
5 temperature, these parameters increase, which results in increases in dissolution rate.
6
7
8
9
10
11 2- Due to the large surfaces of the planar parts of the particles compared to their
12 cylindrical edges, the fraction of the dissolution from the cylindrical edges is
13 insignificant at the beginning of the dissolution process. Therefore, at the start of the
14 process, the assumption of neglecting the effect of the cylindrical edges on the
15 dissolution is reasonable. However, as the dissolution process continues the ratio of
16 the dissolution from the cylindrical edges to that from the planar surfaces increases
17 steeply. In addition, considering the TDFD dissolution mechanism, the number
18 density of the cylindrical edges increases. Consequently including the effect of the
19 dissolution from the cylindrical edges in the model is necessary.
20
21
22
23
24
25
26
27
28
29
30
31
32
33 3- The decreasing trend of the changes in the interface movement rate (dissolution rate)
34 from planar surfaces is due to the increase in the concentrations of the dissolving
35 elements in the matrix, which decreases the concentration gradients and therefore
36 the driving force for dissolution. However, in the case of the cylindrical edges there
37 are four effective parameters on the interface movement rate, namely (i) the
38 decrease in the concentration gradient, (ii) the geometrically necessary condition,
39 (iii) the increase in the concentrations of the dissolving elements at the
40 particle/matrix interface due to the effect of the interface curvature and (iv) the
41 increase in the interfacial area of the cylindrical edge with decreasing size of the
42 solute source relative to the area of the surrounding diffusion zone.
43
44
45
46
47
48
49
50
51
52
53
54
55
56
57 4- At a given particle width, the ratio of the dissolution from the cylindrical edges to
58 that from the planar surfaces is lower at higher temperatures. The only reason for the
59 ratio of the dissolution from the cylindrical edges to that from the planar surfaces at
60

1
2
3 higher temperatures to increase is the lower width of the particles as a result of rapid
4 dissolution of the planar surfaces but not due to the temperature effect. In other
5
6 words, the only effect of the increase in temperature that increases the fraction of the
7
8 dissolution from the cylindrical edges over the planar surfaces is the effect of
9
10 temperature on the decrease in the width of the particle which provides a convenient
11
12 situation from the geometrically necessary condition point of view and also by
13
14 increasing C_{II} by decreasing the radius of the cylindrical edge.
15
16
17
18
19

- 20 5- At the beginning of the dissolution process, the ratio of the dissolution from the
21
22 cylindrical edges to the planar surfaces is small. This ratio increases later on as a
23
24 result of increases in the dissolution rate from the cylindrical edges due to the
25
26 decrease in the radii of the cylindrical edges and by increasing the number density of
27
28 the cylindrical edges. Without considering the occurrence of the discontinuities, the
29
30 ratio of the volume fraction of the particles dissolved from the cylindrical edges to
31
32 that from the planar surfaces increases due to the increases in the concentration
33
34 gradient and the interfacial area of the cylindrical edges. With considering the
35
36 discontinuities, however, this ratio increases almost two times, which is due to the
37
38 increases in the number density of the cylindrical edges of the particles together
39
40 with the other two mentioned effects.

Figure	Caption
Figure 1	The schematic view of the dissolution of an $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle in AA7020 through the TDFD mechanism, (a) the initial particle with perturbations, (b) through (d) thinning of the particle, (e) and (f) occurrence of the discontinuities, leading to an increase in the number density of the cylindrical edges.
Figure 2	The dissolution of an $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle from its planar surfaces and cylindrical edges into the grain interior.
Figure 3	The schematic view of an $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle with initial perturbations. The dissolution from the planar surfaces of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle can be modeled, considering a one-dimensional model for the dissolution of a plate-like particle from its surfaces. The dissolution from the cylindrical edges can be modeled, considering the dissolution from the surface of a half cross section of a two-dimensional cylinder.
Figure 4	Schematic view of the geometrically necessary condition (GNC) which determines the radius of the cylindrical edge of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle during dissolution, a) the geometrically permissible condition, b) and c) the geometrically impermissible conditions.
Figure 5	Low (a) and higher (b) magnification FEG-SEM micrographs showing the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles in the as-cast

	microstructure.
Figure 6	X-ray diffraction pattern of the as-cast material showing the presence of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles.
Figure 7	An $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particle after homogenization at 550 °C for 8 hours, showing the thinning and discontinuation.
Figure 8	The shape of the cylindrical edges of the $\text{Al}_{17}(\text{Fe}_{3.2},\text{Mn}_{0.8})\text{Si}_2$ particles, (a) through (c) in the initial structure, (d) through (f) after homogenization at 550 °C for 8 hours. In (d) through (f), a circle has been drawn on the cylindrical edges of the particles, showing the perfectness of the circular cross section of the cylindrical edges.
Figure 9	Comparison of the model predictions of the volume fraction of the particles dissolved at different temperatures with the results obtained using (a) quantitative FEG-SEM (QSEM) and (b) quantitative XRD analysis (QXRD).
Figure 10	Comparison between the model predictions of the thickness of the particles dissolved during homogenization at different temperatures, and the experimental measurements using FEG-SEM.
Figure 11	A comparison between the supersaturation parameter of the planar surfaces (k_p) and the cylindrical edges (k_t) of the particles at different temperatures as a function of the initial width of the particles.
Figure 12	A comparison between the supersaturation parameter of the planar surfaces (k_p) and the cylindrical edges (k_t) of the particles at different temperatures as a function of the width fraction of the particles

	dissolved ($1-S/S_0$).
Figure 13	(a) The interface position of the planar surface of the particle and (b) The interface position of the cylindrical edges of the particle.
Figure 14	(a) The interface movement rate of the planar surfaces of the particles (v_p) and (b) The interface movement rate of the cylindrical edges of the particles (v_t).
Figure 15	The ratio of the interface movement rate from the cylindrical edges to that from the planar surfaces (v_p / v_t).
Figure 16	The dependence of the interface movement rate of the (a) planar surfaces (v_p) and (b) the cylindrical edges (v_t) on the width fraction of the particles dissolved ($1-S/S_0$) at different temperatures. The y axis is shown in a logarithmic scale.
Figure 17	The ratio of the interface movement rate from the cylindrical edges to that from the planar surfaces (v_p / v_t) as a function of the width fraction of the particles dissolved ($1-S/S_0$) at various homogenization temperatures.
Figure 18	The effect of the geometrically necessary condition (GNC) on the interface movement rate of the cylindrical edges (v_t).
Figure 19	The ratio of the volume fraction of the particles dissolved from the cylindrical edges to that from the planar surfaces (f_p / f_t), with the effect of the occurrence of the discontinuities taken into consideration. The times of occurrence of discontinuities have been also shown on the figure with vertical lines.

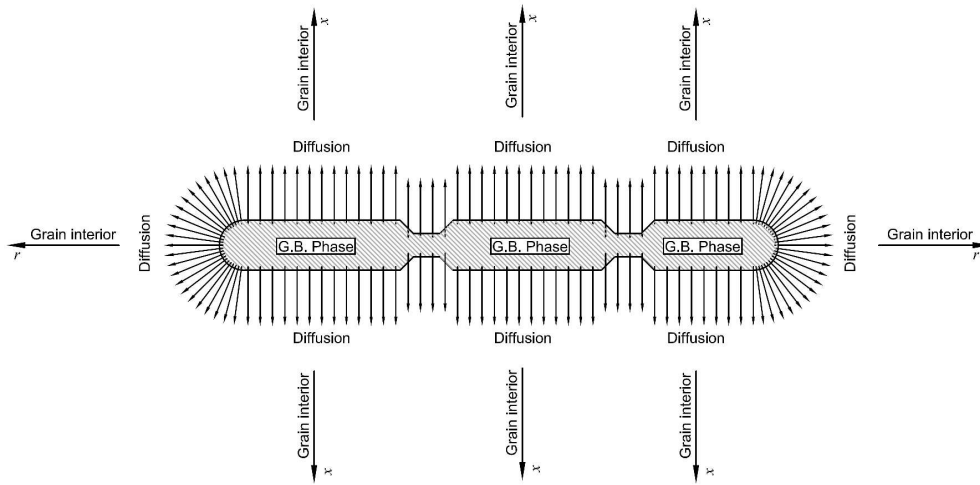

Table	Caption
Table 1	Chemical composition of the alloy used in this study
Table 2	Measured mean compositions (wt %) of the grain boundary constitutive particles in the as-cast material together with the calculated chemical compositions of the suggested phase identity based on the XRD analysis.

For Peer Review Only

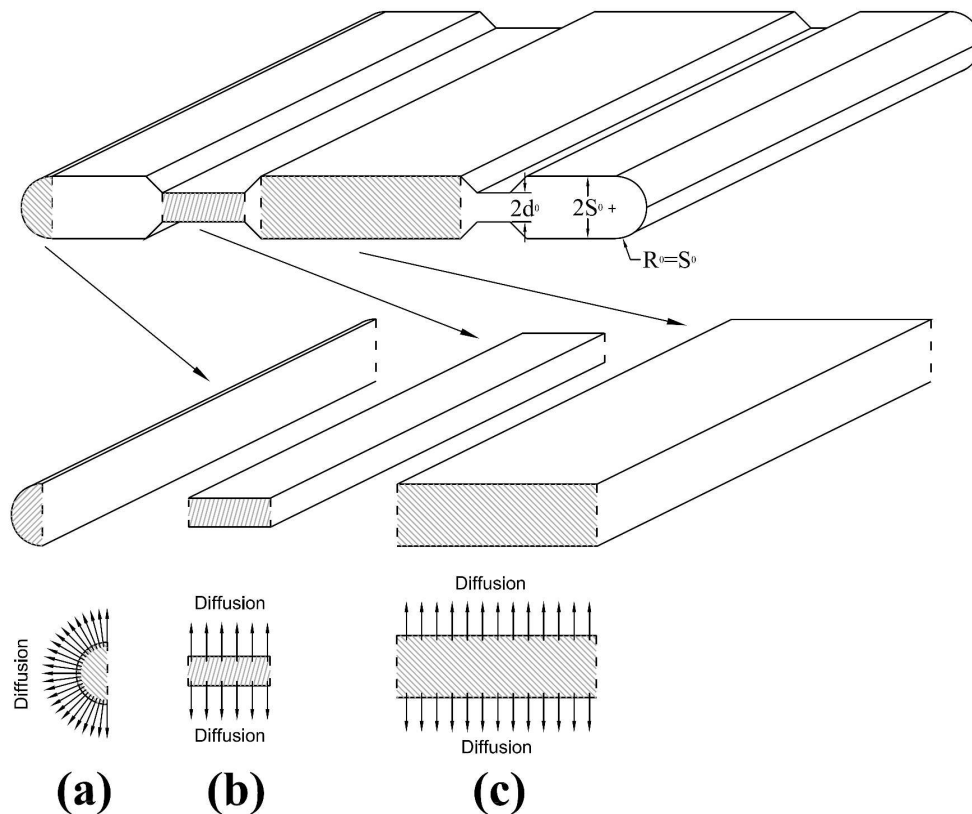

The schematic view of the dissolution of an $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particle in AA7020 through the TDFD mechanism, (a) the initial particle with perturbations, (b) through (d) thinning of the particle, (e) and (f) occurrence of the discontinuities, leading to an increase in the number density of the cylindrical edges.

955x403mm (96 x 96 DPI)

The dissolution of an $\text{Al}_{17}(\text{Fe}_{3.2}, \text{Mn}_{0.8})\text{Si}_2$ particle from its planar surfaces and cylindrical edges into the grain interior.
954x464mm (96 x 96 DPI)
