Abstract

We compute aggregate productivity of manufacturing industries by urban, rural less sparse and rural sparse locations in the UK from firm-specific total factor productivities, which are estimated by a semi-parametric algorithm, within 4-digit manufacturing industries, using FAME data over the period 1994-2001. We analyse the productivity differentials across location categories by decomposing them into industry productivity effect and industry composition effect. Our analysis indicates that at the end of twentieth century a rural-urban divide in manufacturing productivity still remains but there is a tendency of convergence between rural and urban location categories, possibly due to increased competitive pressure. The industry composition effect is positively correlated with the industry productivity effect suggesting that locations with high productivity are also characterised by industrial structure enhancing productivity.

Key words: Total factor productivity, structural estimation, rural-urban definition, UK manufacturing

JEL classification: D24, R11, R30

IS THERE A RURAL-URBAN DIVIDE? LOCATION AND PRODUCTIVITY OF UK MANUFACTURING

INTRODUCTION

Since late 1950s until the end of the century there has been a shift of employment from urban to rural areas and a rise in rural wages which has arguably also been associated with a growth in productivity of all types of rural businesses in the UK (KEEBLE, 2000; NORTH and SMALLBONE, 2000; ANDERSON et al., 2005), in other parts of Europe (ROPER, 2001; TERLUIN, 2003; TERLUIN et al., 2005), and in the USA (ACS and MALECKI, 2003).

Authors argue that this trend has slowed down and even reversed recently (e.g., WEBBER et al., 2008). Therefore the question if differences in aggregate productivity between urban and rural locations still remain and what are the factors affecting rural-urban productivity differentials is of high importance for policies aiming at welfare improvement and economic growth.

Traditional studies commissioned by the Department of the Environment, Food and Rural Affairs (DEFRA) in England and Wales have usually been concerned with productivity differentials at local authority level using aggregate data. However, there are methodological and data problems associated with the *area* approach such as whether to use workplace or residence-based measure and how to incorporate both earnings and profits in the measure of productivity. The alternative is to estimate *business* productivity using micro data at firm or plant level and then aggregate productivity measures to the level of rural and urban location categories. Recently, WEBBER et al. (2008) estimate labour productivity using plant level data and investigate the presence and causes of differences in productivity across the 2004 DEFRA defined urban, rural less sparse and rural sparse location categories.¹ The main finding is that there is a productivity divide across urban and rural locations - plants

1
2
3 in less sparse and sparse rural location categories are 13.5 percent and 21.6 percent less
4
5 productive than plants in urban locations respectively.²
6
7

8 In this paper, similar to WEBBER et al. (2008), we use micro-data. However, the
9
10 widely available dataset used in our study - FAME of Bureau van Dijk - is different from the
11
12 Office for National Statistics (ONS) census data employed by WEBBER et al. (2008). The
13
14 advantage of our data over the one used by WEBBER et al. (2008) is that FAME contains
15
16 consolidated firm level accounts which avoid problems with identifying plants within multi-
17
18 plant firms. Given our ultimate goal to study productivity differences between aggregated
19
20 rural and urban areas and the economic importance of large (multi-national) multi-plant firms
21
22 (MARKUSEN, 1995), we believe that assuming homogeneity of plants within multi-plant
23
24 firms is a less costly trade-off compared to excluding all multi-plant firms from the analysis.
25
26 Furthermore, we apply a structural estimation algorithm to panel data, covering the 1994-
27
28 2001 period, and extend the analysis of location and performance by estimating total factor
29
30 productivity (TFP) at firm level which is a more comprehensive direct measure of firm
31
32 performance compared to the labour productivity estimated for only one year (2004) in the
33
34 WEBBER et al. (2008) paper.
35
36
37
38
39
40

41 Previous studies attempting to link location and productivity apply a two-stage
42
43 analysis. In the first stage authors estimate firm productivity, and in a second stage they
44
45 proceed to link productivity to location characteristics. In our view testing for a relationship
46
47 between location and (unobservable) productivity, *ex-post*, is admitting that there is
48
49 information that should have been used in the structural model of the unobservable while
50
51 estimating the production function in the first instance. Therefore, to estimate unbiased and
52
53 consistent measures of firm productivity, we rely on a behavioural framework which builds
54
55 on models of industry dynamics (ERICSON and PAKES, 1995) and the link between
56
57 productivity and density of economic activity (CICCONE and HALL, 1996). Following
58
59
60

1
2
3 econometric modelling ideas in ACKERBERG et al. (2007), the framework underlines our
4 estimation strategy and helps us specify timing and relational assumptions for the firm
5 decisions in a manner similar to OLLEY and PAKES (1996). In our econometric application
6 we follow ACKERBERG et al. (2007) and an extension suggested in RIZOV and WALSH
7 (2009). We explicitly allow market structure (factor markets, demand conditions and prices)
8 and investment climate (including institutions) to differ across rural and urban locations. We
9 find that there is indeed a rural - urban productivity divide, which is due to both differences in
10 industry composition and industry (and firm) productivity as rural industries lag behind their
11 urban counterparts. The aggregate rural - urban productivity differentials are determined
12 mostly by industry productivity differences while differences in industry composition across
13 rural (especially, less sparse) and urban locations are less pronounced.

29 The paper is organised as follows. In the next section a brief analysis of relevant
30 literature is undertaken to clarify the link between productivity and density of economic
31 activity and a model of (unobservable) productivity is explicitly formulated. Then we
32 introduce the semi-parametric estimation methodology applied in the paper, while in a
33 following section we describes the data and variables used in our econometric analysis and
34 report results of estimating production functions within 4-digit industries. Distributions of
35 productivity estimates by location category are also presented. In the section before the last
36 we analyse the spatial patterns of aggregate productivity and factors affecting it by the means
37 of decompositions in levels and in changes for each location category. The final section
38 concludes.

55 LOCATION, DENSITY OF ECONOMIC ACTIVITY AND FIRM PRODUCTIVITY

56 The origins of the analysis relating location and economic performance of firms can be traced
57 back at least to the work of MARSHALL (1920) who states that urbanisation and thus, the
58
59
60

1
2
3 geographical concentration of economic activities in urban agglomerations can result in a
4
5 snowball effect, where new entrants tend to agglomerate to benefit from higher diversity and
6
7 specialization in production processes. There are also benefits to firms from co-locating in
8
9 close proximity to other firms in the same industry. Both urbanization and localization
10
11 economies can be considered centripetal forces leading to concentration of economic
12
13 activities. However, HENDERSON (1974) building on work by MILLS (1967) demonstrates
14
15 that, in an equilibrium, disamenities from agglomeration may offset the productivity
16
17 advantages thus acting as centrifugal forces. For example, these include increased costs
18
19 resulting from higher wages driven by competition among firms for skilled labour, higher
20
21 rents due to increased demand for housing and commercial land, and negative externalities
22
23 such as congestion.
24
25
26
27
28

29 A second branch of the literature on agglomeration hypothesises economies of scale
30
31 internal to firms (ABDEL-RAHMAN, 1988; FUJITA, 1988; RIVERA-BATIZ, 1988).
32
33 Models with internal increasing returns build on theories of the firm and its market and
34
35 commonly employ the well known formalisation of monopolistic competition of SPENCE
36
37 (1976) and DIXIT and STIGLITZ (1977) to demonstrate that non-transportable intermediate
38
39 inputs produced with increasing returns imply agglomeration. In a related model,
40
41 KRUGMAN (1991) demonstrates that agglomeration will result even when transportation
42
43 costs are small, if most workers are mobile. The essence of all these models is that when local
44
45 markets are more active, a larger number of producers of the differentiated intermediate
46
47 inputs break even and the production of final goods is more efficient when a greater variety
48
49 of intermediate inputs is available.³
50
51
52
53

54 While previous studies focus on returns to economic mass such as city size,
55
56 CICCONE and HALL (1996) focus of spatial density and show that density, defined as the
57
58 intensity of labour, human and physical capital relative to physical space, rather than size is a
59
60

1
2
3 more accurate determinant of productivity. Density affects productivity in several ways. If
4
5 technologies have constant returns themselves, but the transportation of products from one
6
7 stage of production to the next involves costs that rise with distance, then the technology for
8
9 the production of all goods within a particular geographical area will have increasing returns -
10
11 the ratio of output to input will rise with density. If there are externalities associated with the
12
13 physical proximity of production, then density will contribute to productivity for this reason
14
15 as well. A third source of density effects is the higher degree of beneficial specialization
16
17 possible in areas of dense activity. A closely related work is by CARLINO and VOITH (1992)
18
19 who find that total factor productivity across U.S. states increases with urbanization. More
20
21 recently, CICCONE (2002) for Europe and FINGLETON (2003) for Great Britain report
22
23 positive association between employment density and productivity. For the case of Great
24
25 Britain, RICE et al. (2006) explain regional productivity differences by proximity to
26
27 economic mass. They argue that the detailed modelling of proximity, measured by driving
28
29 time, to economic mass is more general than the measures of population density in the own or
30
31 neighbouring regions and that this enables them to derive economically meaningful
32
33 inferences about the spatial scale over which the productivity effects of agglomeration
34
35 operate.
36
37
38
39
40
41
42

43 In this paper we follow the models of CICCONE and HALL (1996) and RICE et al.
44
45 (2006) in directly relating productivity to density of economic activity and proximity to
46
47 economic mass. Given that our strategy is to control for unobservable productivity while
48
49 estimating production functions, rather than explicitly identifying effects, we use as a proxy a
50
51 categorical variable based on the DEFRA definition. In 2005 DEFRA brought out both a new
52
53 classification and a new definition of rural as described in the DEFRA's (2004) strategy
54
55 paper. The *classification* is based on settlement morphology, while the *definition* is based on
56
57 the density of the population. In principle, it is possible to have six types of rural locations –
58
59
60

1
2
3 town (less sparse); town (sparse); village (less sparse); village (sparse); dispersed (less
4
5 sparse); dispersed (sparse) (DEFRA, 2005a) – but, in practice, this grouping cannot be readily
6
7 undertaken for analytical purposes (DEFRA, 2005b) and the combination of the classification
8
9 and the definition makes little sense for policy analysis. In our study, similar to WEBBER et
10
11 al. (2008), the new rural definition is used; a distinction is made between sparse and less
12
13 sparse locations to allow comparisons to be made between broadly different types of rural
14
15 location based on the density of population. The sparse and less sparse rural categories are
16
17 then compared with data for urban locations to examine principal differences in plant
18
19 productivity between rural sparse, rural less sparse and urban locations.
20
21
22
23

24
25 - Table 1 about here -
26

27 Table 1 presents summary statistics of key location characteristics (density of
28
29 population of working age, business density, etc.) by urban, rural less sparse and rural sparse
30
31 categories according to the DEFRA definition. There are clear differences across locations
32
33 with respect to various characteristics of density of economic activity, with urban locations
34
35 exhibiting the highest density and rural sparse locations being the least dense in economic
36
37 activity. Our main hypothesis is that productivity is high in locations with high density of
38
39 economic activity or that have, in some sense, proximity to a large economic mass. We argue
40
41 that the DEFRA definition of location controls for all these effects and encompasses various
42
43 agglomeration mechanisms driving productivity.⁴ For examples, one mechanism can be
44
45 technological externalities; firms learn from co-presence with other firms in related activities,
46
47 so innovating and implementing new technologies efficiently. Another mechanism can be via
48
49 thick capital and labour markets which work more efficiently, by having lower search costs
50
51 and generating improved matching of buyers and sellers. A third mechanism can be simply
52
53 that, in the presence of transport costs, firms gain from having good access both to their
54
55 customers and to suppliers of intermediate goods and services. We do not seek to identify
56
57
58
59
60

1
2
3 each of these effects separately, but to merely control for their combined impact by using
4 location-specific information in modelling firm productivity.
5
6

7
8 Next we explicitly build the productivity and location relationship into a (structural)
9 model of unobservable productivity. We specify productivity of a firm, j , at a point in time, t ,
10 following OLLEY and PAKES (1996) and extensions outlined in ACKERBERG et al. (2007)
11 as a function $\omega_{jt} = h(i_{jt}, k_{jt}, a_{jt}, l_{jt}, r_t)$ of a firm's capital, k_{jt} , labour, l_{jt} , age, a_{jt} , investment,
12 i_{jt} , and the economic environment that the firm faces at a particular point in time, r_t , and treat
13 the function non-parametrically in our estimation algorithm. OLLEY and PAKES (1996)
14 derive the function of productivity by inverting the investment demand function of the firm
15 which itself is a solution to the firm's maximization problem.⁵ The economic environment
16 control, r_t , could capture characteristics of the input markets, characteristics of the output
17 market, or industry characteristics like the current distribution of the states of firms operating
18 in the industry. Note that Olley-Pakes formulation allows all these factors to change over
19 time, although they are assumed constant across firms in a given period.
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35

36
37 In this paper we extend the Olley-Pakes model of (unobservable) productivity in two
38 ways. First, we extend the information content of the economic environment control to vary
39 by type of firm according to the DEFRA definition of rural and denote this by, r_{jt} , where a
40 subscript index j is added. Introducing location-specific market structure in the state space
41 allows for some of the competitive richness of the Markov-perfect dynamic oligopoly model
42 of ERICSON and PAKES (1995). Note also that introducing richer location-specific market
43 structure in the productivity function does minimise the deviations from the original Olley-
44 Pakes scalar unobservable assumption, necessary to invert the investment function, and it
45 may help with the precision of the estimates.
46
47
48
49
50
51
52
53
54
55
56
57

58 Second, we relax the scalar unobservable assumption all together following modelling
59 ideas in ACKERBERG et al. (2007) and an application to firm productivity and trade
60

orientation by RIZOV and WALSH (2009). Furthermore, we adjust the model of productivity to allow for exporting status, e_{jt} , to be an additional (endogenous) control variable in the state space that is driven by lagged productivity as in MELITZ (2003). This formulation leads to modelling productivity as a controlled second-order Markov process, $p(\omega_{jt} | \omega_{jt-1}, \omega_{jt-2})$, where firms operate through time forming expectations of future ω_{jt} s on the basis of information from two preceding periods.⁶ The productivity function then becomes

$$\omega_{jt} = h(i_{jt}, k_{jt}, a_{jt}, l_{jt}, e_{jt}, r_{jt}). \quad (1)$$

Selection to exporting can reveal better productivity due to higher quality products, know-how, and distribution networks that are needed to overcome sunk cost to get into foreign markets. We specify the propensity to export as a non-parametric function of $i_{jt-1}, k_{jt-1}, a_{jt-1}, l_{jt-1}, r_{jt-1}$ and a vector of other firm-specific characteristics such as type of ownership, corporate governance, and industry groupings. Similarly, location choices may also be endogenous, therefore we specify propensity of firms to locate in urban, rural less sparse or rural sparse areas as a non-parametric function of firm specific $(i_{jt-1}, k_{jt-1}, a_{jt-1}, l_{jt-1}, e_{jt-1})$ and location specific characteristics, listed in Table 1, measuring density of economic activity at local authority (LAD) level. In addition, NUTS3 regional dummy variables are included to partially control for spatial spillovers and proximity to economic centres. In equation (1), we use the propensity to export, \hat{e}_{jt} , estimated from a Probit model, and the propensity to locate in area with higher density of economic activity, \hat{r}_{jt} , estimated from an Ordered Probit model, rather than the observed e_{jt} and r_{jt} which allow us to treat the exporting and location decisions as endogenous controls.⁷

ECONOMETRIC FRAMEWORK

1
2
3 To compute unbiased and consistent firm-level (total factor) productivity measure, we need
4
5 to generate first unbiased and consistent estimates of production function parameters.
6
7
8 However, estimating production function parameters is complicated due to the fact that
9
10 productivity is not observed directly in our data. The first complication arises because
11
12 unobservable productivity determines input levels which is the classic simultaneity problem
13
14 analysed by MARSHAK and ANDREWS (1944). The second complication arises out of the
15
16 fact that firms survive based on unobservable productivity type, amongst other factors. If an
17
18 OLS estimator is used, simultaneity means that estimates for variable inputs such as labour,
19
20 when considered non-dynamic input, will be upward biased, assuming a positive correlation
21
22 with unobservable productivity. Exit will depend on productivity type as well as the capital
23
24 stock representing sunk cost. Thus, the coefficient on capital is likely to be underestimated by
25
26 OLS as higher capital stocks induce firms to survive at low productivity levels (OLLEY and
27
28 PAKES, 1996). Besides the two biases, a potential problem afflicting productivity measure is
29
30 associated with the spatial dependency of observations within a geo-space. Spatial
31
32 dependency leads to the spatial autocorrelation problem in statistics since - like temporal
33
34 autocorrelation - this violates standard statistical techniques that assume independence among
35
36 observations (ANSELIN and KELEJIAN, 1997). Furthermore, spatial dependency is a source
37
38 of spatial heterogeneity which means that overall parameters estimated for the entire system
39
40 may not adequately describe the process at any given location.
41
42
43
44
45
46
47
48

49 To deal with the estimation problems outlined above we employ a semi-parametric
50
51 estimation algorithm in the spirit of OLLEY and PAKES (1996) following extensions in
52
53 ACKERBERG et al. (2007) and an application by RIZOV and WALSH (2009). As in
54
55 OLLEY and PAKES (1996) we specify a log-linear production function,
56
57

$$y_{jt} = \beta_0 + \beta_k k_{jt} + \beta_a a_{jt} + \beta_l l_{jt} + \omega_{jt} + \eta_{jt}, \quad (2)$$

58
59
60

where the log of firm, j value added at time, t , y_{jt} , is modelled as a function of the logs of that firm's state variables at t , namely age, a_{jt} , capital, k_{jt} , and labour, l_{jt} . Investment demand, i_{jt} determines the capital stock at the beginning of each period. The law of capital accumulation is given by $k_{jt+1} = (1 - \delta)k_{jt} + i_{jt}$, while age evolves as $a_{jt+1} = a_{jt} + 1$. The error structure comprises a stochastic component, η_{jt} , with zero expected mean, and a component that represents unobserved productivity, ω_{jt} as specified in equation (1). Both ω_{jt} and η_{jt} are unobserved, but ω_{jt} is a state variable, and thus affects firm's choice variables – decision to exit and investment demand, while η_{jt} has zero expected mean given current information, and hence does not affect decisions.

Substituting equation (1) into the production function (2) and combining the constant, k_{jt} , a_{jt} , and l_{jt} terms into function $\phi(i_{jt}, e_{jt}, k_{jt}, a_{jt}, l_{jt}, r_{jt})$ gives

$$y_{jt} = \phi(i_{jt}, e_{jt}, k_{jt}, a_{jt}, l_{jt}, r_{jt}) + \eta_{jt}. \quad (3)$$

Equation (3) is the first step of our estimation algorithm and can be estimated as in OLLEY and PAKES (1996) with OLS and applying semi-parametric methods that treat the function $\phi(\cdot)$ non-parametrically, using a polynomial.⁸ Even though the first stage does not directly identify any of the parameters of the production function, it generates estimates of $\phi(\cdot)$, $\hat{\phi}_{jt}$, needed in the second stage where we can write expected (unobservable) productivity as

$$\hat{\omega}_{jt}(\beta_0, \beta_k, \beta_a, \beta_l) = \hat{\phi}_{jt} - \beta_0 - \beta_k k_{jt} - \beta_a a_{jt} - \beta_l l_{jt}. \quad (4)$$

Next, to clarify timing of production decisions we decompose ω_{jt} into its conditional expectation given the information known by the firm in two prior periods, $t-2$ and $t-1$, and a residual $\omega_{jt} = E[\omega_{jt} | \omega_{jt-2}, \omega_{jt-1}] + \xi_{jt} = g(\hat{\omega}_{jt-2}, \hat{\omega}_{jt-1}) + \xi_{jt}$. By construction ξ_{jt} is uncorrelated with information in $t-2$ and $t-1$ and thus with k_{jt} , a_{jt} , and l_{jt} which are chosen prior to time, t . The specification of the $g(\cdot)$ function is determined by the fact that productivity follows a second-order Markov process as discussed in the previous section.

Note that the firm's exit decision in period t depends directly on ω_{jt} and thus the exit decision will be correlated with ξ_{jt} . This correlation relies on the assumption that firms exit the market quickly, in the same period when the decision is made. If exit is decided in the period before actual exit occurred, then even though there is a selection per-se, exit would be uncorrelated with ξ_{jt} .⁹ To account for endogenous selection on productivity we extend the $g(\cdot)$ function following ACKERBERG et al. (2007) and RIZOV and WALSH (2009) as follows:

$$\omega_{jt} = g'(\hat{\omega}_{jt-2}, \hat{\omega}_{jt-1}, \hat{P}_{jt}) + \xi_{jt}, \quad (5)$$

where \hat{P}_{jt} is propensity score which controls for the impact of selection on the expectation of ω_{jt} , i.e., firms with lower survival probabilities which do survive to time, t likely have higher ω_{jt} s than those with higher survival probabilities. We estimate \hat{P}_{jt} non-parametrically using Probit model with a polynomial approximation. Note that we extend the state variable set with location and trade status information which captures the effects of important determinants of firm exit decision.

The capital, age, and labour coefficients are identified in the second step of our estimation algorithm. We substitute equations (5) and (4) into equation (2) using expressions for the estimated values, $\hat{\phi}_{jt-1}$, $\hat{\phi}_{jt-2}$ which gives us

$$y_{jt} = b_k k_{jt} + b_a a_{jt} + b_l l_{jt} + g'(\hat{\phi}_{jt-1} - b_k k_{jt-1} - b_a a_{jt-1} - b_l l_{jt-1}, \hat{\phi}_{jt-2} - b_k k_{jt-2} - b_a a_{jt-2} - b_l l_{jt-2}, \hat{P}_{jt}) + \varepsilon_{jt}, \quad (6)$$

where the two β_0 terms have been encompassed into the non-parametric function, $g'(\cdot)$ and ε_{jt} is a composite error term comprised of η_{jt} and ξ_{jt} . The lagged $\hat{\phi}$ variables are obtained from the first step estimates at $t-2$ and $t-1$ periods. Because the conditional expectation of ω_{jt} , given information in $t-2$ and $t-1$ periods, depends on ω_{jt-2} and ω_{jt-1} , we need to use estimates

1
2
3 of $\hat{\phi}$ from two prior periods. Equation (6) is estimated with non-linear least squares (NLLS)
4
5 estimator, approximating $g'(\cdot)$ with a polynomial.¹⁰
6
7

8
9 Finally, having estimated unbiased and consistent production function coefficients we
10 are able to back out a unbiased and consistent measure (residual) of total factor productivity
11 (TFP) as $TFP_{jt} = y_{jt} - \hat{\beta}_k k_{jt} - \hat{\beta}_l l_{jt}$.¹¹ In the model of unobservable productivity we have
12
13 explicitly incorporated spatial and time dependencies by merging spatial interactions with
14
15 disaggregated modeling of productivity at firm level. In terms of verifying whether variations
16
17 in location and export status make firms more productive, we have controlled in our model of
18
19 productivity for market-structure specific shocks (such as demand conditions, factor markets,
20
21 exit barrier) that are different across locations and export status. We note that these factors
22
23 remain constant across firms in the same location and export status within a given industry
24
25 and a time period.

34

35 DATA AND PRODUCTIVITY ESTIMATES

36
37 As discussed in previous sections, in our analysis we classify locations as in WEBBER et al.
38
39 (2008) into urban, rural less sparse and rural sparse following the 2004 DEFRA definition of
40
41 rural. We estimate the production functions using the FAME dataset of the Bureau van Dijk.
42
43 The dataset covers all firms at the Companies House in the UK and includes information on
44
45 detailed unconsolidated financial statements, ownership structure, location (by post code),
46
47 activity description, and direct exports. The data used in our analysis contains annual records
48
49 on more than 80,000 manufacturing firms over the period 1994-2001. The coverage of the
50
51 data compared to the aggregate statistics reported by the UK Office for National Statistics
52
53 (ONS) is very good as for sales it is 86 per cent and for employment – 92 per cent.¹² The
54
55 manufacturing sectors are identified on the bases of the current 2003 UK SIC at the 4-digit
56
57 level and range between 1513 and 3663. All nominal monetary variables are converted into
58
59
60

1
2
3 real values by deflating them with the appropriate 4-digit UK SIC industry deflators taken
4 from ONS. We use PPI to deflate sales and cost of materials, and asset price deflators for
5 capital and fixed investment variables.¹³
6
7

8
9
10 In this paper, our goal is to estimate unbiased and consistent TFP measures at firm
11 level, within 4-digit industries, and to document the aggregate productivity gaps between
12 urban, rural less sparse, and rural sparse locations. The strategy of our empirical analysis
13 implies that we run regressions within 4-digit industries which leaves us with the 41 largest
14 4-digit industries, with sufficient number of observations to apply our estimation algorithm.
15 The estimated sample accounts for almost 60 per cent of the manufacturing sales and 56 per
16 cent of the employment in our data. After lags are applied and observations with missing
17 values deleted, there are 23,841 remaining observations for 6,722 firms. The correlations
18 between the ONS aggregate statistics series and the estimated sample series are as follows:
19 value added (used in the regressions as dependent variable) - 0.94, employment - 0.97 and
20 exports - 0.95.
21
22

23
24 The descriptive statistics calculated from the estimated FAME sample of
25 manufacturing firms are reported in Table 2. We compare average firm characteristics across
26 urban, rural less sparse and rural sparse locations. Urban firms, compared to their rural
27 counterparts are larger in terms of value added, employment, and capital, and invest more.
28 Urban firms are also more likely to export and to be owned by foreign investors.¹⁴ These
29 characteristics are in accord with the measures of density of economic activity reported in
30 Table 1. Interestingly, industry concentration characterised by market share of the top four 4-
31 digit industries does not show substantial differences across rural and urban areas. However,
32 there are important similarities and differences in the composition of the top four industries
33 dominating each type of location. In the urban and rural less sparse locations dominant are
34 publishing and printing (2222), general mechanical engineering (2852), - miscellaneous

3 electrical equipment (3162), and miscellaneous manufacturing (3663). The rural sparse
4 locations are dominated by meat and dairy production (1513 and 1551), paper and paper
5 production (2112), and miscellaneous plastic production (2524). The finding that the industry
6 composition is very similar in urban and rural less sparse areas is significant and points to the
7 fact that there is indeed a divide but it is across rural areas by their level of sparsity.

11
12
13
14
15 - Table 2 about here -
16

17
18 Summary of the aggregated coefficients, over the estimated 41 industry production
19 functions, by location category are reported in Table 3. Coefficient estimates from all 41
20 industry regressions, number of observations and test statistics are reported in Appendix 1.
21
22 The aggregated coefficients on labour, capital and age reported in Table 3 are weighted
23 averages using value added as weight. They confirm the differences across urban and rural
24 locations with respect to the shares of capital and labour in output. The coefficient on labour
25 declines systematically across urban and rural areas as its value is 0.71 for urban firms while
26 it is 0.66 for firms in rural sparse areas. The pattern of the capital coefficient is just opposite
27 but differences are quite small – 0.25 for urban firms and 0.26 for firms in rural sparse areas.

40

41
42 Aggregate productivity measures by location category clearly show that urban firms
43 are the most productive; the TFP of urban firms is 3.75, while it is 3.26 and 3.08 - for firms in
44 rural less sparse and rural sparse areas, respectively. Furthermore, not only the mean but the
45 whole distribution of urban firm TFPs dominates the corresponding distributions of rural firm
46 TFPs. Figure 1 illustrates the distributions of firm TFPs across the three categories of urban
47 and rural locations by the means of kernel density estimates. The Kolmogorov-Smirnov two-
48 sample tests for stochastic dominance are significant at the 5 percent level and confirm the
49 fact that firms in urban locations are most productive.

SPATIAL VARIATION IN AGGREGATE PRODUCTIVITY

The discussion in previous sections and information reported in Tables 1 to 3 as well as Figure 1 suggest that there is a systematic relationship between productivity and the spatial characteristics of rural and urban locations related to density of economic activity. In this section we analyse differences in aggregate productivity across rural and urban locations by applying a decomposition of the spatial variation in levels following RICE et al. (2006).¹⁵ Further, we explore sources of productivity by analysing changes in the decomposition indexes. Spatial variation in aggregate productivity derives from two main sources – differences in the individual firm productivities within each industry, resulting in different average productivities across industries, and differences in the industry composition in each location category.

Let q_r^k be the weighted average, using firm value added as weight, of individual firm productivities (TFPs) in location, r and industry, k .¹⁶ Denote the total value added in location, r by $S_r = \sum_k s_r^k$ and the share of industry, k in the total value added in location, r by $\lambda_r^k = s_r^k / S_r$. The average productivity of industry, k for the economy as a whole (i.e., aggregating across all locations, r) is given by $\bar{q}^k = \sum_r s_r^k q_r^k / \sum_r s_r^k$, while $\bar{\lambda}^k = \sum_r s_r^k / \sum_r S_r$ is the share of industry, k in total value added for the economy as a whole. Aggregate productivity, q_r is weighted average of industry productivities in location, r , using industry value added as weight. This aggregate productivity may be decomposed as

$$q_r \equiv \sum_k q_r^k \lambda_r^k = \sum_k q_r^k \bar{\lambda}^k + \sum_k \bar{q}^k \lambda_r^k - \sum_k \bar{q}^k \bar{\lambda}^k + \sum_k (q_r^k - \bar{q}^k)(\lambda_r^k - \bar{\lambda}^k). \quad (7)$$

The first term on the right-hand side of equation (7) is the average level of productivity in location, r conditional on industry composition being the same as for the economy as a whole; we refer to this as *productivity index*. The second term is the average level of productivity of location, r given its industry composition but assuming that the productivity of each industry

1
2
3 equals the economy-wide average for that industry. It is referred to as the *industry*
4
5 *composition index*. Remaining terms measure the *residual covariance* between industry
6
7 productivities and industry shares in location, r . It is important to point out that comparison
8
9 between productivity and industry composition indexes, while taking into account the
10
11 residual covariance terms, in equation (7) can provide useful information about the
12
13 determinants of aggregate productivity in various locations.
14
15

16
17 We compute the productivity index and the industry composition index as specified
18
19 above for the urban, rural less sparse and rural sparse locations in the UK and report the
20
21 results by location category, in Table 4, Panel A. Note that values reported are normalised by
22
23 the term $\sum_k \bar{q}^k \bar{\lambda}^k$ from equation (7). While variation in aggregate productivity by location
24
25 reflects differences in both productivity and industry composition, the spatial variation
26
27 observed in the productivity index derives entirely from spatial variation in industry (firm)
28
29 productivity and is independent of differences in industry composition. A higher value of the
30
31 productivity index in a given location would suggest that industries in this location are more
32
33 productive. The spatial variation in the industry composition index derives entirely from
34
35 differences in the industry composition across locations and is independent of variation in
36
37 productivity. A higher value of the composition industry index in a given location implies
38
39 that the more productive industries are represented by larger industry shares in that location.
40
41 The last covariance term in equation (7) provides information about the link between industry
42
43 shares and productivity; a positive sign of the term in a given location means that the more
44
45 productive industries are also larger.
46
47
48
49
50
51
52

53 - Table 4 about here -
54
55

56 The results in Panel A are computed as averages for the 1997-2001 period and
57
58 confirm that urban locations, with the highest density of economic activity, have the highest
59
60 aggregate productivity. The rural less sparse locations lag behind in aggregate productivity by

1
2
3 13.2 percent, while rural sparse locations are the least productive, with aggregate productivity
4 lower by 18 percent compared to the urban location category. Productivity index and industry
5 composition index also are lower for both rural less sparse and rural sparse location
6 categories compared to the urban location category as the differentials for the productivity
7 index are 12.7 percent and 23.5 percent, while the differentials for the industry composition
8 index are 10.5 percent and 18.5 percent respectively. The magnitudes of the differentials
9 suggest that rural sparse locations are characterised by both the lowest productivity and the
10 worst industry composition. The covariance term is positive for all location categories but its
11 magnitude is the largest for the rural sparse locations suggesting a substantial unexplained
12 reallocation of industry shares towards more productive industries or increases in
13 productivity of larger industries. From policy view point, efforts to increase firm and industry
14 productivity, through technological innovation and competition, rather than modify industry
15 composition might be more fruitful given the larger scope for improvement in the
16 productivity index compared to the industry composition index.¹⁷

31
32
33
34
35
36
37 To explore further the factors affecting aggregate productivity, by location, we
38 analyse changes over time of the decomposition indexes in equation (7). We report results in
39 Table 4 for two periods, in Panel B - for the 1997-1998 pre-Euro period and in Panel C - for
40 the 2000-2001 post-Euro period. The Euro was adopted by the UK's main trading partners in
41 the beginning of 1999 which resulted in a real appreciation of the exchange rate of the Pound
42 against the Euro, over the 2000-2001 period, and led to an increase in competitive pressure
43 on both exporters and non-exporters (through increased import competition). By comparing
44 changes of aggregate productivity in the two periods, with distinct exchange rate regimes and
45 international trade conditions, we are able to derive important results concerning the impact
46 of economic conditions on productivity of various types of location. Specifically, we are able
47 to establish the magnitudes of contributions by both industry productivity and industry

1
2
3 composition changes to the aggregate productivity of urban, rural less sparse and rural sparse
4
5 locations.
6
7

8 The results in Panels B and C show substantial heterogeneity in responses by type of
9
10 location. Aggregate productivity in urban locations increases at a similar pace in both pre-
11
12 and post-Euro periods, by 2.7 and 2.4 percent respectively. There are dramatic changes in
13
14 productivity of rural less sparse locations, with a shift from a negative growth of 4.6 percent
15
16 in the pre-Euro period to a positive but close to zero growth in the post-Euro period. The rural
17
18 sparse locations are characterised by the highest growth rates in aggregate productivity – 4.7
19
20 percent before the Euro implementation and 6.6 percent after that. There is evidence of rural
21
22 sparse locations catching up with rural less sparse and urban locations in terms of aggregate
23
24 productivity over the entire period of analysis. It also seems that rural sparse locations are
25
26 resilient to economic shocks and respond well to increases in competitive pressure, which can
27
28 be seen, in this case, as a substitute for the impact of density of economic activity.
29
30
31
32
33

34 The sources of aggregate productivity growth vary by type of location. For the urban
35
36 location category improvements in both productivity and industry composition indexes are
37
38 evident before and after the implementation of the Euro. There is a relatively substantial
39
40 decline in the growth of the productivity index in the post-Euro period suggesting that during
41
42 periods of increased competitive pressure the within industry productivity improvements
43
44 become less important than the adjustments in industry composition where more productive
45
46 industries expand. For rural less sparse locations improvement in the productivity index is
47
48 more important in the pre-Euro period and there is a decline in the effect after the
49
50 implementation of the Euro, similar to the urban location category. There is also evidence of
51
52 relative improvement in the industry composition in rural less sparse locations under
53
54 increased competitive pressure. Despite this, however, the growth in the industry composition
55
56 index remains negative, over the period of analysis, suggesting that the large surviving
57
58
59
60

1
2
3 industries in rural less sparse locations are relatively less productive. The negative growth in
4
5 the residual covariance term in the pre-Euro period also supports the view that the
6
7 reallocation of industry shares leads to deteriorating industry composition, in the pre-Euro
8
9 period. However, the growth in the residual covariance turns positive in the post-Euro period
10
11 implying that there is a shift of industry shares in favour of more productive industries under
12
13 increased competitive pressure. Aggregate productivity in rural sparse locations is positively
14
15 affected by improvements in productivity index in a manner similar to other location
16
17 categories but the magnitude is much larger. The impact of the industry composition index is
18
19 interesting; the growth in the composition index shifts from negative in the pre-Euro period to
20
21 positive in the post-Euro period implying an improvement in the industry composition under
22
23 increased competitive pressure in the economy. However, the growth in the residual
24
25 covariance term exhibits an opposite pattern by becoming negative in the post-Euro period.
26
27 We interpret this as evidence that there are in the rural sparse locations less productive
28
29 industries that manage to survive and even expand.
30
31
32
33
34
35
36
37
38

39 CONCLUSION

40
41 The focus of the paper is on evaluating the productivity gap between rural and urban
42
43 locations in the UK using micro data. We build a structural model of the unobservable
44
45 productivity emphasising the link between productivity and spatial density of economic
46
47 activity and adapt the semi-parametric estimation approach proposed in OLLEY and PAKES
48
49 (1996) to estimate the parameters of production functions at firm level, within 4-digit UK
50
51 manufacturing industries, for the period 1997 - 2001. We allow market structure to differ by
52
53 endogenous export status and location choices and model productivity as a controlled second-
54
55 order Markov process which greatly enhances our ability to obtain unbiased and consistent
56
57 estimates of the production function parameters and thus, back out unbiased and consistent
58
59
60

1
2
3 TFP measures at firm level. We aggregate the firm TFPs by location category following the
4
5 2004 DEFRA definition of rural and find that aggregate productivity systematically differs
6
7 across urban, rural less sparse and rural sparse locations as the magnitudes of the differentials
8
9 are 13.2 percent and 18.0 percent, respectively. Our results are in line with several recent
10
11 studies, notably WEBBER et al. (2008), and in broader sense - RICE et al. (2006).
12
13

14
15 Next, we decompose aggregate productivity into productivity index and industry
16
17 composition index. The productivity index is the highest in urban locations suggesting that
18
19 (firm and industry) productivity is strongly influenced by density of economic activity and
20
21 proximity to economic mass. The industry composition index captures the extend to which
22
23 manufacturing production in different location categories is allocated to industries that are
24
25 more or less productive compared to the average for the UK economy. Because industry
26
27 composition index is positively correlated with productivity index it is evident that locations
28
29 with high productivity are also characterised by industrial structure enhancing productivity.
30
31 However, the correlation is not perfect. Even though industry composition (of the top four
32
33 industries) in urban and rural less sparse locations is very similar, differences in both
34
35 aggregate productivity and productivity index remain. Further, analysing changes in the
36
37 decomposition indexes over two periods, before and after implementation of the Euro by the
38
39 UK main trading partners, reveals substantial heterogeneity in responses across location
40
41 categories under increased competitive pressure. The main finding is that there is a tendency
42
43 of rural sparse locations catching up with the urban and rural less sparse location categories
44
45 in terms of aggregate productivity over the period of analysis.
46
47
48
49
50
51

52
53 We also find evidence that increased competitive pressure as a result of changes in
54
55 trade conditions after implementation of the Euro by the UK's main trading partners has
56
57 acted as a substitute for the role of density of economic activity in enhancing industry
58
59 composition, especially in rural sparse locations. From welfare and economic growth policy
60

1
2
3 view point, our ultimate interest is in the ability of various locations to efficiently convert the
4
5 set of resources available into output, and improvements in the use of resources by
6
7 reallocating them from less to more productive industries can be just as effective in
8
9 increasing aggregate output as are the productivity improvements within individual firms and
10
11 industries. However, in the light of our decomposition results, efforts to increase firm and
12
13 industry productivity, through technological innovation and within-industry competition,
14
15 rather than relying on induced changes in industry composition might be more fruitful, given
16
17 the larger scope for improvement in the productivity index compared to the industry
18
19 composition index in rural locations.

NOTES

¹ The 2004 DEFRA rural-urban definition is extended also to Scotland and Northern Ireland.

² HARRIS and LI (2009) estimate total factor productivity of UK firms and discuss the role of R&D and absorptive capacity at regional level but they do not consider the 2004 DEFRA definition and do not focus on the rural-urban divide.

³ FUJITA and THISSE (2002) and ROSENTHAL and STRANGE (2004) offer extensive surveys of the literature on economics of agglomeration and its implications for productivity.

⁴ H. M. TREASURY (2001) has defined five generic micro-economic drivers that account for area-based differences in performance: employment and skills; investment; innovation; enterprise; and competition. COURTNEY et al. (2004) regroup the Treasury's classification in an attempt to accommodate less tangible elements of productivity specifically in rural locations. They also postulate five main drivers. Economic capital embraces infrastructure and innovation and human capital accommodates employment, skills and enterprise. Their other three drivers are social capital (for example, networks and partnerships), cultural capital (political consensus, civic engagement), and environmental capital (quality of living space). Whilst the Treasury drivers apply at the aggregate area level, they are less good at explaining productivity at the firm level.

⁵ The invertability of the investment function requires the presence of only one unobservable which OLLEY and PAKES (1996) refer to as scalar unobservable assumption. This assumption means that there can be no measurement error in the investment function, no unobserved differences in investment prices across firms, and no unobserved separate factors that affect investment but not production. However, the monotonicity needed in OLLEY and PAKES (1996) does not depend on the degree of competition in the output market; it just needs the marginal product of capital to be increasing in productivity.

1
2
3 ⁶ Note that the fixed effects estimator can be seen as a special case of the Markov process $p(\cdot)$
4 where productivity, ω_{jt} is set to ω_j and does not change over time.
5
6
7

8 ⁷ Results from estimating propensities to export and to locate in areas with high density of
9 economic activity are available from the authors upon request. Given the availability of two
10 extra controls, besides the investment variable, we experimented also with a third-order
11 Markov process but the estimation results were very similar to the second-order Markov
12 process results reported here. Thus, we conclude that a second-order Markov process
13 approximates well our model of productivity.
14
15
16
17
18
19
20
21

22 ⁸ OLLEY and PAKES (1996) show that kernel and polynomial approximations of the
23 unobservable produce very similar results. In our estimations everywhere we use a
24 computationally easier 4th-order polynomial.
25
26
27
28

29 ⁹ Note that the first stage of the estimation algorithm is not affected by selection because by
30 construction η_{jt} , the residual in equation (2) is not correlated with firm decisions as it is not
31 observed by firm managers.
32
33
34
35
36

37 ¹⁰ WOODRIDGE (2009) presents a concise one-step formulation of the original OLLEY and
38 PAKES (1996) approach using GMM estimator which is more efficient than the standard
39 Olley-Pakes algorithm.
40
41
42

43 ¹¹ Estimating the age coefficient is only used to separate out cohort from selection effects in
44 determining the impact of firm age on productivity and therefore we do not net out the
45 contribution of age from TFP.
46
47
48
49
50

51 ¹² Based on the analysis of HARRIS and LI (2009), FAME is biased towards larger
52 companies, particularly in the non-exporting populations. Even though we size-weight our
53 aggregations over company productivity this is a caveat of using the data.
54
55
56
57

58 ¹³ KATAYAMA et al. (2003), and related studies, point that production functions should be a
59 mapping of data on inputs and outputs. However, most studies tend to use revenue and
60

1
2
3 expenditure data and use industry level deflators for output, raw material and capital assets to
4
5 get back the quantity data needed. It is clear that inputs and outputs can be priced differently
6
7 for different firms within narrowly defined industries. This results in inconsistency discussed
8
9 by KLETTE and GRILICHE (1996) in the case of common scale estimators. We note,
10
11 however, that allowing for endogenous trade orientation in the unobservable as in RIZOV
12
13 and WALSH (2009) and introducing location information in the state space will control for
14
15 persistent pricing gap across locations and between exporters and non-exporters in their use
16
17 of inputs and their outputs within 4-digit industries. Furthermore, FOSTER et al. (2008) find
18
19 that productivity estimates from quantity and deflated revenue data are highly correlated, and
20
21 that the bias vanishes on average and estimated average productivity is unaffected when
22
23 aggregate deflators are used.
24
25
26
27
28

29 ¹⁴ We mark a company as an exporter if we observe in the data exporting by the firm in any
30
31 year within a 3-year moving window. RIZOV and WALSH (2009) also use this data to study
32
33 productivity and trade orientation and here we follow a similar classification scheme where
34
35 exporters are defined as firms that consistently export over entire period of analysis. In fact,
36
37 out of 6,722 firms in the sample, exporters represent between 46 and 56 per cent across the
38
39 three categories of rural and urban locations.
40
41
42

43 ¹⁵ OOSTERHAVEN and BROERSMA (2007) offer detailed discussion of decomposition
44
45 methods.
46
47

48 ¹⁶ Note that industry productivity is determined by individual firm productivities and firm
49
50 market shares, within the industry, as discussed by OLLEY and PAKES (1996) and RIZOV
51
52 and WALSH (2009), among others. Thus, there could be two sources of industry productivity
53
54 – within-firm productivity increases and reallocation of market shares towards more
55
56 productive firms.

¹⁷ There is a large body of literature on international (and regional) specialisation which predicts that general technology (Ricardian) and factor supply (Heckscher-Ohlin) differences jointly determine comparative advantage and thus, specialisation, measured as industry composition. Recent papers, starting with HARRIGAN (1997), show that the estimated impact of non-neutral technology differences is large and in accord with the theory, suggesting that Ricardian effects are an important source of comparative advantage and a determinant of industry composition.

Table 1 Indicators of density of economic activity by location category, 1997-2001

Indicators	Urban	Rural less sparse	Rural sparse
Density of population of working age (number of residents/km ²)	1778.1 (1454.8)	252.2 (223.8)	37.0 (29.6)
Business density (stock of VAT registrations/km ²)	262.2 (157.5)	12.7 (11.6)	2.5 (2.0)
Job density (number of jobs/resident of working age)	2.6 (1.8)	0.8 (0.7)	0.7 (0.6)
Proportion of knowledge intensive business services in all businesses (%)	16.4 (12.2)	14.9 (11.5)	13.1 (8.4)
Proportion of employees in knowledge intensive business services (%)	14.5 (8.7)	11.4 (7.6)	7.7 (6.1)
Proportion of population with higher education (%)	21.8 (9.4)	19.9 (5.1)	17.5 (2.3)
Capital investment by local authority (GBP/resident)	3425.3 (1352.4)	3190.0 (1401.3)	2812.2 (1331.9)

Note: The summary statistics are aggregated from information at local authority (LAD) level (434 observations in total); standard deviations (S.D.) are reported in parentheses. Population of working age comprises men, aged 16-64 and women, aged 16-59.

Source: Office for National Statistics (ONS)

Table 2 Descriptive statistics of firm specific variables by location category, 1997-2001

Variable	Urban, Mean (S.D.)	Rural less sparse, Mean (S.D.)	Rural sparse, Mean (S.D.)
Firm characteristics			
Value added (thousands GBP)	17333.3 (22381.2)	8606.5 (4644.5)	3532.3 (913.6)
Total assets (thousands GBP)	18646.9 (48926.1)	12966.2 (8397.9)	3030.1 (666.1)
Investment (thousands GBP)	4675.1 (14716.6)	4493.9 (4095.9)	582.6 (112.9)
Number of full-time-equivalent employees	425.3 (261.8)	248.7 (68.6)	137.9 (24.6)
Share of exporting firms	0.56 (0.50)	0.55 (0.50)	0.46 (0.50)
Share of foreign owned firms	0.26 (0.44)	0.23 (0.42)	0.11 (0.31)
Age of the firm	29.0 (22.4)	29.1 (22.8)	36.9 (33.3)
Industry composition			
List of top four, 4-digit SIC industries, ordered by market share	3663 2222 2852 3162	2852 3663 3162 2222	2112 1513 1551 2524
Market share of top four industries (C4) (%)	37.7	38.0	35.1
Number of observations (Total 23841)	21469	1747	625

Note: Definitions of 4-digit SIC industries are as follow: 1513 – meat and poultry meat products, 1551 – dairy products, 2112 – paper and paper products, 2222 – publishing and printing, 2524 - miscellaneous plastic products, 3663 – miscellaneous manufacturing, 2852 – general mechanical engineering, 3162 - miscellaneous electrical equipment.

Table 3 Production function coefficients and productivity estimates aggregated by location category, 1997-2001

Coefficient	Urban	Rural less sparse	Rural sparse
Labour	0.709 (0.057)	0.696 (0.064)	0.665 (0.081)
Capital	0.246 (0.038)	0.250 (0.042)	0.255 (0.050)
Age	0.021 (0.070)	-0.124 (0.090)	-0.126 (0.108)
Aggregate productivity	3.752 (0.971)	3.259(1.021)	3.084 (1.019)

Note: The reported coefficients and aggregate productivity are weighted averages, using value added as weight, from 41 industry regressions on firm level data. The R^2 of all industry regressions are very high, close to 1 (see Appendix 1). Standard errors (standard deviations for productivity) are reported in parentheses.

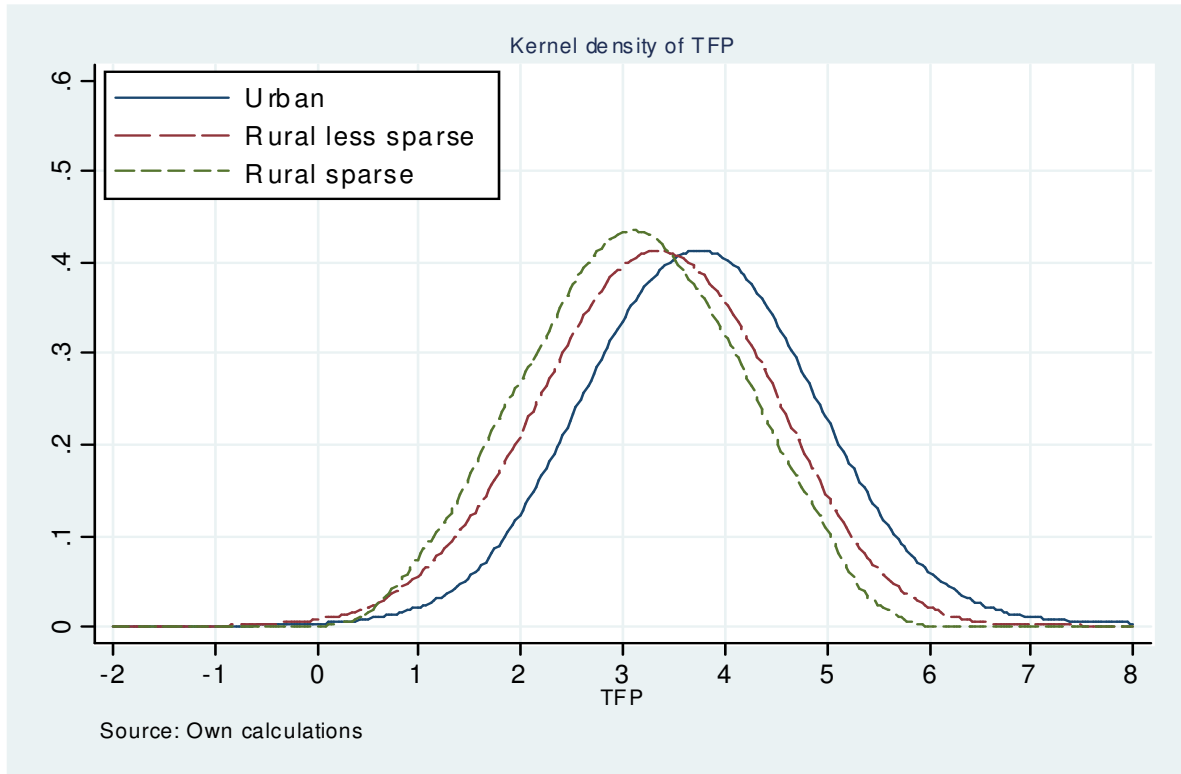

Table 4 Aggregate productivity decompositions by location category, 1997-2001

	$\sum_k q_r^k \lambda_r^k$	$\sum_k q_r^k \bar{\lambda}^k$	$\sum_k \bar{q}^k \lambda_r^k$	$-\sum_k \bar{q}^k \bar{\lambda}^k$	$\sum_k \Delta q_r^k \Delta \lambda_r^k$
Panel A: Levels, average for 1997-2001					
Urban	1.005	1.000	1.004	1.000	0.001
Rural less sparse	0.873	0.873	0.899	1.000	0.101
Rural sparse	0.825	0.765	0.819	1.000	0.241
Panel B: Changes, 1997-1998					
Urban	0.027	0.029	0.024	0.022	-0.004
Rural less sparse	-0.046	0.084	-0.060	0.022	-0.048
Rural sparse	0.047	0.153	-0.230	0.022	0.146
Panel C: Changes, 2000-2001					
Urban	0.024	0.008	0.022	0.013	0.007
Rural less sparse	0.002	0.011	-0.042	0.013	0.046
Rural sparse	0.066	0.078	0.091	0.013	-0.090

Note: Reported R² statistics and number of observations (No) are from the last step of the estimation algorithm. U denotes urban, RLS – rural less sparse and RS – rural sparse location categories. Industries which U, RLS or RS are reported for are in the top four industries for one or more location categories.
