Abstract

This paper examines the link between unemployment volatility and the sectoral composition of economic activity in the regions of the European Union over the period 1980-2004. To that end, I use different spatial econometric techniques, which allow one to investigate the role played in this context by spatial effects and geographical spillovers. The results show that unemployment volatility is positively related to regional specialization in the European Union. This finding does not depend on the use in the analysis of absolute or relative specialization measures.

VOLATILIDAD DE LAS TASAS DE DESEMPLEO Y ESPECIALIZACIÓN REGIONAL EN LA UNIÓN EUROPEA**Abstract**

Este trabajo estudia la relación entre la volatilidad de las tasas de desempleo y la composición sectorial de la actividad económica en las regiones de la Unión Europea a lo largo del período 1980-2004. Para ello el autor utiliza diferentes técnicas de econometría espacial que permiten determinar la importancia en este contexto de la localización geográfica de las distintas regiones. El análisis llevado a cabo muestra que la volatilidad de las tasas de desempleo está correlacionada positivamente con el nivel de especialización regional. De hecho, este resultado no depende de la utilización en el análisis de medidas de especialización absolutas o relativas.

Palabras clave: Desempleo, volatilidad, especialización, regiones, Unión Europea.

For Peer Review Only

1. Introduction

Economic instability is generally viewed as an undesirable characteristic of a regional economy (Siegel et al., 1995; Wagner, 2000). This explains why the analysis of the causes of regional economic instability has been a recurring topic of interest in the literature during the last decades. Specifically, numerous studies have examined the role played in this context by the sectoral composition of economic activity (e.g. Conroy, 1975; Kort, 1981; Brewer and Moomaw, 1985; Attaran, 1986; Malizia and Ke, 1993; Baldwin and Brown, 2004; Trendle, 2006). In this regard, the traditional argument suggests the existence of a positive relationship between volatility and regional specialization. Thus, as a region's economy becomes more diversified, it is less affected by fluctuations caused by factors outside the region (Richardson, 1969). Likewise, regions with low levels of specialization are characterized by the presence of various industries that experience fluctuations of different intensity and timing. Consequently, employment losses in some sectors are offset by employment gains in other sectors, thus stabilizing the regional economy (Malizia and Ke, 1993). In view of these explanations, policy-makers often attempt to attract industries that will diversify their region's productive structure in order to promote economic stability and growth (Schoening and Sweeney, 1992; Izraeli and Murphy, 2003).

During the last decades several studies have examined empirically the link between regional volatility and the sectoral composition of economic activity using mainly US data (see Dissart (2003) for a review of this literature). Various authors have found that more industrial diversification leads to less instability (e.g. Kort, 1981; Malizia and Ke, 1993; Baldwin and Brown, 2004; Trendle, 2006), while the results obtained by other researchers suggest that the relationship is not statistically significant (Jackson, 1984;

1
2
3 Attaran, 1986). Nevertheless, when assessing these findings, it should be noted that, as
4
5 pointed out by Wagner and Deller (1998), most of these studies use small sample sizes,
6
7 highly aggregated data sets, problematic measures of specialization and excessively
8
9 simplistic statistical methods.
10
11

12
13
14
15 Against this background, and in a quest for empirically well-founded, stylized facts, this
16
17 paper aims to investigate the relationship between unemployment volatility and the
18
19 sectoral composition of economic activity, using data on 196 European Union (EU)
20
21 regions over the period 1980-2004. At this point it needs to be said that, as far as I am
22
23 aware, this is the first time that this issue is examined from a sample of EU regions.
24
25 Although Longhi et al. (2005) have analysed the effects of industrial diversity on the
26
27 cross-sectional variation of regional unemployment in the EU, no study has tackled so
28
29 far the role played by regional specialization when attempting to explain unemployment
30
31 fluctuations in this context. Nevertheless, there are several reasons to justify the need to
32
33 analyse this topic in the European case. To start with, it is worth investigating to what
34
35 extent the results obtained for other geographical settings hold for the EU regions.
36
37 Furthermore, the study of the explanatory factors of the unemployment variability
38
39 registered by the European regions is particularly relevant from a policy point of view.
40
41 In that respect, it should be noted that the existence of high levels of unemployment
42
43 volatility is a major threat to the achievement of economic and social cohesion within
44
45 the EU, which is especially important in the context of the integration process currently
46
47 underway (European Commission, 2004, 2007).
48
49
50
51
52
53

54
55
56
57 From a methodological perspective, this paper is characterized by the employment of
58
59 various spatial econometric techniques (Haining, 1990; Anselin and Bera, 1998;
60

1
2
3 Anselin, 2001). To the best of my knowledge, only Trendle (2006) has applied a similar
4 approach to explore the link between industrial diversification and economic instability
5 in the case of the local government areas of the Australian state of Queensland. This
6 methodology allows one to investigate the role played in this context by spatial effects
7 and geographical spillovers, paying particular attention to the spatial characteristics of
8 the data. In relation to this, it needs to be recalled that different authors have found that
9 the outcomes of the labour market in a specific region are affected by the situation of
10 the labour markets in the neighbouring regions (e.g. Molho, 1995; López-Bazo et al.,
11 2002; Overman and Puga, 2002).

26
27 The rest of the paper is structured as follows. In order to establish the conceptual
28 framework in which to fit the study, section 2 presents an overview of the main
29 theoretical arguments that can be used to justify the possible impact of productive
30 specialization on regional instability. After describing briefly in section 3 the data used
31 in the empirical analysis, section 4 examines existing disparities in unemployment
32 variability across the EU regions by applying spatial exploratory techniques. In turn,
33 section 5 uses various alternative specifications of a spatial econometric model to
34 analyse the impact of regional specialization on the intensity of unemployment
35 fluctuations. Finally, section 6 presents the main conclusions of the paper.

36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 **2. Regional specialization and economic instability: Theoretical** 52 **framework**

53
54
55
56
57
58 The relationship among productive specialization, economic growth and instability has
59 been widely examined in the literature using different approaches and methodological
60

1
2
3 options. Within this framework, elementary economic theory emphasizes the important
4 gains in terms of economic performance derived from specialization processes (Wagner
5 and Deller, 1998; Izraeli and Murphy, 2003). In particular, the neoclassical trade model
6 shows that regions (countries) should specialize in those activities in which they enjoy a
7 comparative advantage over their trade partners. This has to do with the presence of
8 spatial differences in relative factor endowments (Ohlin, 1933), or technological
9 differences that apply across industries (Krugman, 1994). Likewise, the relevance of
10 external economies may also lead to specialization at the industry level (Krugman,
11 1994). In view of these arguments, the important advances experienced by the economic
12 integration processes during the last decades suggest that nowadays most regions may
13 depend on a greater degree of specialization to maintain or increase their competitive
14 edge (Baldwin and Brown, 2004)¹.

15
16
17 Although the theoretical benefits derived from sectoral specialization are widely agreed
18 on, various economists, geographers and regional scientists have pointed out repeatedly
19 that specialization in a relatively small number of industries can increase the degree of
20 economic instability (e.g. Conroy, 1975; Kort, 1981; Malizia and Ke, 1993; Wagner and
21 Deller, 1998; Baldwin and Brown, 2004; Trendle, 2006). Specifically, these authors
22 suggest that a high level of specialization may lead to a welfare loss for the economy as
23 a whole that outweighs the potential gains derived from specialization. According to
24 this argument, a brake should be placed on the development of the specialization
25 processes.

26
27
28 The possible negative impact of productive specialization on economic instability
29 follows from the simple observation of the risks faced by those regions with an
30

1
2
3 excessive reliance on a small number of activities (Kort, 1981; Trendle, 2006). In
4
5 particular, if a specific sector experiences a relatively important decline caused by
6
7 demand-side or supply-side disturbances², a region will be affected more severely if a
8
9 large share of total employment is engaged in the sector in question. Accordingly, this
10
11 suggests that regions highly dependent on a small group of industries will tend to be
12
13 characterized by alternating periods of employment losses and out-migration, and
14
15 periods with low unemployment and rapid in-migration (Gilchrist and St. Louis, 1991).
16
17 On the contrary, the greater the dispersion of regional employment among the different
18
19 sectors, the less likely a region is to be affected by severe cyclical fluctuations (Malizia
20
21 and Ke, 1993; Dissart, 2003). Given that the various productive activities often
22
23 experience fluctuations of different intensity and timing, a diversified sectoral structure
24
25 implies in principle that employment losses in some industries can be offset by
26
27 employment gains in other industries. Accordingly, low levels of productive
28
29 specialization should contribute to reduce the intensity of unemployment variations,
30
31 thus stabilizing the regional economy. Therefore, sectoral diversification can be
32
33 interpreted in this context as a risk-spreading strategy to minimize the effects of external
34
35 shocks on regional performance (Frenken et al., 2007).
36
37
38
39
40
41
42
43
44
45

46 Economic stability is generally considered as a positive characteristic of a regional
47
48 economy since it promotes economic growth, stable incomes and low unemployment
49
50 levels (Wagner, 2000). For this reason, reducing volatility has long been an important
51
52 concern for regional policy-makers (e.g. Schoening and Sweeney, 1992). In that respect,
53
54 the different arguments presented above suggest that a region wishing to decrease its
55
56 degree of instability should see a diversified productive structure as a relevant goal of
57
58 economic development. In order to achieve this aim, regional policy-makers often
59
60

1
2
3 attempt to attract new industries that will diversify their region's economic base
4
5 (Baldwin and Brown, 2004).
6
7
8
9

10 Nevertheless, as pointed out by Malizia and Ke (1993), in this context it is important to
11 recall that the potential benefits derived from industrial diversity are conditioned in the
12 final instance by differences in occupational staffing patterns among industries. The
13 effectiveness of sectoral diversification in reducing unemployment requires that workers
14 laid off in one industry should be able to find work in another regional industry.
15 Likewise, it should not be overlooked that what really makes a region particularly
16 vulnerable to economic shocks is its degree of specialization in cyclically sensitive
17 activities (Garcia-Milá and McGuire, 1993).
18

30
31

32 **3. Data**

33
34
35
36 All the data used in this paper were drawn from the Cambridge Econometrics regional
37 database, which is mainly based on information supplied by Eurostat. The sample
38 consists of 196 NUTS-2 regions in the EU over the period 1980-2004³. Nevertheless,
39 the lack of complete series obliged to exclude from the study the countries incorporated
40 into the EU in 2004 and 2007, the *Länder* of former East Germany, the Portuguese
41 islands in the Atlantic, and the French Overseas Departments and Territories.
42
43
44
45
46
47
48
49
50
51
52

53 NUTS-2 data were chosen rather than other potential alternatives for various reasons.
54 Thus, there are numerous works in which NUTS-2 regions have been used to
55 investigate regional issues in the European context, which facilitates the comparison of
56 the results with those of other studies. Furthermore, the employment of NUTS-2 regions
57
58
59
60

1
2
3 is justifiable from the point of view of EU regional policy considerations. Indeed, since
4 the 1989 reform of European regional policy, it is at this spatial level that eligibility
5 under Objective 1 of the Structural Funds is determined. Finally, it should not be
6 overlooked that this is the finest level at which there exists the statistical information
7 needed to carry out this empirical study. Accordingly, the use of NUTS-2 data enables
8 us to maximize the number of observations used in the econometric analysis performed
9 in the paper.

18
19
20
21

22 **4. The spatial distribution of unemployment volatility across the** 23 **European regions** 24 25 26 27 28 29

30 Following the earlier studies by Attaran (1986) and Wagner and Deller (1998) for the
31 US case, the present paper is focused on the analysis of the unemployment fluctuations
32 experienced by the EU regions. Accordingly, the main study variable is the standard
33 deviation of annual unemployment rates in each region over the period 1980-2004. As
34 in Wagner and Deller (1998), I consider that larger fluctuations (i.e. higher standard
35 deviation) in unemployment are associated with greater levels of economic instability.
36 In that respect, it is well-known that important changes in the unemployment rate are
37 often disruptive to a regional economy.
38
39
40
41
42
43
44
45
46
47
48
49
50

51 The empirical analysis begins by presenting in Figure (1) a first picture of the spatial
52 distribution of the variable object of study across the sample regions. As can be
53 observed, there are significant disparities in unemployment variability within the EU.
54 Despite this fact, all the countries considered are characterized by the presence of
55 regions with relatively low values of the study variable. Nevertheless, although there are
56
57
58
59
60

1
2
3 some exceptions, the greatest fluctuations in the unemployment rate tend to be
4 registered by regions situated in the periphery of the Union. In any event, leaving aside
5
6 other considerations, it is important to note that this initial examination suggests that
7
8 unemployment volatility is not randomly distributed across space in the EU. On the
9
10 contrary, there seems to be a positive spatial relationship between adjacent areas,
11
12 neighbouring regions registering similar values of the standard deviation of the
13
14 unemployment rate over the sample period.
15
16
17
18
19
20
21

22 [INSERT FIGURE 1 AROUND HERE]
23
24
25
26

27 However, some caution is recommended when interpreting the information supplied by
28
29 Figure (1), since the conclusions that might be drawn are highly sensitive to the number
30
31 and width of the different intervals employed to represent the variable of interest. This
32
33 suggests that additional analyses should be performed to determine with greater
34
35 accuracy the degree of spatial interdependence between the values of the study variable
36
37 at different geographical locations. Bearing this in mind, the preliminary evidence
38
39 provided by Figure (1) was supplemented with a formal analysis of the possible
40
41 presence of spatial autocorrelation in the sample under study⁴. To that end, I proceeded
42
43 by calculating Moran's I and Geary's c global tests, defined respectively as (Cliff and
44
45 Ord, 1972; Haining, 1990):
46
47
48
49
50
51
52

$$I = \frac{n \sum_{i=1}^n \sum_{j=1}^n w_{ij} (y_i - \bar{y})(y_j - \bar{y})}{S_0 \sum_{i=1}^n (y_i - \bar{y})^2} \quad (1)$$

53
54
55
56
57
58
59
60

and

$$c = \frac{(n-1) \sum_{i=1}^n \sum_{j=1}^n w_{ij} (y_i - y_j)^2}{2S_0 \sum_{i=1}^n (y_i - \bar{y})^2} \quad (2)$$

where, in the present context, y_i is the standard deviation of annual unemployment rates in region i over the period 1980-2004, and \bar{y} is the sample average. Likewise, w_{ij}

denotes the corresponding element of the spatial weight matrix W , with $\sum_{i=1}^n \sum_{j=1}^n w_{ij} = S_0$.

In relation to their interpretation, it should be noted, that after standardization, a significant and positive (negative) value of Moran's I (Geary's c) will indicate the existence of positive spatial autocorrelation, while a significant and negative (positive) value of Moran's I (Geary's c) will indicate the presence of a pattern of spatial association between dissimilar values.

As can be checked in expressions (1) and (2), before performing these tests it is necessary to define a spatial weight matrix to capture the strength of the interdependence between each pair of regions i and j . To do so, a first option is to use the concept of first order contiguity, according to which $w_{ij} = 1$ if regions i and j are physically adjacent and 0 otherwise. However, the use of this type of matrix may raise problems in the European context, given that the presence of islands means that W will include rows and columns containing only zeros. This implies that the observations in question are not considered in the analysis, which in turn has an effect on the interpretation of the results obtained. For this reason, the spatial weight matrix used in

1
2
3 this paper takes into account interactions beyond adjacent regions. In particular, I
4
5 considered a row-standardized matrix based on the inverse distance between the
6
7 centroids of the various regions. This matrix relies on the idea that only geographical
8
9 proximity matters in describing the interactions across regions, which is consistent with
10
11 the recommendations of Anselin and Bera (1998). In any event, in order to check the
12
13 robustness of the results, I considered different cutoff parameters above which spatial
14
15 interactions are assumed negligible. Following the strategy adopted by Le Gallo and
16
17 Dall'erba (2006), these cutoff parameters were defined according to the different
18
19 quartiles of the distance distribution. Nevertheless, the findings were in all cases very
20
21 similar to those described in the paper.
22
23
24
25
26
27
28

29 [INSERT TABLE 1 AROUND HERE]
30
31
32
33
34
35

36 Table 1 shows that the Moran's I (Geary's c) statistic calculated for the standard
37
38 deviation of the unemployment rate in the sample regions is positive (negative) and
39
40 statistically significant, which is clear evidence of the existence of a pattern of positive
41
42 spatial association in this context, thus confirming the initial impression drawn from
43
44 Figure (1). Accordingly, this shows that, in the European setting, spatially adjacent
45
46 regions tend on the whole to exhibit similar levels of unemployment volatility. When
47
48 interpreting this result, it is worth recalling that the empirical evidence provided by
49
50 various studies reveals that the outcomes of the labour market in a specific region are
51
52 related to the situation of the labour market in the neighbouring regions (e.g. Molho,
53
54 1995; López-Bazo et al., 2002; Overman and Puga, 2002).
55
56
57
58
59
60

1
2
3 It is important to keep in mind, however, that Moran's I and Geary's c are calculated on
4 a global basis for the whole of the sample. Hence, we do not know whether, irrespective
5 of the overall dependence pattern, there are clusters of regions in which unemployment
6 variability is higher or lower than in the neighbouring zones. This is particularly
7 relevant when characterizing the spatial distribution of unemployment volatility across
8 the EU regions. For this reason, and in order to complete the previous findings, I
9 constructed the Moran scatterplot for the variable of interest (Figure 2). The Moran
10 scatterplot is a graph on which the standardized values of the variable to be considered
11 are plotted on the horizontal axis and the standardized spatial lag of the same variable
12 on the vertical axis. Thus, the four quadrants correspond to different types of spatial
13 association. As can be seen from Figure 2, 79% of the regions considered are located in
14 quadrants I and III. This confirms that the EU is characterized by the presence of spatial
15 clusters of regions with similar levels of unemployment volatility, while there are
16 relatively few cases in which a region registers a value of the variable under analysis
17 markedly different from the average of its neighbours. Accordingly, the intensity of
18 unemployment fluctuations in the EU follows specific spatial patterns, which highlights
19 the importance of the geographical location of the sample regions in this context.

46 [INSERT FIGURE 2 AROUND HERE]
47
48
49

50 In Figure 3 the information provided by the Moran scatterplot is used to show the sign
51 of spatial association in the different areas. Specifically, the clusters of regions with
52 relatively low levels of unemployment volatility surrounded by regions with the same
53 characteristic are situated in Denmark, the Netherlands, Belgium, Germany, Austria, the
54 North of Italy and the United Kingdom. On the contrary, the map indicates that most of
55
56
57
58
59
60

1
2
3 Spain, Greece and Sweden, as well as the South of Italy and several French regions are
4 characterized by registering relatively high values of unemployment variability
5 surrounded by high values of the variable of interest. Leaving other considerations
6 aside, these findings confirm clearly the relevance of spatial effects in this setting,
7 which should be taken into account when investigating the causes of existing
8 differences in the levels of unemployment variability within the EU.

24 **5. Unemployment volatility and regional specialization**

25
26
27
28

29 The analyses performed in the preceding pages reveal the presence of significant
30 disparities in the intensity of the unemployment fluctuations experienced by the EU
31 regions. In order to investigate this issue more deeply, this section examines the
32 possible influence in this context of regional specialization.
33
34
35
36
37
38
39

40 To do so, first it is necessary to measure the level of specialization of the sample
41 regions. To that end, the literature uses a variety of indexes that enables the researcher
42 to summarize the sectoral composition of the spatial unit object of analysis in a unique
43 scalar (Combes and Overman, 2004; Duranton and Overman, 2005). Within this
44 framework, I employed initially the Herfindahl index in order to quantify the degree of
45 industrial diversification of the various regions considered in the study. This
46 specialization index is defined as follows:
47
48
49
50
51
52
53
54
55
56
57
58
59
60

$$H_i = \sum_{s=1}^S \left(\frac{E_{is}}{\sum_{s=1}^S E_{is}} \right)^2 \quad (3)$$

where E_{is} is the level of employment of region i in sector s ⁵. As can be checked, the value of the Herfindahl index ranges from $\frac{1}{S}$ when employment is evenly spread across the S sectors, to 1 when all the employment is concentrated in the same sector. Therefore, the higher is the value of the index, the less sectorally diverse would a given region be.

The Herfindahl index is employed in this analysis rather than other indicators of sectoral diversity proposed in the literature because of its relation to the measure of risk in the portfolio theory (Baldwin and Brown, 2004). Nevertheless, it should be noted that the Herfindahl index is an absolute measure of specialization, since it does not take into account the productive structure of the remaining sample regions. In view of this, and in order to check the robustness of the results, I also employed a frequently used dissimilarity index popularized by Krugman (1991):

$$K_i = \sum_{s=1}^S \left| \frac{E_{is}}{\sum_{s=1}^S E_{is}} - \frac{\sum_{j \neq i}^n E_{is}}{\sum_{j \neq i}^n \sum_{s=1}^S E_{is}} \right| \quad (4)$$

This relative measure takes value 0 if region i has a sectoral structure identical to that of the other regions. In turn, the upper bound for K is 2, which is obtained in the case of maximum dissimilarity between the region in question and the remaining sample

1
2
3 regions. This index represents the distance between the vector of sector shares in region
4
5 i and the vector of sector shares in the regions other than i . Accordingly, it measures the
6
7 extent to which region i differs from the remaining sample regions in terms of sectoral
8
9 composition⁶.
10
11

12
13
14
15 To compute the Herfindahl index and the dissimilarity measure described above, the
16
17 finest level of sectoral disaggregation with data availability in the EU at the NUTS-2
18
19 level during the study period was used. In particular, the sectoral classification
20
21 employed is based on the following fifteen activities: Agriculture, Mining and energy,
22
23 Food, beverages and tobacco, Textiles, Chemical products, Electrical and optical
24
25 equipment, Transport equipment, Other manufacturing, Construction, Distribution
26
27 services, Hotels and restaurants, Transport, storage and communications, Financial
28
29 intermediation, Real estate, renting and business activities, and Non-market services.
30
31 Accordingly, the data set covers the full range of economic activities, including
32
33 agricultural and services. Using this information, both specialization indexes were
34
35 calculated annually for each region, and averaged over the study period (see Table A1
36
37 in the Appendix for further details).
38
39
40
41
42
43
44
45

46 As mentioned in the introduction, the main aim of this paper is to investigate the link
47
48 between unemployment volatility and regional specialization in the EU. To that end, let
49
50 us consider the following model:
51
52
53
54

$$\log y_i = \alpha + \beta \log SPE_i + X_i \delta + \sum_c \phi_c N_{ic} + \varepsilon_i \quad (5)$$

55
56
57
58
59
60

1
2
3 According to the notation employed above, the independent variable is the standard
4 deviation of annual unemployment rates in each region over the sample period. As for
5 the independent variables, *SPE* denotes the specialization index, and X is a set of
6 additional regressors that control for other factors that are assumed to influence
7 unemployment variability. In addition, by including national dummies, N , I also control
8 for different institutional and structural factors, which may affect the independent
9 variable (Longhi et al., 2005). Finally, ε is the corresponding disturbance term.
10
11
12
13
14
15
16
17
18
19
20
21

22 Before discussing several technical issues in relation to the estimation of model (5), the
23 series of variables that make up the vector X are described. At this point, a word of
24 warning is required. In particular, it should be noted that, while the choice of the
25 selected variables is based on the literature on regional economic instability, it
26 ultimately depends on the availability of reliable statistical data for the level of spatial
27 disaggregation on which the study is focused.
28
29
30
31
32
33
34
35
36
37
38

39 Within this framework, I began by considering the possible relevance in this context of
40 the size of the sample regions. In that respect, it needs to be recalled that various authors
41 have pointed out that regional size is likely to be an important factor when explaining
42 spatial differences in economic instability (e.g. Kort, 1981; Brewer and Moomaw, 1985;
43 Begovic, 1992). For example, Malizia and Ke (1993) argue that regional instability will
44 be greater in smaller economies than in larger ones. According to Trendle (2006), larger
45 regions may have a greater ability to face the unfavourable effects of economic shocks
46 than smaller regions as a result of the size of the regional labour market. More job
47 seekers and more job offers mean more choice at both sides of the labour market, which
48 leads in principle to better and quicker matches (Elhorst, 2001). Nevertheless, the
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 opposite may also be true. In particular, larger regions are characterized by selling a
4 relatively higher proportion of their production in the local market (Fujita et al., 1999).
5
6 As mentioned by Baldwin and Brown (2004), this dependency of the local market
7
8 implies that the growth rates in a region's industries will be correlated, since they are
9
10 affected by the same economic shocks. Accordingly, if there are two regions with
11
12 similar levels of productive specialization but different sizes, the larger region may
13
14 register greater unemployment variability. In view of these arguments, the level of total
15
16 employment was included in the model to capture the size of the sample regions.
17
18
19
20
21

22
23
24 In relation to this, it is important to recall that there are considerable differences in the
25
26 geographical area of the various NUTS-2 regions (see Figure (1)). In this context it is
27
28 likely that two regions with similar levels of total employment but different areas have
29
30 labour markets with different characteristics, which may have influence on their ability
31
32 to soak up the adverse effects of the economic cycle. In view of this, I consider that
33
34 model (5) should take into account the degree of spatial concentration of employment
35
36 within the various regions, in addition to the level of total employment. For this reason,
37
38 I decided to incorporate in the list of regressors the employment density of the sample
39
40 regions. Nevertheless, it needs to be said that it is difficult to determine beforehand the
41
42 final effect of this variable on unemployment volatility. On the one hand, employment
43
44 density may exert a positive influence on the efficiency of matching workers to jobs
45
46 (Blackley, 1989; Partridge and Rickman, 1997). Consequently, this would imply that,
47
48 *ceteris paribus*, employment losses in some activities will be offset more easily by
49
50 employment gains in other activities in those regions with greater employment density.
51
52 On the other hand, it should not be overlooked that a more dense labour market may
53
54 increase the time needed to obtain information on job vacancies and job seekers and
55
56
57
58
59
60

1
2
3 may present spatial frictions, which would have a negative effect on the probability of
4 quick matches (Taylor and Bradley, 1997).
5
6
7
8
9

10 Malizia and Ke (1993) and Trendle (2006) have shown the relevance of the labour force
11 characteristics in explaining economic instability. Bearing this in mind, I attempted to
12 include in model (5) information on the quality of the labour force of the sample
13 regions. However, this is not an easy task in the European regional context, since there
14 are not data on the quality of the labour force at this level of territorial disaggregation
15 throughout the study period. In view of this, I decided to use the ratio of active
16 population to total population⁷. According to Fleisher and Rhodes (1976), low values in
17 this variable in a specific region would be reflecting low levels of investment in human
18 capital, which would result in higher risks for people with this characteristic to be laid
19 off (Elhorst, 2003). This seems to suggest that regions with relatively higher ratios of
20 active to total population will tend to register less fluctuations in their unemployment
21 rates. At this point it needs to be mentioned that the relationship between
22 unemployment and the ratio of active to total population is rather complex. In particular,
23 as pointed out by Elhorst (2003), the ratio of active to total population may affect the
24 unemployment rate and, in turn, be affected by this variable. This potential endogeneity
25 problem should be borne in mind when considering the results derived from the
26 estimation of model (5).
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50

51
52 Furthermore, the role played in this context by regional growth patterns was examined.
53 In relation to this, it is worth noting that Malizia and Ke (1993) have identified a U-
54 shaped relationship between growth and regional economic instability. Accordingly,
55 initially greater growth rates are associated with a lower degree of economic instability.
56
57
58
59
60

1
2
3 Nevertheless, beyond a certain level, increases in the growth rates lead to higher
4
5 instability. As pointed out by Baldwin and Brown (2004), there are different reasons
6
7 that contribute to explain this non-linear relationship. To start with, those regions with
8
9 very low or very high growth rates may be affected by specific economic shocks, which
10
11 would tend to increase economic instability. In addition, regions with high growth rates
12
13 are characterized in many cases by the presence of new industries that are inherently
14
15 more volatile than mature industries. Additionally, it needs to be said that growth is
16
17 often linked to the entry of new firms that register higher exit rates than older firms
18
19 (Baldwin et al., 1999). Bearing this in mind, I included in the model the average annual
20
21 growth rate of per capita GDP over the study period, as well as its square. Nevertheless,
22
23 some caution is needed at this point. Specifically, it is worth mentioning that growth
24
25 may be potentially endogenous in this context (Aghion and Banerjee, 2005), which
26
27 should be taken into account when interpreting the results of the empirical analysis.
28
29
30
31
32
33

34
35
36 During the last decade most of the EU regions have experienced an important process of
37
38 structural change, with an increasing relevance of the tertiary sector at the expense of
39
40 the primary and secondary sectors (Gil et al., 2002). According to Trendle (2006),
41
42 regions affected by structural change processes are generally characterized by jobs
43
44 being either destroyed or created, or both simultaneously, which leads to the existence
45
46 of discontinuities in regional labour markets. This suggests that structural change is
47
48 likely to be an important determinant of unemployment volatility. In particular, it is
49
50 expected that regions with higher levels of structural change tend to register higher
51
52 unemployment volatility. In view of this, I calculated the amount of structural change
53
54 experienced by each of the sample regions between 1980 and 2004 using the following
55
56 formula (Trendle, 2006):
57
58
59
60

$$SCH_i = \sum_{s=1}^S \left| \frac{E_{is,t_1}}{\sum_{s=1}^S E_{is,t_1}} - \frac{E_{is,t_0}}{\sum_{s=1}^S E_{is,t_0}} \right| \quad (6)$$

As can be observed, *SCH* quantifies the amount of structural change as the absolute value of the share of regional employment in sector *s* in t_1 (2004) less the share of regional employment in that sector in t_0 (1980), summed over all sectors.

With the only exception of the structural change indicator, all the explanatory variables described above were obtained for each of the 25 years considered and averaged over time. Table A1 in the Appendix provides different descriptive statistics for these variables. In addition, Table A2 shows the correlation coefficients between the various explanatory variables used in the analysis.

Table 2 presents the main results obtained when the chosen model was estimated using the Herfindahl index to measure the level of regional specialization of the EU regions. In order to reduce any potential problem of endogeneity, different specifications were considered. As can be observed in the first three columns of the table, I began by estimating various versions of model (5) by ordinary least squares (OLS). Before discussing the results, however, it needs to be said that several tests were carried out to assess the adequacy of the approach employed. Specifically, the normality of the distribution of the error terms was examined. To that end, I calculated the Shapiro-Wilk test from the regression residuals. Nevertheless, the value of the statistic does not allow us to accept the null hypothesis of normality in all cases. This may be particularly

1
2
3 relevant to justify the employment of various subsequent testing procedures. However, a
4
5 detailed analysis of the distribution of the residuals shows that the non-normality is due
6
7 exclusively to the existence of three extreme values corresponding to Kriti (Greece),
8
9 Bolzano-Bozen (Italy) and Lancashire (United Kingdom). Once these observations have
10
11 been removed from the sample, the distribution of the error terms is normal in all cases.
12
13 Given that the results are very similar in both cases, I decided to keep all the
14
15 observations in the analysis in order to maintain the whole sample of European regions.
16
17
18
19
20
21

22 Furthermore, the analyses performed in the previous section highlighted clearly the
23
24 importance of spatial effects in explaining the regional distribution of unemployment
25
26 variability in the EU. Bearing this in mind, I calculated various spatial dependence tests
27
28 based on the residuals provided by the OLS estimations. In particular, I computed the
29
30 Moran's I test (Cliff and Ord, 1972), the Lagrange multiplier tests for the spatial error
31
32 model (LMERR) and the spatial lag model (LMLAG) proposed respectively by
33
34 Burridge (1980) and Anselin (1988a), plus their robust versions (R-LMERR and R-
35
36 LMLAG) (Anselin et al., 1996). These tests were calculated initially using the spatial
37
38 weight matrix defined in the previous section. As mentioned above, this spatial weight
39
40 matrix is based on pure geographical distance. Accordingly, it is strictly exogenous to
41
42 the model, thus avoiding the identification problems raised by Manski (1993). Table 2
43
44 shows that the results of the Moran's I test lead in all cases to the rejection of the null
45
46 hypothesis of absence of residual spatial dependence, despite that model (5) includes
47
48 national dummies. In order to decide the most appropriate specification in this context, I
49
50 followed the classical approach in the spatial econometric literature and considered the
51
52 degree of statistical significance of the various Lagrange multiplier tests (Anselin and
53
54 Rey, 1991). Since LMLAG and R-LMLAG are respectively more significant than
55
56
57
58
59
60

1
2
3 LMERR and R-LMERR in all cases, I selected the spatial lag model as the best
4 specification⁸. Accordingly, the spatial lag of the dependent variable should be included
5
6 in the list of regressors. That is,
7
8

$$\log y_i = \alpha + \beta \log SPE_i + X_i \delta + \lambda W \log y_i + \sum_c \phi_c N_{ic} + \varepsilon_i \quad (7)$$

9
10
11
12
13
14
15
16
17
18 where λ is the spatial autoregressive parameter.
19
20
21

22
23 [INSERT TABLE 2 AROUND HERE]
24
25
26
27

28 The estimation of model (7) by OLS is inconsistent due to simultaneity induced by the
29 spatial lag. Maximum likelihood (ML) estimators have been proposed to provide
30 consistent estimates (Anselin, 1988b). In view of this, the last three columns in Table 2
31 show the ML estimates of various versions of the spatial lag model (7). Following the
32 suggestion of White (1982) and Davidson and MacKinnon (1993), reported standard
33 errors come from the heteroskedasticity consistent estimator of the covariance matrix of
34 the maximum likelihood parameters.
35
36
37
38
39
40
41
42
43
44
45
46

47 As can be seen, the spatial autoregressive parameter is positive and statistically
48 significant in all cases. In fact, the results of the Wald test and the Lagrange multiplier
49 test for $\lambda = 0$ confirm the statistical adequacy of the spatial lag model in this context.
50
51 Accordingly, the empirical evidence provided by Table 2 indicates clearly that the
52 degree of unemployment volatility in the neighbouring regions contributes to explain
53 the variation of the dependent variable, which is in line with the findings in section 4.
54
55
56
57
58
59
60

1
2
3 In any event, as stated earlier, the main aim of this paper is to investigate the link
4
5 between unemployment volatility and sectoral specialization in the EU regions. In that
6
7 respect, the estimation of the spatial lag model specified above yields interesting results.
8
9 Thus, the information supplied by Table 2 reveals that the coefficient of the Herfindahl
10
11 index is in all cases positive and statistically significant. This indicates the existence of
12
13 a positive relationship between unemployment variability and sectoral diversification in
14
15 the EU regions. This result is in fact robust to the inclusion in the analysis of additional
16
17 explanatory variables. Hence, the estimates support the hypothesis that those regions
18
19 characterized by greater levels of sectoral diversification tend to register lower
20
21 unemployment volatility in the European context, which is consistent with the results
22
23 obtained previously for the US states by Wagner and Deller (1998) using a different
24
25 methodological approach based on a regional input-output model. Likewise, several
26
27 authors have provided empirical evidence for various geographical settings showing
28
29 that industrial diversity has a positive impact on economic stability (e.g. Kort, 1981;
30
31 Malizia and Ke, 1993; Baldwin and Brown, 2004; Trendle, 2006). Nevertheless, some
32
33 caution is required when comparing the results of the present paper with the findings
34
35 obtained in these earlier studies, since in most cases there are differences in the
36
37 dependent variable⁹.
38
39
40
41
42
43
44
45
46
47

48 With respect to the different control variables mentioned above, Table 2 indicates that
49
50 all of them are statistically significant. In particular, the size of the regional labour
51
52 market is negatively correlated with the dependent variable, suggesting that larger
53
54 regions experience lower unemployment volatility. In turn, employment density has a
55
56 positive influence on the dependent variable. The analysis carried out also reveals that
57
58 regions with higher ratios of active population to total population register less
59
60

1
2
3 fluctuations in their unemployment rates. Furthermore, Table 2 suggests the existence of
4 a non-linear relationship between economic growth and the dependent variable.
5 Specifically, the signs of the coefficients associated with the average annual growth rate
6 and with its square show a U-shaped link between economic performance and regional
7 instability. Finally, the indicator used to quantify the amount of structural change
8 experienced by the sample regions is positively correlated with the dependent variable.
9 This means that structural change processes contribute to increase unemployment
10 volatility. Nevertheless, according to the above discussion, these findings should be
11 treated with some caution, due to the possible mutual dependency between several of
12 the regressors included in vector X and the dependent variable. In any event, it is
13 important to note that the coefficient of the Herfindahl index is positive and statistically
14 significant in the different specifications of model (7) considered, regardless of the
15 specific control variables included in each case. This suggests that the main result of the
16 paper is not affected by potential endogeneity between some of the regressors and the
17 dependent variable.

18
19
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40
41 Having reached this point, it is worth noting that the observed link between
42 unemployment volatility and industry mix may be sensitive to the specific measure of
43 specialization used in the study. Bearing this in mind, previous analyses were repeated
44 substituting the Herfindahl index with the dissimilarity index defined above. The results
45 are shown in Table 3. As can be observed, the coefficient of the dissimilarity index is
46 positive and statistically significant in all cases, which supports the previous
47 conclusions. Hence, the detected relationship between unemployment volatility and the
48 sectoral composition of economic activity within the EU still holds when a measure of
49 relative specialization is employed in the analysis¹⁰. Additionally, with regard to the
50
51
52
53
54
55
56
57
58
59
60

1
2
3 remaining explanatory variables, it is interesting to note that the results in Table 3 are
4
5 very similar to those discussed above.
6
7
8
9

10 [INSERT TABLE 3 AROUND HERE]
11
12
13
14

15 The empirical evidence provided by Tables 2 and 3 confirms clearly that regional
16
17 specialization has a positive impact on the intensity of unemployment fluctuations in the
18
19 EU. Nevertheless, the analysis carried out thus far does not supply any information on
20
21 the role played in this context by the various sectors, which prevents us from isolating
22
23 the effects of different productive structures on unemployment volatility. In view of
24
25 this, and in order to complete the previous results, I decided to use an alternative
26
27 specification of model (5) in which the specialization index was replaced with the
28
29 employment share in each of the fifteen sectors with data availability at the level of
30
31 territorial disaggregation considered in the study.
32
33
34
35
36
37
38

39 Table 4 summarizes the main results of this analysis. It is worth noting that, following
40
41 the specification search approach adopted above, and given the values of the different
42
43 spatial dependence tests calculated from the OLS residuals, the estimation of the spatial
44
45 lag model by ML is again the preferred specification in all cases. That said, we can
46
47 observe that the employment share in Mining and energy is positively correlated with
48
49 unemployment volatility. When interpreting this result, it needs to be recalled that this
50
51 industry is highly variable and provides basic inputs to many other activities. As pointed
52
53 out by Garcia-Milá and McGuire (1993), this implies that a relatively important
54
55 presence of this sector increases the degree of exposure of the region to the shifts in the
56
57 economic cycle. The Construction sector has a similar effect on unemployment
58
59
60

variability, which is not particularly surprising if we take into account that this industry is highly cyclical. By contrast, those regions specialized in relatively low-tech and labour-intensive activities, such as Food, beverages and tobacco, Textiles, and Other manufacturing, experience less fluctuations in their unemployment rates. This suggests that these sectors may contribute to diversify the risks of a downturn in the regional economy. In turn, the estimates indicate that the employment share in Non-market services is positively correlated with the dependent variable. In that respect, it should be recalled that regions with a large non-market oriented sector are by definition less affected by changes in the overall economic conditions (e.g. Kangasharju and Pekkala, 2004). In this context, public employment and transfers play a relevant role (Rodríguez-Pose and Fratesi, 2007). This means that the creation and destruction of employment in these regions tends to be more related to political than to economic decisions, which may have repercussions on their level of stability in the long term. Finally, it is worth mentioning that, as can be seen in Table 4, the coefficients of the employment shares in the remaining sectors are not statistically significant.

6. Conclusions

This paper has investigated the link between unemployment volatility and the sectoral composition of economic activity in 196 EU regions during the period 1980-2004. To that end, I have applied spatial exploratory techniques and spatial econometric models, which has allowed me to take into account explicitly the role played by spatial effects in this context.

1
2
3
4
5
6 The results show that there are relatively important differences in the intensity of the
7
8 unemployment fluctuations experienced by the European regions. Although there are
9
10 some exceptions, the highest levels of volatility tend to be registered by regions in the
11
12 EU periphery. On the contrary, the regions with less variability in their unemployment
13
14 rates are generally located in the central areas of the Union. This spatial pattern suggests
15
16 that the study variable is not randomly distributed across the European space.
17
18 Specifically, the analysis carried out reveals the existence of positive spatial
19
20 autocorrelation in this context. Accordingly, neighbouring regions tend on the whole to
21
22 experience similar levels of unemployment volatility.
23
24
25
26
27
28

29 The information provided by estimating a spatial lag model indicates that
30
31 unemployment volatility is positively related to regional specialization. Hence, those
32
33 EU regions with relatively low levels of sectoral specialization are characterized in
34
35 general by registering less fluctuations in their unemployment rates. This result is in fact
36
37 robust to the inclusion in the analysis of additional explanatory variables, such as the
38
39 level of total employment, employment density, the ratio of active population to total
40
41 population, the economic growth rate, and the amount of structural change experienced
42
43 by the region in question. Likewise, the estimates show that the observed link between
44
45 unemployment variability and the sectoral composition of economic activity does not
46
47 depend on the employment in the analysis of absolute or relative specialization
48
49 measures.
50
51
52
53
54
55
56

57 In order to complete these findings, I have also examined the role played in this context
58
59 by the various sectors considered. This has allowed me to determine the influence of
60

1
2
3 different sectoral structures on unemployment variability. In that respect, the results
4
5 reveal that the intensity of unemployment fluctuations is positively correlated with the
6
7 regional employment share in Mining and energy, Construction and Non-market
8
9 services. By contrast, regions specialized in Food, beverages and tobacco, Textiles, and
10
11 Other manufacturing, register relatively low levels of unemployment volatility.

Notes

¹ During the last fifteen years different studies have examined the links between economic integration, productive specialization and the degree of symmetry in the economic cycle. See, for example, Krugman (1993), Frankel and Rose (1998) or Kalemli-Ozcan et al. (2001).

² The analysis of the different sources of economic instability is beyond the scope of this paper. For further details, see Siegel et al. (1995).

³ NUTS is the French acronym for “Nomenclature of Territorial Units for Statistics”, a hierarchical classification of subnational spatial units established by Eurostat. In this classification, NUTS-0 corresponds to country level, while increasing numbers indicate increasing levels of subnational disaggregation.

⁴ Spatial autocorrelation can be defined as the coincidence of value similarity with locational similarity (Anselin, 2001).

⁵ I decided to use the level of employment as the reference variable instead of production to avoid problems of currency conversion inherent in value data (Brühlhart and Traeger, 2005).

⁶ As a sensitivity analysis, I also employed an alternative index similarly defined except using the square rather than the absolute value in expression (4). The results, however, were very similar in both cases.

⁷ The participation rate was not employed due to the lack of data on the working-age population for the sample regions.

⁸ In order to check the validity of the decision rule used to choose this specification, I also estimated an alternative model including a spatial autoregressive structure in the error term (spatial error model). The results are presented in Table A3 in the Appendix. It is worth noting that the spatial lag model achieves a better fit than the spatial error model in all cases, thus confirming that the spatial lag model is the preferred specification in this context.

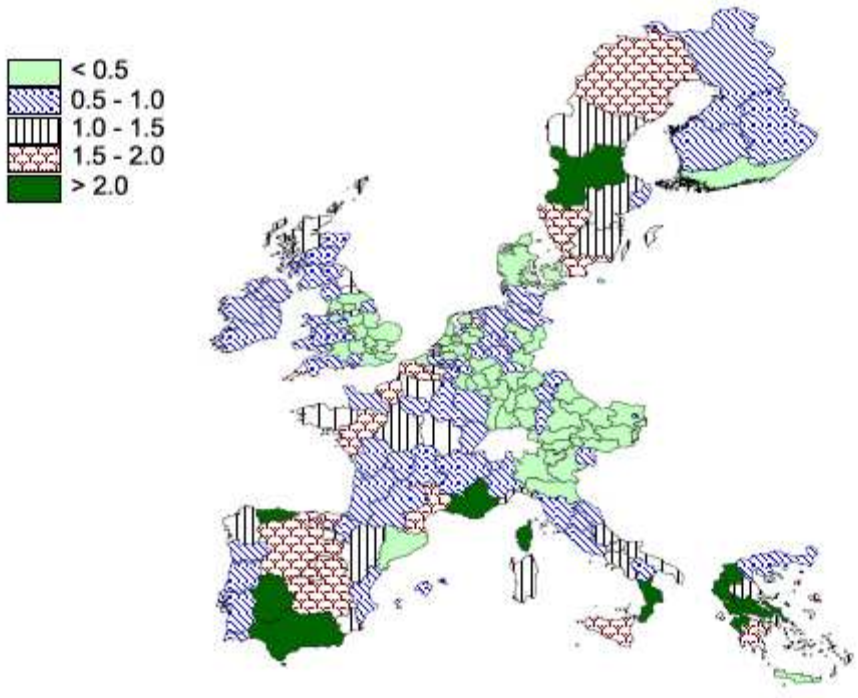

⁹ Although there are some exceptions, most of these studies use a variance-based statistic applied to employment data. See Dissart (2003) for further details on this issue.

¹⁰ I also investigated the possible presence of a non-linear relationship between the specialization indexes and the dependent variable. To that end, I considered different alternative specifications including the square of the two specialization measures employed. Nevertheless, the coefficients of these variables were not statistically significant in any case.

6 Notes: (1) The dependent variable is in all cases the logarithm of the standard deviation of annual unemployment rates in each region over the period 1980-2004. (2) With the
7 only exception of the ratio of active population to total population, and the annual growth rate and its square, all the explanatory variables are expressed in logarithms. (3) *,
8 ** and *** denotes significant at 10%, 5% and 1%, respectively. (4) Robust standard errors are reported in parentheses (White, 1980, 1982).

Non market services	0.042***	0.008	-96.492	3.739***	0.000	6.120**	12.265***	18.385***

Notes: (1) The dependent variable is in all cases the logarithm of the standard deviation of annual unemployment rates in each region over the period 1980-2004. (2) Spatial lag models estimated by ML. The various spatial dependence tests were calculated from the OLS residuals. (3) *, ** and *** denotes significant at 10%, 5% and 1%, respectively. (4) Robust standard errors were calculated according to White (1980, 1982). (5) All the regressions include national dummies and the following control variables: total employment, employment density, the ratio of active population to total population, the annual growth rate, the square of the annual growth rate and the amount of structural change. (6) The number of observations is 196 in all cases.

Table A1: Descriptive statistics for the explanatory variables considered in the analysis.

Variable	Mean	St. Dev.
Herfindahl index	0.151	0.031
Dissimilarity index	0.310	0.144
Total employment (000s)	760.931	681.523
Employment density	201.094	640.234
Ratio of active to total population (%)	45.774	7.572
Average annual growth rates of per capita GDP (%)	2.222	1.129
Structural change	0.406	0.090
Agriculture (employment share, %)	8.089	8.482
Mining and energy (employment share, %)	1.457	1.179
Food, beverages and tobacco (employment share, %)	2.684	1.078
Textiles (employment share, %)	2.214	2.392
Chemical products (employment share, %)	2.658	1.456
Electrical and optical equipment (employment share, %)	2.061	1.252
Transport equipment (employment share, %)	1.810	1.311
Other manufacturing (employment share, %)	8.288	3.487
Construction (employment share, %)	7.366	1.399
Distribution services (employment share, %)	14.464	2.391
Hotels and restaurants (employment share, %)	4.516	2.494
Transport, storage and communications (employment share, %)	5.925	2.223
Financial intermediation (employment share, %)	2.772	1.355
Real estate, renting and business activities (employment share, %)	8.409	3.923
Non-market services (employment share, %)	27.287	5.949

Notes: The number of observations is 196 in all cases.
