Abstract:

In this paper we propose a new approach to evaluate the predictable components in stock indices using a boosting-based classification technique, and we use this method to examine causality among the three main stock market indices in the world during periods of large positive and negative price changes. The empirical evidence seems to indicate that the Standard & Poors 500 index contains incremental information that is not present in either the FTSE 100 index or the Nikkei 225 index, and that could be used to enhance the predictability of the large positive and negative returns in the three main stock market indices in the world. This in turn would suggest a causality relationship running from the Standard & Poors 500 index to both the FTSE 100 and the Nikkei 225 indices.

JEL Classification Numbers: G15, C32

Keywords: International stock markets, Causality

## 1. Introduction

Interdependence among national stock markets is an important concern for investors since in recent years the global market has become more integrated as a result of a broad tendency toward liberalisation and deregulation in the money and capital markets of developed as well as developing countries, thereby reducing the opportunities for international diversification. Furthermore, market co-movements can also lead to market contagion as investors incorporate information about price changes in other markets into their trading decisions in an attempt to form a complete information set, carrying the risk that errors in one market may be transmitted elsewhere (see, e. g., King and Wadhvani, 1990).

As traders place orders and take positions simultaneously using different indices, one expects that different indices would be closely linked by both hedging activities and cross-market arbitrage (see, e. g., Karoly and Stulz, 1996). Furthermore, modern technological advancements and computerised trading systems have greatly facilitated the transfer of information from market to market.

One strand of research has examined long-term interdependence in international stock markets using multivariate cointegration techniques [see, Kasa (1992), Corhay, Rad and Urbain (1993), Blackman, Holden and Thomas (1994), Bachman, Choi, Jeon and Kopecky (1996) and Fernández-Serrano and Sosvilla-Rivero (2001, 2003), among others]. The other main area of research has attempted to investigate short-run market

1  
2  
3  
4  
5  
6 relationships through correlation tests [see, e. g., DeFusco *et al.* (1996) and Aggarwall *et*  
7 *al.* (1999)] or price and volatility spillovers using variations of the GARCH approach  
8  
9 [see, e. g., Hamo, Masulis and Ng (1990), Koutmos and Booth (1994), Chiang and  
10  
11 Chiang (1996) and Fratzscher (2002)].  
12  
13  
14  
15

16  
17  
18 More recently, there has been a growing interest in the market dynamics and the  
19  
20 transmission mechanism driving international market linkages [see, e. g., Eun and Shim  
21  
22 (1989), Arshanapalli and Doukas (1993), Masih and Masih (1997) and Connolly and  
23  
24 Wang (2002)].  
25  
26

27  
28  
29 Recent advances in machine learning and statistics have contributed to the appearance  
30  
31 of robust classification and evaluation techniques. In particular, these techniques allow us  
32  
33 to focus on the predictability of specific price changes (codified into populations).  
34  
35 Especially, one would like to discriminate positive from negative returns and/or large  
36  
37 positive or negative price changes from the rest of price movements. Doing so allows us  
38  
39 to test whether or not lagged returns from a main stock market index provide incremental  
40  
41 information concerning the classification of financial movements. Moreover, it permits us  
42  
43 to compare and determine which set of explanatory variables provides more information  
44  
45 to discriminate index movements.  
46  
47  
48  
49

50  
51  
52 The purpose of this paper is to investigate the casual relationships between the three  
53  
54 major stock markets in the world using daily data covering the period February 1986-  
55  
56 June 2004. Our study differs from the previously published papers in several ways. First,  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 while traditional studies focus on markets that are located in neighbouring geographic  
7 areas, we examine linkages across global markets. Second, instead of employing short-  
8 run market relationships through correlation tests or long-run co-movements, we  
9 investigate the relevance of lagged returns for discriminating price changes by using a  
10 boosting-based classification technique. Finally, while a growing body of research is  
11 devoted to the impact of financial crises on stock market linkages, we examine their  
12 relationships both during periods of high, positive and negative returns.  
13

23  
24

25 By evaluating and comparing the ‘overall’ discriminatory accuracy of the boosting-  
26 based algorithms (The Gradient Boosting Machine) trained under three different sets of  
27 explanatory variables, we find that the S&P 500 does provide incremental information to  
28 enhance the predictability of the large price changes in the three main stock market  
29 indices in the world. Moreover, this predictive structure behaviour is neither present in  
30 the FTSE 100 nor in the Nikkei 225.

32  
33  
34  
35  
36  
37  
38  
39  
40

41 The paper is organised as follows. In Section 2, we provide a brief review of the  
42 Gradient Boosting Machine classification technique. Section 3 discusses the receiver  
43 operating characteristic (ROC) curve and the area under it, both used to evaluate  
44 discriminatory accuracy. In Section 4, we report the empirical results. Finally, Section 5  
45 provides some concluding remarks.  
46

57  
58 <sup>2</sup> We also consider other criteria for identifying large positive price change (such those representing 10 and  
59 30 per cent of the probabilistic distribution of the returns), obtaining similar qualitative results.  
60

## 2. The Gradient Boosting Machine classification technique

In the function approximation problem, one has a system consisting of a random response variable  $y$  and a set of random explanatory variables  $\mathbf{x}=\{x_1, x_2, \dots, x_n\}$ . Given a training sample  $\{y_i, \mathbf{x}_i\}_1^N$  of known  $(y, \mathbf{x})$ -values, the goal is to find a function  $F^*(\mathbf{x})$  that maps  $\mathbf{x}$  to  $y$ , such that over the joint distribution of all  $(y, \mathbf{x})$ -values, the expected value of some loss function is minimised.

Regression and classification problems can be viewed as a task in function approximation. In a classification problem, the goal is to discriminate between two (or more) populations, given a set of explanatory variables. In our particular case, the relevant question is if lagged price changes are capable of providing information for discriminating large positive financial movements.

To answer such question empirically, we must test the out-of-sample discriminatory accuracy of the classifier chosen, in order to understand specific movements. Moreover, this out-of-sample performance should be evaluated with a technique that is invariant to *a-priori* class probabilities and that is independent of the decision threshold (or the cut-off value).

In this paper, we have employed the Gradient Boosting Machine classification technique, which we now proceed to review. Regarding the evaluation of the discriminatory accuracy, in the next section we discuss the receiver operating characteristic (ROC) curve and the area under it.

1  
2  
3  
4  
5  
6 The underlying idea of boosting is to combine simple “rules” (or tree-based  
7 models) to form an ensemble (or weighted committee) such that the performance of the  
8 single ensemble member is improved (e.g., “boosted”). Boosting was proposed in the  
9 machine learning literature by Freund and Schapire (1997) with the creation of  
10 AdaBoost, and has since received much attention.  
11  
12  
13  
14  
15  
16  
17  
18  
19

20 From the statistician’s point of view, the breakthrough took place with the paper  
21 by Friedman, Hastie and Tibshirani (2000). They show that AdaBoost is an optimisation  
22 method for finding a classifier that minimises a particular exponential loss function, and  
23 that this loss function is very similar to the (negative) binomial log-likelihood. For an  
24 excellent paper that traces the developments of boosting methodology and its applications  
25 to the exponential family and proportional hazards regression models see Ridgeway  
26 (1999).  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37

38 Using the connection between boosting and optimisation, Friedman (2001)  
39 proposes the Gradient Boosting Machine (hereafter GBM). Using this technique, function  
40 approximation is viewed from the perspective of numerical optimisation in the function  
41 space, rather than in the parameter space. The estimation algorithm of the GBM is shown  
42 in Chart 1.  
43  
44  
45  
46  
47  
48  
49

50 [Chart 1, here]  
51  
52  
53

54 With the purpose of increasing execution speed, approximation accuracy and  
55 robustness against over-fitting, we incorporated randomness in the procedure as  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 described in Friedman (2002). At each iteration, a sub-sample consisting of 50 percent of  
7  
8 the total observations ( $\widehat{N}/N = 50\%$ ) is drawn at random (without replacement) from the  
9  
10 training sample. This sub-sample is then used to fit the tree and compute the model  
11  
12 output for the current iteration. The loss function employed in all our experiments with  
13  
14 the GBM was the Bernoulli function, and the loss function used to generate the “rules”  
15  
16 (or tree-based models) was the Gini index.  
17  
18  
19  
20  
21  
22

23 The GBM has three tweaking parameters: the total number of iterations  $M$ , the  
24  
25 learning rate (shrinkage parameter  $\nu$ ) and the level of interaction among explanatory  
26  
27 variables  $J$ . It is widely known that fitting the data too well can lead to over-fitting,  
28  
29 which degrades the accuracy power on independent data bases. However,  $M$  and  $\nu$  do not  
30  
31 operate independently: smaller values of  $\nu$  lead to larger values of the “optimal”  $M$ .  
32  
33  
34  
35  
36

37 Empirically, via simulation, Friedman (2001) finds that low values of  $\nu$  ( $\nu < 1\%$ )  
38  
39 favour better accuracy on test samples. In this paper, we fixed the shrinkage parameter ( $\nu$ )  
40  
41 to one percent and allowed 500 boosting iterations ( $M$ ). Clearly, better results can be  
42  
43 obtained if we monitor these parameters in a validation set. Nevertheless, this was not  
44  
45 done in order to maximise the number of observations in the test sample. Regarding the  
46  
47 level of interaction ( $J$ ), experience indicates, hitherto, that  $4 \leq J \leq 8$  works well in the  
48  
49 context of boosting, with results being fairly insensitive to particular choices in this range  
50  
51 (Hastie, Tibshirani, and Friedman (2001)). Consequently, we fixed  $J$  equal to five in all  
52  
53 our experiments. The implementation was carried out in R: Environment for Statistical  
54  
55  
56  
57  
58

7  
8 Ridgeway).  
9

### 10 11 12 13 **3. Assessing the discriminatory accuracy** 14

15  
16 The receiver operating characteristic (ROC) curve is a well-established method  
17  
18 for summarising performances of diagnostic tests [see, Hanley (1999); Zhou, McClish  
19  
20 and Obuchowski (2002), among others]. Now, it is widely used for evaluating machine  
21  
22 learning algorithms [see, e. g., Weiss and Provost (2003); Provost, Fawcett and Kohavi  
23  
24 (1998); Bradley (1998)].  
25  
26

27  
28  
29 A ROC curve is obtained by plotting Sensitivity versus 1 - Specificity for various  
30  
31 cut-off values. The points on a ROC curve are either joined by line segments or smooth  
32  
33 curves with the use of non-parametric and parametric procedures, respectively.  
34  
35

36  
37  
38 The area under a ROC curve (AUC) is equal to the probability that a randomly  
39  
40 selected observation from population one scores higher than a randomly selected  
41  
42 observation from population two (Hanley and McNeil (1982). Formally, the AUC can be  
43  
44 expressed as:  
45  
46

$$47 \quad \text{AUC} = P(y > x) + \frac{1}{2}P(y = x) \quad (1)$$

48  
49  
50  
51 where  $y$  and  $x$  denote the classifier output (class probability) for a randomly  
52  
53 selected observation from population one and two, respectively.  
54  
55  
56  
57  
58  
59  
60

In this paper, we make use of the Mann-Whitney-U Statistic, a non-parametric approach to obtain the AUC. The Mann-Whitney-U Statistic is given by:

$$\text{AUC} = \hat{\Theta} = \frac{1}{mn} \sum_{i=1}^m \sum_{j=1}^n Z_{ij} \quad (2)$$

where  $Z_{ij} = I(y_i > x_j) + \frac{1}{2}I(y_i = x_j)$  and  $I(\bullet)$  is an indicator function. The variables  $m$  and  $n$  are the total number of observations for population one and two, respectively.

The variance of the AUC can be obtained from the following:

$$\text{Var}(\hat{\Theta}) = \frac{\hat{\Theta}(1-\hat{\Theta}) + (m-1)(Q_1 - \hat{\Theta}^2) + (n-1)(Q_2 - \hat{\Theta}^2)}{mn} \quad (3)$$

and  $Q_1 = \hat{\Theta}/2 - \hat{\Theta}$ ;  $Q_2 = 2\hat{\Theta}^2/1 + \hat{\Theta}$ . Equation 3 is the exponential approximation formula of Hanley and McNeil (1982).

Another important application of the ROC curve is to compare the *overall* discriminatory accuracy of classifiers. The term ‘overall’ is emphasised, since the interest is in the global picture of a test and not in the accuracy performance at a particular cut-off value. See Metz et al. (1998) to understand how different ROC-curve estimates can be compared.

#### 4. Data and empirical results

The data set comprises daily time series on closing values for the three major stock market indices: the FTSE 100 index (United Kingdom), the Nikkei 225 index (Japan), and the Standard & Poors 500 index (United States). The sample period examined spans from June 2, 1986 to June 25, 2004. The data set was obtained from Econwin.

We employed the Gradient Boosting Machine classification technique to extract patterns from the explanatory variables in order to classify large positive and negative price changes, and we used the area under the ROC curve to evaluate and compare the ‘overall’ discriminatory accuracy of the classifiers. In order to identify large positive price changes, for each index we chose the returns that satisfy the following condition:  $prob(\text{return} < (\text{large, positive return})) = 80\%$ . In other words, the large positive returns represent 20 per cent of the probabilistic distribution of the returns (or right-tail of the distribution of the returns)<sup>2</sup>. Concerning the large negative price changes, we chose those observations that represented the left-tail of the distributions of the returns (e.g.,  $prob(\text{return} < (\text{large, negative return})) = 20\%$ ). Observations that satisfied the condition were codified with 1’s, and those that did not were codified as 0’s.

Once the dependent (or response) variable was codified, we analysed three sets of exploratory factors per index: lags in Standard & Poors 500 index, lags in the FTSE 100 index, and lags in the Nikkei 225 index. These explanatory variables were incorporated in the GBM algorithm depending on the trading hours. Note that the Japanese stock

1  
2  
3  
4  
5  
6 market is the first to open among the three considered, followed by the UK stock market,  
7  
8 and the US stock market is the last one to open<sup>3</sup>. Therefore, when examining each  
9  
10 particular stock market, we will successively incorporate the publicly available  
11  
12 information on stock prices taking into account these trading hours. For example, to  
13  
14 analyse the Japanese stock market, we first take into account only lags in the Nikkei 225  
15  
16 index, then we introduce lags in the FTSE 100 index, and finally we consider also the  
17  
18 lags in the Standard & Poors 500 index.  
19  
20  
21  
22  
23  
24

25 As is well known, keeping a test set additionally to the training set is a general  
26  
27 method to estimate the accuracy of a classifier. Therefore, we have split our sample into  
28  
29 two sub-samples: the training sample runs from June 2, 1986 to December 31, 2000,  
30  
31 while the testing sample covers the period January 3, 2001- June 25, 2004. Usually a  
32  
33 fraction of 20-30 per cent of the available data is chosen as the testing set if the size of  
34  
35 the test set is larger than 1000. Therefore, our testing sample satisfies the train-and-test  
36  
37 procedure (see, e.g., Henery, 1994). Note also that the testing period is long enough to  
38  
39 reduce the effects of data snooping.  
40  
41  
42  
43  
44

45 In the top section of Table 1 (Panel I), we evaluate the discriminatory accuracy of  
46  
47 the GBM for the US stock market under different sets of explanatory variables. Test A  
48  
49 shows the GBM classifying power when only lags of the Standard & Poors 500 index are  
50  
51 used. For the large positive price changes, the discriminatory power is 0.6129, meaning  
52  
53 that the probability that a randomly selected observation from the large positive price  
54

change cases (returns greater than 0.68%) scores higher than a randomly chosen observation from price changes from returns lower than 0.68% is 61.29 per cent. Notice that when there is no difference between the two populations, the area under the ROC curve will be 0.5 (or coin-toss classifications). The 95 per cent confidence interval for the area can be used to test the hypothesis that the theoretical area is 0.5. Since the confidence interval in this case (0.5758, 0.6482) does not include the 0.5 value, there is evidence that the GBM technique is able to distinguish between the two groups (or populations). Test B reports the results when we use lags of both Standard & Poors 500 and Nikkei 225 indices as explanatory factors, while Test C presents the results when lags of the all three are used. As can be seen, including those lags leads to a small reduction in the discriminatory power of the GBM technique (61.09 and 60.75 per cent, respectively), although the new confidence intervals do not include the 0.5 value either. Concerning the large negative price changes, predictable components were non-existent, since the GBM, trained under the three different sets of explanatory variables, was not able to beat a coin-toss (or random) classification.

In the lower section of Table 1 (Panel II), we report the  $z$  statistic, testing the difference between areas under the ROC curves, as well as the  $p$ -value. As can be seen for the large positive price changes, the  $z$  statistics obtained when comparing Test A *vs.* Test B and Test A *vs.* Test C are positive, suggesting that Test A has a greater area under the ROC curves than those of Tests B and C. Moreover, the  $p$ -values suggest that the pair-wise comparisons of all three ROC curves are not significantly different. Therefore, based on this evidence we can conclude that including more explanatory variables does

1  
2  
3  
4  
5  
6 not generate any incremental information to improve the discriminatory power of the  
7  
8 GBM technique when identifying the large positive price changes in the Standard &  
9  
10 Poors 500 index.  
11

12  
13  
14  
15 However, when analyzing large negative price changes, none of the explanatory  
16  
17 variable sets contained any useful information to discriminate large negative price  
18  
19 changes from the rest of price movements. Furthermore, in one of our experiments the  
20  
21 ROCKIT software did not converge since the data set was degenerated. In general,  
22  
23 degeneracy should be found only in very small datasets and/or in those with many tied  
24  
25 values, and in our case it was due to the existence of many tied values.  
26  
27  
28  
29  
30  
31

32 [Table 1, here]  
33  
34  
35

36 Regarding the FTSE 100 index, we observe in Panel I of Table 2 that there is a  
37  
38 significant improvement in the discriminatory accuracy for the large positive price  
39  
40 changes (returns greater than 0.74%) when the lags of the Standard & Poors 500 and the  
41  
42 Nikkei 225 indices are introduced in the information set. As can be seen, Test C presents  
43  
44 the greatest area under the ROC curve. Moreover, when comparing the areas under the  
45  
46 ROC curves for the three sets of explanatory variables, we obtain a negative value for the  
47  
48 z-statistic, suggesting that Tests B and C have a greater area under the ROC curve than  
49  
50 Test A, being also statistically significant at the usual levels. These results, jointly taken  
51  
52 with the results when comparing Test B vs. Test C, indicate that the Standard & Poors  
53  
54  
55  
56  
57  
58  
59

5  
6 500 index provides incremental information to enhance the discriminatory power of large  
7  
8 positive returns in the FTSE 100 index.  
9

10  
11  
12  
13 Furthermore, the same pattern emerges in the predictability of large negative price  
14 changes, where the Standard & Poors 500 index provide useful information for  
15 discriminating the FTSE 100 large negative price changes from the rest of price  
16  
17 movements.  
18  
19  
20

21  
22 [Table 2, here]  
23  
24  
25  
26

27 Finally, Table 3 reports the results for the Nikkei 225 index. As can be seen in the  
28 table, the information provided by the lags in the Nikkei 225 index is not relevant for  
29 discriminating large positive price changes (returns greater than 0.82%). In contrast, both  
30 the Standard & Poors 500 index and the FTSE 100 index contain relevant information in  
31 this context. Nevertheless, the results obtained when comparing Test B vs. Test C suggest  
32 that the Standard & Poors 500 index contains incremental information that is not present  
33 in the FTSE 100 index and that could be used to increase the discriminatory accuracy of  
34 the large positive returns in the Nikkei 225 index. Moreover, the predictability of the  
35 large negative price changes is greatly enhanced due to the information extracted from  
36 the Standard & Poors 500 index lags.

The traditional method for testing causality in economic time series makes use of the well-known Granger definition of causality (Granger, 1969). Given two variables,  $x$  and  $y$ ,  $x$  is said to Granger-cause  $y$  if the latter can be predicted better by past values of  $x$  and  $y$ , rather than by past values of  $y$  alone. From this definition, the results in Tables 1 to 3 could be taken as empirical evidence of causality running from the Standard & Poors 500 index to both the FTSE 100 and the Nikkei 225 indices.

## 5. Concluding remarks

In this paper, we extend the previous literature by examining stock market linkages during large positive and negative price changes. The main novelty of the paper lies in its use of the Gradient Boosting Machine classification technique to examine the relevance of lagged returns for discriminating price changes.

The empirical evidence presented in this paper seems to indicate that the Standard & Poors 500 index contains incremental information that is not present either in the FTSE 100 index or in the Nikkei 225 index and that could be used to enhance the forecastability of the large positive and negative returns in the three main stock market indices in the world. This in turn would suggest a causality relationship running from the Standard & Poors 500 index to both the FTSE 100 and the Nikkei 225 indices.

Therefore, our results indicate that the US index plays a prominent role in price leadership across global markets. This is consistent with the fact that the US market has long been the centre of financial transactions as well as the most influential producer of

1  
2  
3  
4  
5  
6 information. Indeed, there is a large literature on the fact that investors tend to react more  
7  
8 to news from the US market than from other markets [ see, e. g., Eum and Shim (1989),

Becker, Finnerty and Friedman (1995), and Masih and Masih (2001)].

Our evidence is also consistent with that presented in Karoly and Stulz (1996), who conclude that large return shocks propagate more internationally than small return shocks.

Our findings support the conclusion coming from agent-based models for financial market which account for behavioural phenomena such as herding, overreaction and the common use of trading rules, that are likely to spread non fundamental price variations across markets (Day and Huang, 1990; Brock, Lakonish and LeBaron, 1992; Connoly and Wang, 2002, Daniel, Hirshleifer and Teoh, 2002, and Hirshleifer and Teoh, 2003). In this sense, King and Wadhvani (1990) argue that trading of stocks in one market per se affects stock prices in other markets, even if the source of the trading is purely noise. This is called the “market-contagion hypothesis”. Karoly and Stulz (1996) also find evidence consistent with this interpretation, pointing out that “[c]ontagion effects results when enthusiasm from stocks in one market brings about enthusiasm for stocks in other markets, regardless of the evolution of market fundamentals”.

Chart 1. Friedman's (Stochastic) Gradient Boosting Machine Algorithm

---

Initialise  $\hat{F}_0(\mathbf{x}) = \arg \min \sum_{i=1}^N L(y_i, \rho)$ .

For  $m = 1, \dots, M$  do:

1. Given a training sample,  $\{y_i, \mathbf{x}_i\}_1^N$ , perform a random permutation of the integers  $\{1, \dots, N\}$  and obtain a sub-sample ( $\hat{N} < N$ )

$$\{\pi(i)\}_1^N = \text{rand\_perm} \{i\}_1^N \rightarrow \{y_{\pi(i)}, x_{\pi(i)}\}_1^{\hat{N}}$$

2. Compute the negative gradient as the working response/output

$$g_{\pi(i)m} = - \left. \frac{\partial L(y_{\pi(i)}, F(\mathbf{x}_{\pi(i)}))}{\partial F(\mathbf{x}_{\pi(i)})} \right|_{F(\mathbf{x}_{\pi(i)}) = \hat{F}_{m-1}(\mathbf{x}_{\pi(i)})}$$

3. Fit a classification tree,  $T(\mathbf{x}_{\pi(i)}; \Theta_m)$ , predicting  $g_{\pi(i)m}$  from the explanatory variables  $\mathbf{x}$ .

4. Choose a gradient descent step size as

$$\rho = \arg \min_{\rho} \sum_{i=1}^{\hat{N}} L(y_{\pi(i)}, \hat{F}_{m-1}(\mathbf{x}_{\pi(i)}) + \rho T(\mathbf{x}_{\pi(i)}; \Theta_m))$$

5. Given a learning rate  $\nu$ , update the estimate of  $F_m(\mathbf{x})$ , as

$$\hat{F}_m(\mathbf{x}) \leftarrow \hat{F}_{m-1}(\mathbf{x}) + \nu \rho T(\mathbf{x}_{\pi(i)}; \Theta_m)$$

End For

| Discriminatory accuracy: | $0.6702 \pm 0.0174$      | $0.6115 \pm 0.0177$      |
| Test sample:             | 01/03/2000-06/25/2004    |                          |

II.- Comparing the 'overall' discriminatory power (z-statistic, one-tailed p-value).

|                      | Large Positive Movements | Large Negative Movements |
|----------------------|--------------------------|--------------------------|
| Panel A vs. Panel B: | $(-3.1261, 0.0009)$      | $(-4.7505, 0.0000)$      |
| Panel A vs. Panel C: | $(-3.6474, 0.0001)$      | $(-4.1322, 0.0000)$      |
| Panel B vs. Panel C: | $(-1.3775, 0.0842)$      | $(1.2333, 0.1088)$       |

**Table 3.** Results for the Nikkei 225

Summary of movement codification:

Nikkei 225 Large positive movements: returns > 0.82%

Nikkei 225 Large negative movements: returns < -0.82%

I.- Assessing the discriminatory power.

A. Using  $Nikkei_{t-1}$  to  $Nikkei_{t-24}$  as explanatory variables

|                          | Large Positive Movements | Large Negative Movements |
|--------------------------|--------------------------|--------------------------|
| Discriminatory accuracy: | $0.5350 \pm 0.0190$      | $0.5345 \pm 0.0188$      |
| Test sample:             | 01/03/2000-06/25/2004    |                          |

B. Using  $Nikkei_{t-1}$  to  $Nikkei_{t-24}$  and  $FTSE_{t-1}$  to  $FTSE_{t-24}$  as explanatory variables

|                          | Large Positive Movements | Large Negative Movements |
|--------------------------|--------------------------|--------------------------|
| Discriminatory accuracy: | $0.5872 \pm 0.0184$      | $0.6033 \pm 0.0179$      |
| Test sample:             | 01/03/2000-06/25/2004    |                          |

C. Using  $FTSE_{t-1}$  to  $FTSE_{t-24}$ ,  $Nikkei_{t-1}$  to  $Nikkei_{t-24}$  and  $S\&P_{t-1}$  to  $S\&P_{t-24}$  as explanatory variables

|                          | Large Positive Movements | Large Negative Movements |
|--------------------------|--------------------------|--------------------------|
| Discriminatory accuracy: | $0.6379 \pm 0.0175$      | $0.6635 \pm 0.0168$      |
| Test sample:             | 01/03/2000-06/25/2004    |                          |

II.- Comparing the 'overall' discriminatory power (z-statistic, one-tailed p-value).

|                      | Large Positive Movements | Large Negative Movements |
|----------------------|--------------------------|--------------------------|
| Panel A vs. Panel B: | $(-4.1795, 0.0000)$      | $(-4.3122, 0.0000)$      |
| Panel A vs. Panel C: | $(-6.0609, 0.0000)$      | $(-6.3780, 0.0000)$      |
| Panel B vs. Panel C: | $(-4.0159, 0.0000)$      | $(-4.1185, 0.0000)$      |
